¹While the Poisson probability law is alive and well today, perhaps the more important part of that research — the stochastic nature of judicial proceedings — is seldom acknowledged.

11.1 POISSON RANDOM VARIABLES

In this section we focus on individual Poisson random variables, but we make use of Poisson random processes as a way of elucidating the properties of the variables. We look first at two basic principles, independence and rarity, from which the Poisson probability law can be derived.

11.1.1 Poisson and independence

The fundamental postulates that lead to the Poisson probability law are discussed by many authors, for example Davenport and Root (1958), Barrett and Swindell (1981, 1996) and Goodman (1985). Our treatment will rely heavily on these previous works.

We could state the postulates in abstract form, but it will help to develop mental imagery if we consider a specific experimental setup. Imagine a beam of radiation falling on a detector and producing photoelectrons. Each photoelectron will produce an impulse of current in an external circuit, and we assume that the circuit includes a counter that will tally the total number N of impulses produced in some time interval of duration T . The probability of N photoelectrons in this interval is denoted $\Pr(N \text{ in } T)$. Since each photoelectron causes a current impulse and thus a change in counter reading, $\Pr(N \text{ in } T)$ can also be interpreted as the probability law for the number of current impulses in time T or for the change in counter reading during time T . In the jargon of nuclear physics and radiology, each impulse is referred to as a *count*, and N is then the number of counts in time T . If we further assume that each photoelectron is produced by absorption of a single photon (see Sec. 10.1.4), then N is also the number of detected photons. More generally, of course, N is simply the number of events of an unspecified nature in time T , and we shall refer to the events here as counts.

Poisson postulates The postulates that will lead to the Poisson law are:

(a) The number of counts in any time interval $t_1 < t \leq t_2$ is statistically independent of the number in any other *nonoverlapping* interval $t_3 < t \leq t_4$, where $t_1 < t_2 \leq t_3 < t_4$.

(b) If we consider a very small time interval of duration ΔT , the probability of a single count in this interval approaches some constant a times ΔT , *i.e.*, up through terms linear in ΔT ,

$$\Pr(1 \text{ in } \Delta T) = a\Delta T. \quad (11.1)$$

(c) The probability of more than one count in a vanishingly small interval ΔT is zero. Thus, again through terms linear in ΔT ,

$$\Pr(1 \text{ in } \Delta T) + \Pr(0 \text{ in } \Delta T) = 1. \quad (11.2)$$

Discussion of the postulates Postulate (a) is a clear statement of the independence of the counts; no matter how many counts are observed in (t_1, t_2) , that number has no influence on the number observed in (t_3, t_4) . Postulate (c) also requires that the counts be independent; if, for example, counts always came in pairs, postulate (c)

would not hold since then $\Pr(2 \text{ in } \Delta T)$ would be linear in ΔT and $\Pr(1 \text{ in } \Delta T)$ would be zero.

Postulate (b) goes beyond statistical independence. As stated here, it also requires that $\Pr(1 \text{ in } \Delta T)$ be independent of the absolute time; if the small interval ΔT is defined as $T < t \leq T + \Delta T$, the probability depends only on ΔT and is independent of T . As we shall see in more detail in Sec. 11.2, this condition implies that we are dealing with a stationary random process. A more general form of postulate (b) would allow $\Pr(1 \text{ in } \Delta T)$ to have the form $a(t)\Delta T$, in which case we would be dealing with a nonstationary random process. Later in this section we shall consider the case where $a(t)$ is a nonrandom function of time, and in Secs. 11.1.4 and 11.3.7 we shall allow $a(t)$ to be random. For now we treat a as a constant and hence concentrate on the stationary case. In this case the parameter a is the average rate of counts. From (11.1) it can be seen that a has dimensions of reciprocal time since probabilities are dimensionless.

Bernoulli trials and independence Another familiar situation involving independent events is Bernoulli trials, such as successive flips of a coin. (See Sec. C.6.1 in App. C.) The common assumption in this problem is that the trials are statistically independent, but the result is the binomial law, not the Poisson. It is easy to see that our postulates are not satisfied for Bernoulli trials. If we think of coins being flipped at a regular pace, say once per second, then the numbers of heads in two different time intervals are not statistically independent. If we consider a half-second interval containing a flip, then the number of heads in the next half second is fully determined; it can only be zero since no flip takes place. Moreover, the number of heads in N flips (where N is nonrandom) is not statistically independent of the number of tails. Since the total is N , the number of tails is fully determined by the number of heads. Thus, even though the individual flips are independent, Bernoulli trials have a degree of statistical regularity not consistent with the postulates and not characteristic of Poisson processes.

Derivation of the Poisson law As a first step toward computing $\Pr(N \text{ in } T)$, we consider an interval of duration $T + \Delta T$ and compute the probability of getting *no* counts in this interval. This probability is denoted $\Pr(0 \text{ in } T + \Delta T)$. The only way we can find no counts in $(0, T + \Delta T)$ is to find none in $(0, T)$ and also none in the subsequent interval of $(T, T + \Delta T)$. Since the intervals are statistically independent, we have

$$\Pr(0 \text{ in } T + \Delta T) = \Pr(0 \text{ in } T) \Pr(0 \text{ in } \Delta T) = \Pr(0 \text{ in } T) (1 - a\Delta T), \quad (11.3)$$

where the last step makes use of (11.1) and (11.2). Some simple algebra gives

$$\Pr(0 \text{ in } T + \Delta T) - \Pr(0 \text{ in } T) = -a\Delta T \Pr(0 \text{ in } T). \quad (11.4)$$

Dividing through by ΔT and passing to the limit, we find

$$\frac{d}{dT} \Pr(0 \text{ in } T) = -a \Pr(0 \text{ in } T). \quad (11.5)$$

The solution of this elementary differential equation, with the boundary condition $\Pr(0 \text{ in } 0) = 1$, is

$$\Pr(0 \text{ in } T) = \exp(-aT). \quad (11.6)$$

Thus the probability of getting no counts decays exponentially with the length of the interval.

Next consider the event where exactly one count occurs in $T + \Delta T$. There are two mutually exclusive ways in which this can happen: one count in the first interval of T and none in the subsequent interval of ΔT ; or none in T and one in ΔT . The probability of one count in the overall interval is thus

$$\Pr(1 \text{ in } T + \Delta T) = \Pr(1 \text{ in } T) \Pr(0 \text{ in } \Delta T) + \Pr(0 \text{ in } T) \Pr(1 \text{ in } \Delta T). \quad (11.7)$$

With (11.1), (11.2), (11.6) and a smidgen of algebra, we find

$$\Pr(1 \text{ in } T + \Delta T) - \Pr(1 \text{ in } T) = -a\Delta T \Pr(1 \text{ in } T) + a\Delta T \exp(-aT). \quad (11.8)$$

Again dividing through by ΔT and passing to the limit, we find

$$\frac{d}{dT} \Pr(1 \text{ in } T) = -a \Pr(1 \text{ in } T) + a \exp(-aT). \quad (11.9)$$

With the boundary condition $\Pr(1 \text{ in } 0) = 0$, the solution to this differential equation is

$$\Pr(1 \text{ in } T) = aT \exp(-aT). \quad (11.10)$$

Now consider the general situation. What is the probability of getting exactly N counts in $T + \Delta T$? Again, there are two ways in which this event can occur: N counts in T followed by 0 in ΔT ; or $N - 1$ in T followed by 1 in ΔT . By the third postulate, there is vanishingly small probability as $(\Delta T \rightarrow 0)$ of getting more than one count in ΔT . Since the two outcomes that lead to N counts in $T + \Delta T$ are mutually exclusive, and since the counts in the two time intervals are statistically independent, we have

$$\begin{aligned} \Pr(N \text{ in } T + \Delta T) &= \Pr(N \text{ in } T) \Pr(0 \text{ in } \Delta T) + \Pr(N - 1 \text{ in } T) \Pr(1 \text{ in } \Delta T) \\ &= \Pr(N \text{ in } T) (1 - a\Delta T) + \Pr(N - 1 \text{ in } T) a\Delta T. \end{aligned} \quad (11.11)$$

If we presume $\Pr(N - 1 \text{ in } T)$ is known, we obtain the recursion relation

$$\frac{d}{dT} \Pr(N \text{ in } T) = -a \Pr(N \text{ in } T) + a \Pr(N - 1 \text{ in } T). \quad (11.12)$$

It can be verified by substitution (or induction) that the solution is

$$\Pr(N \text{ in } T) = \frac{(aT)^N}{N!} \exp(-aT). \quad (11.13)$$

Equations (11.6) and (11.10) are special cases of (11.13) for $N = 0$ and 1, respectively. (Note that $0! \equiv 1$.)

From the discussion in Sec. C.6.2 of App. C, (11.13) is recognized as the Poisson probability law with parameter aT . As shown in the appendix, the parameter is also the mean of a Poisson distribution. That the mean number of counts in time T is aT should come as no surprise; from (11.1) a is the mean rate, and mean rate times total time is the mean total number of counts.

Time-dependent rate There are many circumstances in which the number of counts in a small interval $(t, t + \Delta T)$ depends on t as well as ΔT . One simple example is radioactive decay, where the mean rate $a(t)$ decays as $2^{-t/\tau}$, where τ is the half-life. A fundamentally different example is an unstable light source, where $a(t)$ fluctuates randomly. The random case is considered briefly in Sec. 11.1.4 and in more detail in Sec. 11.3.7, but we investigate here the case where $a(t)$ is a prescribed function of time, such as an exponential decay. The derivation parallels the one just given for $a = \text{constant}$, but now a more elaborate notation is required. The probability of getting N counts in a time interval $(t, t + T)$ will be denoted $\Pr[N \text{ in } (t, t + T)]$.

If $a(t)$ is a nonrandom function of time, (11.3) becomes

$$\begin{aligned} \Pr[0 \text{ in } (t, t + T + \Delta T)] &= \Pr[0 \text{ in } (t, t + T)] \Pr[0 \text{ in } (t + T, t + T + \Delta T)] \\ &= \Pr[0 \text{ in } (t, t + T)] [1 - a(t + T)\Delta T]. \end{aligned} \quad (11.14)$$

Thus the differential equation (11.5) becomes

$$\frac{d}{dT} \Pr[0 \text{ in } (t, t + T)] = -a(t + T) \Pr[0 \text{ in } (t, t + T)], \quad (11.15)$$

with the solution

$$\Pr[0 \text{ in } (t, t + T)] = \exp \left[- \int_t^{t+T} dt' a(t') \right]. \quad (11.16)$$

To verify that (11.16) solves (11.15), one uses Leibniz' rule, according to which

$$\frac{d}{dT} \int_t^{t+T} dt' a(t') = a(t + T). \quad (11.17)$$

Equation (11.16) differs from (11.6) in that the product of the mean rate and the elapsed time has been replaced by the time-integral of the rate. If $a(t)$ is constant, (11.6) is recovered easily. The remainder of the derivation follows the derivation for the stationary case ($a = \text{constant}$) with similar modifications. The final result is

$$\Pr[N \text{ in } (t, t + T)] = \frac{\bar{N}^N}{N!} \exp(-\bar{N}), \quad (11.18)$$

where now \bar{N} is a function of time given by

$$\bar{N} = \int_t^{t+T} dt' a(t'). \quad (11.19)$$

The key point is that a Poisson law for the number of counts is obtained even if the mean rate is a function of time; all that is required is that the expected number of counts be computed by integrating the rate. We emphasize, however, that this conclusion requires that the mean rate be nonrandom; it does not hold if $a(t)$ fluctuates randomly.

11.1.2 Poisson and rarity

Another route to the Poisson law — indeed, the one used by Poisson himself — is to take the limit of a binomial law. Consider a set of M Bernoulli trials (coin flips,

say), where the probability of success (heads) is p . We know that the total number N of successes in M trials is given by the binomial law, (C.161). We denote this probability as $\Pr(N|M, p)$, and we recall from (C.163) that the mean number of successes, \bar{N} , is given by Mp .

Now let M become very large and p become very small in such a way that Mp (or \bar{N}) remains constant. Since the probability of success is getting vanishingly small, success is a rare event. In the context of coin flipping, very few of the flips (on average, \bar{N}/M) result in heads.

With $p = \bar{N}/M$ and some algebra, the binomial law can be written as

$$\begin{aligned} \Pr(N|M, p) &= \frac{M!}{(M-N)!N!} p^N (1-p)^{M-N} \\ &= \left[\frac{M(M-1)\cdots(M-N+1)}{M^N} \left(1 - \frac{\bar{N}}{M}\right)^{-N} \right] \left(1 - \frac{\bar{N}}{M}\right)^M \frac{\bar{N}^N}{N!}. \end{aligned} \quad (11.20)$$

As $M \rightarrow \infty$, the factor in square brackets tends to 1. Also, since $(1 - \bar{N}/M)^M$ limits to $\exp(-\bar{N})$, the remaining factors limit to the Poisson law, *i.e.*,

$$\lim_{M \rightarrow \infty} \Pr(N|M, p) = \frac{(\bar{N})^N}{N!} \exp(-\bar{N}), \quad (\bar{N} = Mp = \text{const}). \quad (11.21)$$

This formula gives the correct mean \bar{N} by construction, and it also gives the correct variance. From App. C, we know that the variance of a binomial law is $Mp(1-p)$, which here is $\bar{N}(1-p)$. In the limit $p \rightarrow 0$, this variance approaches \bar{N} , as it must for a Poisson.

Another way to see that the binomial limits to a Poisson is to show that the Poisson postulates are satisfied in the limit. Consider a sequence of coin flips at a regular pace, one every ΔT seconds. The total time over which the flips occur is held constant at T , so the number of flips $M = T/\Delta T$ goes to infinity as $\Delta T \rightarrow 0$. As before, the probability of success is taken as $p = \bar{N}/M$, where \bar{N} is constant.

Since the flips are independent, the number in any time interval is statistically independent of the number in any nonoverlapping interval, providing we consider only intervals given by integer multiples of ΔT . In the limit as $\Delta T \rightarrow 0$, this restriction is irrelevant and the first postulate holds. Similarly, since $p = \bar{N}/M = \bar{N}\Delta T/T$, the second postulate holds with $a = \bar{N}/T$. Finally, the third postulate holds easily since there is only one flip in any interval of length ΔT . Thus all three postulates are satisfied in the limit, and the Poisson law is inevitable.

11.1.3 Binomial selection of a Poisson

In most discussions of the binomial law, it is implicitly assumed that the number of trials M is a predetermined constant. In many physical situations, however, M is random. An important example in optics is radiation detection by an inefficient photon-counting detector. We analyze this problem here using the intuitive picture where discrete photons fall on the detector and produce photoelectrons with some probability; in Sec. 11.5 we shall revisit the problem from the viewpoint of quantum electrodynamics.

Suppose M photons are incident on the detector in time T and that each has a probability η (called the *quantum efficiency*) of producing a photoelectron. If the

photoelectric interactions are statistically independent, then the *conditional* probability $\Pr(N|M)$ for getting N photoelectrons is a binomial; the problem is formally equivalent to Bernoulli trials with η being the probability of success (detection). The marginal probability $\Pr(N)$, however, is given by

$$\Pr(N) = \sum_{M=N}^{\infty} \Pr(N|M) \Pr(M). \quad (11.22)$$

Note the lower limit of the sum; getting N photoelectrons requires that there be at least N photons.

Now suppose that the photons satisfy the three postulates so that M is a Poisson random variable. With $\Pr(N|M)$ being binomial, we have

$$\Pr(N) = \sum_{M=N}^{\infty} \binom{M}{N} \eta^N (1-\eta)^{M-N} \exp(-\bar{M}) \frac{\bar{M}^M}{M!}. \quad (11.23)$$

A change of variables, $K = M - N$, and a little algebra shows that (Barrett and Swindell, 1981, 1996)

$$\Pr(N) = \exp(-\eta\bar{M}) \frac{(\eta\bar{M})^N}{N!}. \quad (11.24)$$

Thus N obeys a Poisson law with mean $\bar{N} = \eta\bar{M}$. This result should come as no surprise; if the postulates are satisfied for M , they are also satisfied for N . No statistical dependence is introduced by the selection process.

This fundamental result is known as *binomial selection theorem*; we restate it for emphasis as:

Binomial selection of a Poisson yields a Poisson, and the mean of the output of the selection process is the mean of the input times the binomial probability of success.

An interesting corollary of this theorem is that the number of times that the photon is *not* detected is also a Poisson random variable. Moreover, the number of nondetections is statistically independent of the number of detections. These statements will come as a surprise to someone used to thinking about Bernoulli trials in terms of coin flipping. If a coin with probability of heads equal to η is flipped exactly M times, the number of heads N_h is binomial with parameter η , the number of tails N_t is binomial with parameter $1 - \eta$, and N_h and N_t are not statistically independent since $N_h + N_t = M$. The situation is entirely different when M itself is a Poisson random variable. Then N_h is Poisson with parameter $\eta\bar{M}$, N_t is Poisson with parameter $(1-\eta)\bar{M}$, and N_t and N_h are statistically independent. This peculiar result is obtained *only* if M is Poisson-distributed. Haight (1967) states it in formal terms as follows: In a sequence of Bernoulli trials where the number of attempts is random, the number of successes is independent of the number of failures if and only if the number of attempts is a Poisson random variable.

Cascaded binomial selection Many situations in imaging can be described mathematically as a cascade of binomial-selection stages. Consider, for example, the optical system depicted in Fig. 11.1. A light bulb emits photons randomly in all directions, some of the photons are collected with a lens, pass through a neutral-density filter, and illuminate the photocathode of a photomultiplier tube. We assume that the photons are fully independent, in the sense that neither the direction

nor the time of emission of one photon has any influence on the properties of any other photon, and hence that the photons satisfy the Poisson postulates. The number of photons M emitted in some observation time T is then a Poisson random variable with mean \overline{M} .

Fig. 11.1 An optical system to illustrate the idea of binomial selection of a Poisson distribution.

Since the photons are independent in all respects, including direction, collection of photons by the lens can be treated as a binomial selection. If the lens subtends a solid angle Ω from the source and the emission is isotropic, on average a fraction $\Omega/4\pi$ of the photons pass through the lens. The binomial probability of success p in this case is $\Omega/4\pi$, and the mean number of photons passed by the lens is $\overline{M}\Omega/4\pi$. Since we know that the binomial selection of a Poisson yields a Poisson, and that a Poisson is fully characterized by its mean, we now have the full probability law for the number of photons passed by the lens: it is a Poisson with mean $\overline{M}\Omega/4\pi$.

The neutral-density filter is another binomial selection. Each photon is either passed by the filter or it is not. If the average transmittance of the filter is τ , then the probability of success (in getting through) for an individual photon is also τ , and the mean number passed by the filter is $\overline{M}\tau\Omega/4\pi$. Again we have a binomial selection of a Poisson, which yields a Poisson, so the probability law on the number of photons passing the filter is Poisson with mean $\overline{M}\tau\Omega/4\pi$.

Next we come to the photocathode, which we assume to have quantum efficiency η . That is, each photon can independently produce a photoelectron with probability η . This is another binomial selection, and again the input to the selection is a Poisson, so we know at once that the probability law on the number of photoelectrons is Poisson with mean $\overline{M}\tau\eta\Omega/4\pi$.

We can extend this kind of reasoning indefinitely. If we know that at some stage in a system we have photons (or particles of any nature) that satisfy the Poisson postulates and that subsequent stages in the chain are well modeled as binomial selections, we need only compute the *average* number of photons passing through, and the binomial-selection theorem will then demonstrate that the probability law on this number is Poisson with the computed mean. Since the Poisson law is so ubiquitous, this is a very powerful means of analyzing the statistical properties of imaging systems.

11.1.4 Doubly stochastic Poisson random variables

A random variable for which a parameter of the probability law is itself random is said to be *doubly stochastic*. In this section we discuss Poisson random variables where the Poisson mean is random. Such variables are called *doubly stochastic Poisson random variables*. The closely related topic of doubly stochastic Poisson random processes is discussed in Secs. 11.3.6 and 11.3.7.

To understand the usefulness of doubly stochastic Poisson random variables, suppose that a large supply of light bulbs is available for use with a photon-counting detector. Assume that each bulb produces a steady light output and that the photons satisfy the Poisson postulates. Then, as we have seen, the counting distribution is Poisson so long as only that light bulb is used. In an experiment where the number of counts N in a fixed interval T is observed, N is a Poisson random variable. That means that if we repeat the experiment a large number of times (always with the same light bulb), a histogram of the observed values of N would approach $\Pr(N|\bar{N})$, where \bar{N} is related to the brightness of the particular light bulb. A different bulb produces a different amount of light, however, so this is only a conditional probability law, conditional on the particular bulb.

On the other hand, if we used a different light bulb for each measurement, then the histogram of observed counts would be broadened because of the variation in bulb output (see Fig. 11.2). To describe this situation fully, we now need to account for two kinds of randomness, the Poisson randomness in photon counting and the manufacturing randomness in bulb output. To do so, we allow \bar{N} to be a random variable.

Fig. 11.2 Illustration of the broadening of $\Pr(N)$ that occurs when the Poisson rate is a random variable.

Another situation in which \bar{N} is random is when only one light source is used but the mean count rate $a(t)$ is random. For any particular realization of $a(t)$, the calculation in Sec. 11.1.1 holds and the probability law on N is a Poisson with mean \bar{N} given by the integral in (11.19). If $a(t)$ is random, however, \bar{N} is also necessarily random. In Sec. 11.3.7 we develop the tools needed to discuss this case fully, but we shall now consider what happens if we simply let \bar{N} be a random *variable* (ultimately derived from some random *process*), with an unspecified probability law.

Poisson transform Though N is a discrete random variable with only integer values, its mean \bar{N} can take on any value in $(0, \infty)$. Thus, when we consider \bar{N} to be random, it must be described by a probability density function $\text{pr}(\bar{N})$. The usual rule for computing a marginal from a joint density, (C.75), then leads to

$$\text{Pr}(N) = \int_0^\infty d\bar{N} \text{Pr}(N|\bar{N}) \text{pr}(\bar{N}) = \frac{1}{N!} \int_0^\infty d\bar{N} \bar{N}^N \exp(-\bar{N}) \text{pr}(\bar{N}). \quad (11.25)$$

This expression is called the *Poisson transform* of $\text{pr}(\bar{N})$. Many properties of Poisson transforms and a table of examples are given in (Saleh, 1978). Of note is the fact that the Poisson transform of an exponential is a Bose-Einstein; the relevance of this result to optics will be explored in Sec. 11.5.3.

Though it is necessary to carry out the integral in the Poisson transform if one wants the full probability law on N , the mean and variance of N can be obtained more simply. The mean is given by

$$\langle N \rangle = \sum_{N=0}^\infty N \text{Pr}(N) = \sum_{N=0}^\infty \frac{N}{N!} \int_0^\infty d\bar{N} \bar{N}^N \exp(-\bar{N}) \text{pr}(\bar{N}). \quad (11.26)$$

Interchanging order of summation and integration, we find

$$\langle N \rangle = \int_0^\infty d\bar{N} \left[\sum_{N=0}^\infty \frac{N}{N!} \bar{N}^N \exp(-\bar{N}) \right] \text{pr}(\bar{N}). \quad (11.27)$$

The quantity in square brackets is recognized as the mean of the Poisson distribution with parameter \bar{N} , and we know from App. C that this mean is just the parameter. Therefore,

$$\langle N \rangle = \int_0^\infty d\bar{N} \bar{N} \text{pr}(\bar{N}) \equiv \overline{\bar{N}}. \quad (11.28)$$

The double-overbar notation indicates that two separate averages are being performed, one with respect to the probability $\text{Pr}(N|\bar{N})$ and the other with respect to the probability density function $\text{pr}(\bar{N})$.

Computation of the second moment of N proceeds similarly. After the interchange of order of summation and integration, we have

$$\langle N^2 \rangle = \int_0^\infty d\bar{N} \left[\sum_{N=0}^\infty \frac{N^2}{N!} \bar{N}^N \exp(-\bar{N}) \right] \text{pr}(\bar{N}) = \int_0^\infty d\bar{N} (\bar{N} + \bar{N}^2) \text{pr}(\bar{N}), \quad (11.29)$$

where we have used the result from (C.168) for the second moment of a Poisson.

We can express (11.29) in a neater form by recognizing that, for any random variable x ,

$$\langle x^2 \rangle = \text{Var}(x) + \langle x \rangle^2. \quad (11.30)$$

For the problem at hand, x is \bar{N} , so

$$\langle N^2 \rangle = \bar{\bar{N}} + \text{Var}(\bar{N}) + \bar{N}^2. \quad (11.31)$$

Finally,

$$\text{Var}(N) = \langle N^2 \rangle - \bar{N}^2 = \bar{\bar{N}} + \text{Var}(\bar{N}). \quad (11.32)$$

The first term on the right is just the Poisson variance appropriate to the average value of the mean, while the second term, often called the *excess variance*, is the result of randomness in the Poisson mean.

Another way to derive (11.32) is to apply a general result from Sec. C.4.4 of Appendix C. In the notation used there, $\text{Var}_{\bar{N}} \text{E}\{N|\bar{N}\} = \text{Var}\{\bar{N}\}$ and $\text{E}_{\bar{N}} \text{Var}\{N|\bar{N}\} = \bar{\bar{N}}$, so (11.32) is equivalent to (C.84).

One trivial case of this formalism is when \bar{N} is not really random. In that case, $\text{pr}(\bar{N}) = \delta(\bar{N} - \bar{N}_0)$ and $\text{Var}(\bar{N}) = 0$. Then $\text{Pr}(N)$ is just a Poisson of mean \bar{N}_0 , so $\text{Var}(N) = \bar{N}_0$ and the excess variance vanishes.

For any $\text{pr}(\bar{N})$ other than a delta function, however, the excess variance is positive, and the variance associated with $\text{Pr}(N)$ is greater than that associated with $\text{Pr}(N|\bar{N})$. Within the confines of the theory as developed so far, therefore, the *minimum* variance of any counting process is its mean value, and this minimum is achieved only when the mean itself is nonrandom, *i.e.*, for a Poisson random variable. Any randomness of the mean will lead to an increase in the variance over the Poisson value. Curiously, this statement breaks down in the world of quantum optics, where sub-Poisson statistics are indeed possible. This point will be discussed further in Sec. 11.5.

Binomial selection from a non-Poisson source We now revisit the binomial-selection theorem for the case where the source does not obey Poisson statistics (Barrett and Swindell, 1981, 1996). The probability law on N is given by (11.22), where $\text{Pr}(N|M)$ is a binomial with probability of success η and $\text{Pr}(M)$ is unspecified. With this problem statement and some properties of binomial distributions, the mean of N is given by

$$\begin{aligned} \langle N \rangle &= \sum_{N=0}^{\infty} \sum_{M=N}^{\infty} N \text{Pr}(N|M) \text{Pr}(M) = \sum_{M=0}^{\infty} \sum_{N=0}^M N \text{Pr}(N|M) \text{Pr}(M) \\ &= \sum_{M=0}^{\infty} M \eta \text{Pr}(M) = \bar{M} \eta, \end{aligned} \quad (11.33)$$

and the second moment is given by

$$\begin{aligned} \langle N^2 \rangle &= \sum_{M=0}^{\infty} \sum_{N=0}^M N^2 \text{Pr}(N|M) \text{Pr}(M) \\ &= \sum_{M=0}^{\infty} [M \eta (1 - \eta) + M^2 \eta^2] \text{Pr}(M) = \bar{M} \eta (1 - \eta) + \eta^2 [\text{Var}(M) + \bar{M}^2], \end{aligned} \quad (11.34)$$

where we have used (11.30). Finally, the variance of N is

$$\text{Var}(N) = \langle N^2 \rangle - \bar{N}^2 = \eta(1 - \eta) \bar{M} + \eta^2 \text{Var}(M). \quad (11.35)$$

There are several interesting features of (11.35). First, if $\text{Var}(M) = 0$ so that M is not really random, (11.35) shows that $\text{Var}(N) = \eta(1 - \eta)M$, just as we would expect from the binomial law. Second, if η is small, (11.35) can be approximated as

$$\text{Var}(N) \approx \bar{N}, \quad (11.36)$$

just as we would expect for a Poisson random variable. For η small enough, the excess variance is negligible.

Additional insight can be obtained by using $\bar{N} = \eta\bar{M}$ and rewriting (11.35) as (Barrett and Swindell, 1981, 1996)

$$\text{Var}(N) - \bar{N} = \eta^2 [\text{Var}(M) - \bar{M}]. \quad (11.37)$$

This form shows that a sufficient condition for having $\text{Var}(N) = \bar{N}$ is that $\text{Var}(M) = \bar{M}$. This condition is, of course, satisfied if M is Poisson, in which case (11.37) is in accord with the binomial selection theorem. We see also from (11.37) that $\text{Var}(N) \rightarrow \bar{N}$ as $\eta \rightarrow 0$, regardless of the statistics of M . Once again, rarity begets Poissonicity.

Equations (11.35) and (11.37) are general results for binomial selection where the input to the selection process, M , has arbitrary statistics. If M is specifically a doubly stochastic Poisson random variable, its mean is denoted $\bar{\bar{M}}$ and its variance is given by [cf. (11.32)]

$$\text{Var}(M) = \langle M^2 \rangle - \bar{\bar{M}}^2 = \bar{\bar{M}} + \text{Var}(\bar{M}). \quad (11.38)$$

Inserting these results into (11.35), we obtain

$$\text{Var}(N) = \eta(1 - \eta)\bar{\bar{M}} + \eta^2 [\bar{\bar{M}} + \text{Var}(\bar{M})] = \eta\bar{\bar{M}} + \eta^2 \text{Var}(\bar{M}). \quad (11.39)$$

Now the factor $\eta(1 - \eta)$ usually seen in binomial variances does not appear explicitly. Instead, we see that the Poisson part of the variance scales as η while the excess variance scales as η^2 . Again, small efficiency reduces the excess variance relative to the Poisson part.

11.2 POISSON RANDOM VECTORS

Many photon-counting detectors have a discrete output array, where the output value in each element is the number of counts that occurred within the area of the element during the exposure time. For simplicity, we can think of an array of discrete detector elements, each with its own electronic system and counter. Suppose that there are J elements and let the number of photons detected by element j be denoted g_j , ($j = 1, \dots, J$). We wish to find a probability law for the set $\{g_j\}$. In this section we shall call this probability $\text{Pr}(\{g_j\})$, but later it will be convenient to consider the set $\{g_j\}$ as components of a J -dimensional vector \mathbf{g} , so the probability can be denoted more compactly as $\text{Pr}(\mathbf{g})$.

11.2.1 Multivariate Poisson statistics

It is easy to find $\text{Pr}(\{g_j\})$ for a Poisson source since it emits photons independently. Suppose that detector element j has probability P_j of detecting a photon from the

source, and that the mean number emitted by the source during time T is the non-random quantity \overline{M} . Then, by the binomial-selection theorem (Sec. 11.1.3), g_j is a Poisson with mean $\overline{g}_j = P_j \overline{M}$.

Since the photons arriving at different elements are independent, the multivariate probability law $\Pr(\{g_j\})$ on the set of all counts $\{g_j, j = 1, \dots, J\}$ is a product of Poissons of the form

$$\Pr(\{g_j\}) = \prod_{j=1}^J \exp(-P_j \overline{M}) \frac{(P_j \overline{M})^{g_j}}{g_j!} = \prod_{j=1}^J \exp(-\overline{g}_j) \frac{(\overline{g}_j)^{g_j}}{g_j!}. \quad (11.40)$$

Because of this product form, counts in different elements are uncorrelated. Also, the variance of the counts in one element is equal to its mean, so we can write the covariance matrix elements as

$$K_{jk} = \langle \Delta g_j \Delta g_k \rangle = \overline{g}_j \delta_{jk}, \quad (11.41)$$

where $\Delta g_j = g_j - \overline{g}_j$. This relation will prove very useful in later chapters where we discuss statistical properties of images.

Multinomial statistics Another way of obtaining (11.40) is by generalizing the discussion in Sec. 11.1.3 on binomial selection of a Poisson. Suppose that the total number of photons detected by an array is N and that element j has probability α_j of getting any particular photon. If the photons are independent, the conditional multivariate probability law on g_j for fixed N is the multinomial (see App. C):

$$\Pr(\{g_j\}|N) = N! \prod_{j=1}^J \frac{(\alpha_j)^{g_j}}{g_j!}, \quad (11.42)$$

where

$$\sum_{j=1}^J g_j = N, \quad \sum_{j=1}^J \alpha_j = 1. \quad (11.43)$$

Note that (11.42) cannot be factored into independent probabilities because of the factor $N!$.

If N is itself a random variable, we have

$$\Pr(\{g_j\}) = \sum_{N=0}^{\infty} \Pr(\{g_j\}|N) \Pr(N) = \sum_{N=0}^{\infty} \Pr(N) N! \prod_{j=1}^J \frac{(\alpha_j)^{g_j}}{g_j!} \delta\left(N, \sum_{j=1}^J g_j\right), \quad (11.44)$$

where $\delta(\cdot, \cdot)$ is another notation for the Kronecker delta. If $\Pr(N)$ is a Poisson of mean \overline{N} , we have

$$\Pr(\{g_j\}) = \sum_{N=0}^{\infty} \exp(-\overline{N}) (\overline{N})^N \prod_{j=1}^J \frac{(\alpha_j)^{g_j}}{g_j!} \delta\left(N, \sum_{j=1}^J g_j\right). \quad (11.45)$$

Since $\overline{N} = \sum_j \overline{g}_j$, we can rewrite this expression as

$$\Pr(\{g_j\}) = \sum_{N=0}^{\infty} \prod_{j=1}^J \exp(-\overline{g}_j) \frac{(\overline{N} \alpha_j)^{g_j}}{g_j!} \delta\left(N, \sum_{j=1}^J g_j\right). \quad (11.46)$$

The Kronecker delta allows us to perform the sum, with the result:

$$\Pr(\{g_j\}) = \prod_{j=1}^J \exp(-\alpha_j \bar{N}) \frac{(\alpha_j \bar{N})^{g_j}}{g_j!}. \quad (11.47)$$

We have thus generalized the binomial selection theorem:

Multinomial selection of a univariate Poisson yields a multivariate Poisson, and the mean of each cell after multinomial selection is the mean of the input times the probability of the event going to that cell.

Equation (11.47) has the same form as (11.40), but it does not seem to be identical; $\alpha_j \bar{N}$ appears in (11.47) while $P_j \bar{M}$ appears in (11.40). (Recall that \bar{N} is the total number of *detected* photons and α_j is the probability that one of them goes in detector j , while \bar{M} is the total number of photons *emitted* by the source and P_j is the probability that an emitted photon is detected in detector j .) The distinction between $\alpha_j \bar{N}$ and $P_j \bar{M}$ is, however, illusory. Of the M photons emitted by the source, a fraction β on average is detected *somewhere* in the array. (As discussed in Sec. 11.1.3, β is the product of the solid-angle factor $\Omega/4\pi$ and the quantum efficiency η if the photons are emitted isotropically and independently, but we can just leave β as a general parameter, interpreted as the overall probability of detection.) Thus $\bar{N} = \beta \bar{M}$.

Moreover, under the same independence assumptions, N is a binomial selection from M , so $\Pr(N)$ is a Poisson of mean $\bar{N} = \beta \bar{M}$ if $\Pr(M)$ is a Poisson of mean \bar{M} . The counts g_j in any single detector element are obtained by another *binomial* selection with probability of success P_j , so the univariate probability $\Pr(g_j)$ is a Poisson of mean $P_j \bar{N} = \beta P_j \bar{M}$. Finally, we can argue from independence that the multivariate law $\Pr(\{g_j\})$ is just the product of the individual probabilities $\Pr(g_j)$ as given in (11.40) or (11.47); the two are equivalent since $\alpha_j \bar{N} = P_j \bar{M}$, with $P_j = \beta \alpha_j$.

Preset counts vs. preset time We used the multinomial law above as a mathematical device to derive the multivariate Poisson, but there are circumstances where the multinomial itself is the correct multivariate distribution.

In many event-counting systems, data can be acquired either for a given time or until a given number of events is reached. In the nuclear-medicine literature, these two acquisition modes are referred to as preset time and preset counts, respectively, and we shall adopt that terminology here also. The key distinction is that the total number of events N is a random variable for preset time but a fixed number for preset counts.

For preset counts, $\Pr(\{g_j\}|N)$ as given in (11.42) is directly the multivariate probability law for the set $\{g_j\}$. Even though the multinomial is derived on the assumption that the *events* are independent, the *numbers of counts* in different elements are not independent because of the constraint on the total number.

Multinomials and rarity Consider a preset-counts acquisition by a detector array where the number of elements J is large and the counts are spread fairly evenly over the elements, so that α_j is small for all j . Small α_j means that the event of a count going into the j^{th} detector is rare. Since we almost always collect a large total number of counts N , the arguments of Sec. 11.1.2 apply, and the univariate law on any g_j is well approximated by a Poisson of mean $N\alpha_j$.

It is a little trickier to see how the multinomial limits to a multivariate Poisson. The problem is that the total number of counts is fixed, so any one of the g_j is fully determined by the sum of all of the others. Thus the variance of one of the g_j conditional on all of the others is zero.

Let us arbitrarily (and without loss of generality) single out the detector with index $j = J$ as the one with zero conditional variance. Then, with algebra similar to that in (11.20), (11.42) becomes

$$\Pr(\{g_j\}|N) = \delta\left(g_J, N - \sum_{j=1}^{J-1} g_j\right) \prod_{j=1}^{J-1} \exp(-\alpha_j N) \frac{(\alpha_j N)^{g_j}}{g_j!}. \quad (11.48)$$

If we leave out one detector, the probability law on the rest of them is multivariate Poisson in this approximation. Even for the one we leave out, it is easy to show that the mean equals the variance:

$$\langle g_j \rangle = N\alpha_j, \quad \text{Var}(g_j) = \langle g_j \rangle = N\alpha_j. \quad (11.49)$$

Moreover, to the same approximation, the covariance matrix is still given by the Poisson covariance, (11.41).

Once again, we see two routes to the Poisson: independence and rarity. In a preset-time acquisition mode, the counts are independent and the Poisson results from binomial-selection arguments. In a preset-counts mode, strict independence is lost but the Poisson is an excellent approximation if counts in any one detector are rare compared to total counts.

11.2.2 Doubly stochastic multivariate statistics

The lack of correlation and the product form in (11.40) are consequences of the Poisson (independent) nature of the source. They do not apply when the source is random. There are two distinct kinds of randomness that could invalidate those results: either the overall source strength could change from measurement to measurement, or the spatial configuration of the source could change. The first circumstance could occur in passive imaging where a static object is illuminated with a fluctuating external source; then the effective source strength is a constant spatial distribution of reflectance or scattering amplitude times a random illumination. The second circumstance could occur if an ensemble of objects is imaged with a steady source; the statistical properties of interest then include both counting statistics and object statistics.

Variable source strength Assume first that the source fluctuates only in overall strength, and that the spatial distribution of radiation on the detector array is constant. This means that the probabilities P_j are not random variables, and the only random variable describing the source is the strength \bar{M} .

Under these assumptions, the joint probability $\Pr(\{g_j\})$ is obtained simply by averaging (11.40) over the source fluctuations, *i.e.*,

$$\begin{aligned} \Pr(\{g_j\}) &= \int_0^\infty d\bar{M} \text{pr}(\bar{M}) \Pr(\{g_j\}|\bar{M}) \\ &= \int_0^\infty d\bar{M} \text{pr}(\bar{M}) \prod_{j=1}^J \exp(-P_j \bar{M}) \frac{(P_j \bar{M})^{g_j}}{g_j!}. \end{aligned} \quad (11.50)$$

Any marginal $\Pr(g_i)$ can be recovered by summing (11.50) over all g_j for $j \neq i$. All of the sums are one by the normalization of the Poisson probability, and we are left with

$$\Pr(g_i) = \int_0^\infty d\bar{M} \operatorname{pr}(\bar{M}) \exp(-P_i \bar{M}) \frac{(P_i \bar{M})^{g_i}}{g_i!}. \quad (11.51)$$

This equation is a Poisson transform, just as in our original discussion of doubly stochastic Poisson random variables [*cf.* (11.25)]. Indeed, we could have obtained it just by ignoring all other elements.

Of more interest is a pairwise marginal like $\Pr(g_i, g_k)$ for $i \neq k$. Summing (11.50) over all of the g_j except $j = i$ and $j = k$, we find

$$\Pr(g_i, g_k) = \int_0^\infty d\bar{M} \operatorname{pr}(\bar{M}) \exp(-P_i \bar{M}) \frac{(P_i \bar{M})^{g_i}}{g_i!} \exp(-P_k \bar{M}) \frac{(P_k \bar{M})^{g_k}}{g_k!}. \quad (11.52)$$

Various moments can be obtained from this probability via methods used previously. It will be left as an exercise to show that

$$\langle g_i \rangle = P_i \bar{\bar{M}}; \quad (11.53)$$

$$\langle g_i g_k \rangle = P_k \bar{\bar{M}} \delta_{ik} + P_i P_k \left[\operatorname{Var}(\bar{M}) + \bar{\bar{M}}^2 \right]; \quad (11.54)$$

$$[\mathbf{K}_{\mathbf{g}}]_{ik} = \langle \Delta g_i \Delta g_k \rangle = P_k \bar{\bar{M}} \delta_{ik} + P_i P_k \operatorname{Var}(\bar{M}), \quad (11.55)$$

where $\Delta g_i = g_i - \langle g_i \rangle$. Another useful form for the covariance is obtained by use of (11.32) for $\operatorname{Var}(\bar{M})$ (see Barrett and Swindell, 1981, Sec. 3.4, 1996), which leads to

$$[\mathbf{K}_{\mathbf{g}}]_{ik} = P_k \bar{\bar{M}} \delta_{ik} + P_i P_k \left[\operatorname{Var}(M) - \bar{\bar{M}} \right]. \quad (11.56)$$

Equation (11.55) shows that the off-diagonal elements of $\mathbf{K}_{\mathbf{g}}$ vanish if \bar{M} is non-random, which means that the individual counts g_i and g_k are Poisson. Equation (11.56) shows that the off-diagonal elements also vanish if $\operatorname{Var}(M) = \bar{\bar{M}}$; substituting M for N in (11.32), we see that this condition can occur if and only if the density on \bar{M} is a delta function, again implying that the individual counts are Poisson. In addition, both (11.55) and (11.56) show that the off-diagonal elements are small if $P_i P_k$ is small so that detection events are rare (compared to emission events).

Variable source distribution Next we consider what happens if the spatial configuration of the source is random. Different realizations of the source produce different values of the mean counts $\{\bar{g}_j\}$. A full description of the source randomness now requires a specification of the multivariate density $\operatorname{pr}(\{\bar{g}_j\})$, not just the univariate $\operatorname{pr}(\bar{M})$. Note that variable source strength, treated above, is a special case of variable source distribution where all of the \bar{g}_j covary together as a result of the common factor \bar{M} . Here we analyze the more general case.

The joint probability $\Pr(\{g_j\})$ is obtained by averaging (11.40) over the set $\{\bar{g}_j\}$, and (11.50) generalizes to

$$\begin{aligned}
\Pr(\{g_j\}) &= \int_0^\infty d\bar{g}_1 \int_0^\infty d\bar{g}_2 \cdots \int_0^\infty d\bar{g}_J \Pr(\{\bar{g}_j\}) \Pr(\{g_j\}|\{\bar{g}_j\}) \\
&= \int_0^\infty d\bar{g}_1 \int_0^\infty d\bar{g}_2 \cdots \int_0^\infty d\bar{g}_J \Pr(\{\bar{g}_j\}) \prod_{j=1}^J \exp(-\bar{g}_j) \frac{(\bar{g}_j)^{g_j}}{g_j!}. \quad (11.57)
\end{aligned}$$

This expression appears formidable, but it is actually fairly easy to obtain means and covariances from it. Showing all of the steps for pedagogical purposes, we find the mean of g_k via

$$\begin{aligned}
\langle g_k \rangle &= \sum_{g_1=0}^\infty \cdots \sum_{g_k=0}^\infty \cdots \sum_{g_J=0}^\infty g_k \Pr(\{g_j\}) \\
&= \int_0^\infty d\bar{g}_1 \int_0^\infty d\bar{g}_2 \cdots \int_0^\infty d\bar{g}_J \Pr(\{\bar{g}_j\}) \sum_{g_1=0}^\infty \cdots \sum_{g_k=0}^\infty \cdots \sum_{g_J=0}^\infty g_k \prod_{j=1}^J \exp(-\bar{g}_j) \frac{(\bar{g}_j)^{g_j}}{g_j!} \\
&= \int_0^\infty d\bar{g}_1 \int_0^\infty d\bar{g}_2 \cdots \int_0^\infty d\bar{g}_J \Pr(\{\bar{g}_j\}) \sum_{g_k=0}^\infty g_k \exp(-\bar{g}_k) \frac{(\bar{g}_k)^{g_k}}{g_k!} \\
&= \int_0^\infty d\bar{g}_k \Pr(\bar{g}_k) \bar{g}_k = \bar{\bar{g}}_k. \quad (11.58)
\end{aligned}$$

Along the way, we have used the normalization of the Poisson law (from line 2 to line 3) and the definition of marginal densities (line 3 to line 4). The final result, of course, could have been written down virtually by inspection.

Similar manipulations yield the second moment. Under Poisson statistics alone, $\langle g_i g_k \rangle = \bar{g}_i \delta_{ik} + \bar{g}_i \bar{g}_k$, but with the additional randomness in the means, we have

$$\langle g_i g_k \rangle = \int_0^\infty d\bar{g}_i \int_0^\infty d\bar{g}_k \Pr(\bar{g}_i, \bar{g}_k) [\bar{g}_i \delta_{ik} + \bar{g}_i \bar{g}_k] = \bar{\bar{g}}_i \delta_{ik} + [\mathbf{K}_{\bar{\mathbf{g}}}]_{ik} + \bar{\bar{g}}_i \bar{\bar{g}}_k, \quad (11.59)$$

where $\mathbf{K}_{\bar{\mathbf{g}}}$ is the covariance matrix for the means,

$$[\mathbf{K}_{\bar{\mathbf{g}}}]_{ik} = \langle [\bar{g}_i - \bar{\bar{g}}_i] [\bar{g}_k - \bar{\bar{g}}_k] \rangle. \quad (11.60)$$

The final covariance matrix for the counts themselves is

$$[\mathbf{K}_{\mathbf{g}}]_{ik} = \langle [g_i - \bar{g}_i] [g_k - \bar{g}_k] \rangle = \bar{\bar{g}}_i \delta_{ik} + [\mathbf{K}_{\bar{\mathbf{g}}}]_{ik}. \quad (11.61)$$

Several limits and special cases of this result are of interest. First, if none of the means is random, we are back to Poisson statistics, and the covariance matrix has the diagonal form given in (11.41). Second, if the randomness in the means comes from randomness in overall source strength without any variation in source configuration, then all of the means covary together, $[\mathbf{K}_{\bar{\mathbf{g}}}]_{ik}$ is $P_i P_k \text{Var}(\bar{M})$, and (11.55) is recovered.

Finally, as in the case of randomness in overall source strength [*cf.* (11.55)], the two terms in (11.61) have different dependencies on average number of counts. The first term $\bar{\bar{g}}_i \delta_{ik}$ varies as the mean number of counts, which means it is linear in source strength, detector efficiency or counting time. The second term $[\mathbf{K}_{\bar{\mathbf{g}}}]_{ik}$ is

quadratic in all of these quantities, so it becomes relatively more important as mean counts increase. Conversely, when there are relatively few counts, the second term can be neglected and the covariance matrix \mathbf{K}_g is diagonal in spite of randomness in the individual means \bar{g}_j . Thus Poisson sources always produce uncorrelated, Poisson-distributed counts, and non-Poisson sources produce approximately uncorrelated and approximately Poisson-distributed counts in inefficient detectors.

11.3 RANDOM POINT PROCESSES

A random point process is a random process for which each sample function is localized to a set of spatial or temporal points (Snyder and Miller, 1991). A sample function of a point process is thus a sum of delta functions in some number of dimensions. The amplitude and arguments of the delta functions can be random variables, and the number of terms in the sum can be random as well.

In this section we develop the mathematical tools necessary to describe the first- and second-order statistics of point processes. As in Sec. 11.1, we cast the discussion in terms of radiation falling on a photon-counting detector since this is the most common manifestation of point processes in optics and imaging.

11.3.1 Temporal point processes

Consider first a detector that produces a current pulse for each photoelectric interaction, and assume that this current pulse is independent of the spatial coordinates of the event. If the properties of the detector and its associated electronic circuitry are time-invariant (though the radiation source need not be temporally stationary), the current waveform can be expressed as

$$i(t) = \sum_{n=1}^N i_0(t - t_n), \quad (11.62)$$

where $i_0(t)$ is the current pulse produced by a count at $t = 0$, t_n is the time of occurrence of the n^{th} count ($0 < t_n \leq T$), and N is the total number of counts in $(0, T)$.

This current waveform can be written as

$$i(t) = z(t) * i_0(t), \quad (11.63)$$

where $z(t)$ is a random point process defined by

$$z(t) = \sum_{n=1}^N \delta(t - t_n), \quad (0 < t \leq T). \quad (11.64)$$

Since the delta function is a generalized function, $z(t)$ is a generalized random process. Once the statistical properties of $z(t)$ are understood, those of $i(t)$ can be derived by using the methods developed in Sec. 8.2 for filtered random processes.

Invocation of the Poisson postulates A full specification of the statistics of $z(t)$ requires knowledge of the probability laws for each of the random variables involved.

In (11.64) there are $N + 1$ random variables, namely each of the t_n and N itself. We require, therefore, the joint probability law on N and the arrival times $\{t_n\}$, which we can write as $\text{pr}(\{t_n\}|N)\text{Pr}(N)$. It is easiest to specify this probability law in the case of a Poisson point process where the postulates of Sec. 11.1.1 are satisfied, and that is what we do here. Deviations from the Poisson model are considered in Sec. 11.3.6 and 11.3.7.

First, note that the index n labels the individual counts but does not specify the order of arrival. The counts are assumed to be indistinguishable, so $\text{pr}(\{t_n\}|N)$ must be invariant to permutations of the labels. Second, under the Poisson postulates the counts are assumed to be statistically independent. With these assumptions, the variables $\{t_n\}$ are *i.i.d.* (independent and identically distributed) and we have

$$\text{pr}(\{t_n\}|N) = \prod_{n=1}^N \text{pr}(t_n). \quad (11.65)$$

Note that $\text{pr}(t_n)$ cannot depend on the total number N if the counts are to be statistically independent.

We can relate $\text{pr}(t_n)$ to the mean arrival rate $a(t)$ introduced in Sec. 11.1.1. If we allow $a(t)$ to be a nonrandom function of time, postulate (b) states that the probability of getting one count in $(t, t + \Delta T)$ is given by

$$\text{Pr}[1 \text{ in } (t, t + \Delta T)] = a(t)\Delta T, \quad (\Delta T \rightarrow 0). \quad (11.66)$$

This same probability is also the probability that *one* of the t_n lies in this time interval. The event that t_n lies in the interval $(t, t + \Delta T)$ and the event that $t_m (m \neq n)$ lies in the same interval are mutually exclusive by postulate (c) as $\Delta T \rightarrow 0$. Thus the probability that either t_n or t_m is in the interval is the sum of the individual probabilities, or twice the probability that specifically t_n is in the interval. By extension, if exactly N counts occur in $(0, T)$ and both t and $t + \Delta T$ lie in this interval, then the probability that one count occurs in $(t, t + \Delta T)$ is given by

$$\text{Pr}[1 \text{ in } (t, t + \Delta T)|N] = N \text{Pr}(t < t_n \leq t + \Delta T) = N \int_t^{t+\Delta T} dt_n \text{pr}(t_n) \approx N\Delta T \text{pr}(t). \quad (11.67)$$

The approximation in the last step becomes exact as $\Delta T \rightarrow 0$.

The probability $\text{Pr}[1 \text{ in } (t, t + \Delta T)]$ is obtained by averaging over N :

$$\text{Pr}[1 \text{ in } (t, t + \Delta T)] = \sum_{N=0}^{\infty} \text{Pr}(N) \text{Pr}[1 \text{ in } (t, t + \Delta T)|N] = \bar{N}\Delta T \text{pr}(t). \quad (11.68)$$

Comparison of (11.68) with (11.66) shows that

$$\bar{N} \text{pr}(t_n) = a(t_n). \quad (11.69)$$

Thus $a(t)$, originally introduced in Sec. 11.1 as a mean arrival rate at time t , now takes on a second meaning. When evaluated at t_n , it is the constant \bar{N} times the probability density for occurrence of a count at $t = t_n$. (Note that both $\text{pr}(t_n)$ and $a(t_n)$ have dimensions of reciprocal time.)

Since we know from (11.19) that \bar{N} is the integral of $a(t)$, we also have

$$\text{pr}(t_n) = \frac{a(t_n)}{\int_0^T dt a(t)}, \quad (11.70)$$

which shows immediately that

$$\int_0^T dt_n \operatorname{pr}(t_n) = 1. \quad (11.71)$$

Thus the probability density on arrival times is just the mean arrival rate properly normalized.

When do the postulates break down? The essence of the Poisson postulates is the independence of the events. Thus the statistical independence expressed in (11.65) is required by the postulates. We shall now consider several physical circumstances in which independence is not a valid assumption.

One such circumstance is detector saturation, manifested as dead time or loss of efficiency at high counting rates. If one photon temporarily paralyzes the detector and there is a significant probability of another photon arriving before it recovers, the probability of detection of the second photon is dependent on the presence of the first.

Statistical independence also fails in random multiplication processes where one primary event gives rise to a random number of secondary events. In a scintillation detector, for example, a single gamma-ray photon produces a large number of optical photons, and these secondary events are not statistically independent since they arise from the same gamma-ray photon. This situation will be discussed further in Sec. 11.4.

Statistical independence also breaks down if $a(t)$ is itself random, in which case we refer to $z(t)$ as a *doubly stochastic Poisson random process*. The effect of such processes on the statistics of the total number of counts was discussed in Sec. 11.1.4, and the effect on the mean and autocorrelation of $z(t)$ will be discussed below in Sec. 11.3.7.

The postulates are intimately related not only to the probability density on the arrival times but also to the probability law on the total number of counts. The postulates cannot be satisfied unless N is a random variable, and specifically a Poisson random variable. With photon-counting detectors, it is always possible to remove the randomness in N ; all we have to do is to count for a preset number of counts rather than for a preset time. When exactly N_0 counts have been accumulated, the accumulation is terminated. Under these conditions, $\operatorname{Pr}(N)$ is the Kronecker delta δ_{N,N_0} , but this form of $\operatorname{Pr}(N)$ is incompatible with postulate (a). Suppose that $N_0 - 1$ counts occur in an interval $(0, t')$ and the total number of counts is constrained to be N_0 . Then the number of counts in (t', T) is fully determined, in contradiction to postulate (a); it can only be one.

In summary, the Poisson postulates can be satisfied only if the arrival times are statistically independent and identically distributed as in (11.65), the probability density on each arrival time is a normalized version of the mean arrival rate as in (11.70), and the total number of counts N is a Poisson random variable.

11.3.2 Spatial point processes

The spatial counterpart of the temporal point process $z(t)$ is $g(\mathbf{r})$, defined by

$$g(\mathbf{r}) = \sum_{n=1}^N \delta(\mathbf{r} - \mathbf{r}_n), \quad (11.72)$$

where \mathbf{r} is a spatial position vector in q dimensions. For example, with $q = 2$, $g(\mathbf{r})$ could describe the pattern of photon interactions on a piece of film.

As in the temporal case, there are $N + 1$ random variables in $g(\mathbf{r})$, namely the N positions \mathbf{r}_n and N itself. A full specification of the statistics of $g(\mathbf{r})$ requires the joint probability law $\text{pr}(\{\mathbf{r}_n\}|N) \text{Pr}(N)$.

Spatial Poisson postulates and their consequences As in the temporal case, there are certain postulates that will lead to $g(\mathbf{r})$ being a Poisson random process. For definiteness we take $q = 2$ and speak in terms of areas, but the extension to 3D volumes or regions in spaces of other dimensionalities is straightforward. We consider an overall area A and an exposure time T during which counts occur at points $\{\mathbf{r}_n\}$ contained in A . The spatial counterparts of the postulates given for the temporal case in Sec. 11.1.1 are:

(a) The number of counts in any area A_1 is statistically independent of the number in any other nonoverlapping area A_2 , where A_1 and A_2 are subareas of A .

(b) If we consider a very small area ΔA contained in A and centered on point \mathbf{r} , the probability of a single count in this area during an observation time approaches a deterministic function $b(\mathbf{r})$ times ΔA , *i.e.*, up through terms linear in ΔA ,

$$\text{Pr}(1 \text{ in } \Delta A) = b(\mathbf{r}) \Delta A. \quad (11.73)$$

(c) The probability of more than one count in a vanishingly small area ΔA is zero. Thus, again through terms linear in ΔA ,

$$\text{Pr}(1 \text{ in } \Delta A) + \text{Pr}(0 \text{ in } \Delta A) = 1. \quad (11.74)$$

Note that we have allowed $\text{Pr}(1 \text{ in } \Delta A)$ to be a function of position, but that $b(\mathbf{r})$ in (11.73) is a fixed function and not yet a random process.

By arguments analogous to those of the temporal case, these postulates can be satisfied only if

$$\text{pr}(\{\mathbf{r}_n\}|N) = \prod_{n=1}^N \text{pr}(\mathbf{r}_n); \quad (11.75)$$

$$\text{pr}(\mathbf{r}_n) = \frac{b(\mathbf{r}_n)}{\int_A d^2r b(\mathbf{r})}; \quad (11.76)$$

$$\text{Pr}(N) = \frac{\bar{N}^N}{N!} \exp(-\bar{N}); \quad (11.77)$$

$$\bar{N} = \int_A d^2r b(\mathbf{r}). \quad (11.78)$$

As in the temporal case, we see that $b(\mathbf{r})$ has a dual interpretation. It is the *count density* or mean number of counts per unit area, and after normalization as in (11.76), it is also the probability density on the position of any individual count. In the language of radiometry (see Chap. 10), $b(\mathbf{r})$ is the mean *photon fluence* if $g(\mathbf{r})$ represents a photon distribution.

The spatial Poisson postulates can break down for reasons similar to those discussed above in the temporal case. In particular, they do not hold for random multiplication processes where two or more correlated secondary events are produced by one primary event. This issue is discussed further in Sec. 11.4.

11.3.3 Mean and autocorrelation of point processes

Since sample functions of a point process are generalized functions (sums of delta functions) with no finite values other than zero, a probability density function does not have much meaning. As with many other random processes, the most we can do is compute the first- and second-order statistics of the process, or its mean and autocorrelation function. We carry out this calculation here for the spatial point process $g(\mathbf{r})$; simple changes in notation will yield the corresponding results for the temporal case.

Mean of a general spatial point process To compute the expectation value of $g(\mathbf{r})$, we must average over the random variables $\{\mathbf{r}_n, n = 1, \dots, N\}$ and N itself. Equations (11.75) – (11.78) specify the probability laws of these variables for Poisson processes, but we shall delay for a while invoking these equations. Instead, we first derive a general expression that will prove useful later.

The joint probability law for $\{\mathbf{r}_n\}$ and N can be written as $\text{pr}(\{\mathbf{r}_n\}|N) \text{Pr}(N)$, and the general formula of interest is obtained by first taking the conditional expectation of $g(\mathbf{r})$ for fixed N and then averaging over N . With the definition of $g(\mathbf{r})$ from (11.72), the first step requires evaluation of

$$E\{g(\mathbf{r})|N\} = \int_A d^2r_1 \int_A d^2r_2 \cdots \int_A d^2r_N \text{pr}(\{\mathbf{r}_n\}|N) \sum_{n=1}^N \delta(\mathbf{r} - \mathbf{r}_n). \quad (11.79)$$

For any particular n , all of the integrals over \mathbf{r}_j except the one with $j = n$ can be performed by use of (C.75). What remains after performing these $N - 1$ integrals is the marginal density for \mathbf{r}_n , so

$$E\{g(\mathbf{r})|N\} = \sum_{n=1}^N \int_A d^2r_n \text{pr}(\mathbf{r}_n|N) \delta(\mathbf{r} - \mathbf{r}_n). \quad (11.80)$$

With the sifting property of delta functions, we have

$$E\{g(\mathbf{r})|N\} = \sum_{n=1}^N \text{pr}(\mathbf{r}|N) = N \text{pr}(\mathbf{r}|N). \quad (11.81)$$

The notation here is a bit tricky; $\text{pr}(\mathbf{r}|N)$ must be interpreted as $\text{pr}(\mathbf{r}_n|N)$ after the substitution $\mathbf{r}_n = \mathbf{r}$. The random variable is \mathbf{r}_n , and \mathbf{r} is a deterministic position vector. A further average over N yields

$$E\{g(\mathbf{r})\} = \langle N \text{pr}(\mathbf{r}|N) \rangle_N = \sum_{N=0}^{\infty} \text{Pr}(N) N \text{pr}(\mathbf{r}|N). \quad (11.82)$$

Mean of a Poisson point process The expression (11.82) holds for any point process; we have not used any specific characteristics of Poisson point processes. For the Poisson case, $\text{pr}(\mathbf{r}|N)$ is independent of N , and we can use (11.76) to write

$$\text{pr}(\mathbf{r}) = \frac{b(\mathbf{r})}{\int_A d^2r' b(\mathbf{r}')}. \quad (11.83)$$

With (11.78) we have, finally,

$$E\{g(\mathbf{r})\} = \bar{N} \text{pr}(\mathbf{r}) = b(\mathbf{r}). \quad (11.84)$$

This result provides a third interpretation of $b(\mathbf{r})$ for Poisson processes. We have already seen that it is both the mean number of counts per unit area and, when normalized, the probability density on the position of any individual count. We now see from (11.84) that it is also the expectation value of the random process $g(\mathbf{r})$. All three of these interpretations are dimensionally consistent since counts per unit area, $\text{pr}(\mathbf{r}_j)$ and $g(\mathbf{r})$ all have dimensions of reciprocal area (see Sec. 2.4.6 for a discussion of dimensions of delta functions).

Autocorrelation function of a general point process We consider next the autocorrelation function for the random point process $g(\mathbf{r})$. Initially we avoid use of the Poisson model in order to obtain a general result; then we specialize to the Poisson case.

The nonstationary autocorrelation function of $g(\mathbf{r})$ is defined by

$$R_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = E\{g(\mathbf{r})g(\mathbf{r}')\}. \quad (11.85)$$

Again we do the calculation in two stages, first over the set $\{\mathbf{r}_n\}$ for fixed N , then over N . The first stage requires computation of

$$E\{g(\mathbf{r})g(\mathbf{r}')|N\} = \int_A d^2r_1 \int_A d^2r_2 \cdots \int_A d^2r_N \text{pr}(\{\mathbf{r}_n\}|N) \sum_{n=1}^N \delta(\mathbf{r}-\mathbf{r}_n) \sum_{j=1}^N \delta(\mathbf{r}'-\mathbf{r}_j). \quad (11.86)$$

The double sum over j and n has N^2 terms, N of which have $j = n$ and $N^2 - N$ of which have $j \neq n$. Consider first a term with $j = n$. All of the integrals over \mathbf{r}_l except the one with $l = j = n$ can be performed by (C.75), resulting in the marginal density for \mathbf{r}_n . Then, with a property of delta functions given in (2.78) and (2.79), we have

$$\begin{aligned} & \int_A d^2r_1 \int_A d^2r_2 \cdots \int_A d^2r_N \text{pr}(\{\mathbf{r}_n\}|N) \delta(\mathbf{r}-\mathbf{r}_n) \delta(\mathbf{r}'-\mathbf{r}_n) \\ &= \int_A d^2r_n \text{pr}(\mathbf{r}_n|N) \delta(\mathbf{r}-\mathbf{r}_n) \delta(\mathbf{r}'-\mathbf{r}_n) = \text{pr}(\mathbf{r}|N) \delta(\mathbf{r}-\mathbf{r}'), \end{aligned} \quad (11.87)$$

where again $\text{pr}(\mathbf{r}|N)$ is to be interpreted as $\text{pr}(\mathbf{r}_n|N)$ evaluated at $\mathbf{r}_n = \mathbf{r}$. Note that (11.87) is independent of n . There are N terms with $j = n$, and all of them have the same expectation. Thus the contribution to $E\{g(\mathbf{r})g(\mathbf{r}')|N\}$ from all terms with $j = n$ is

$$[E\{g(\mathbf{r})g(\mathbf{r}')|N\}]_{j=n} = N \text{pr}(\mathbf{r}|N) \delta(\mathbf{r}-\mathbf{r}'). \quad (11.88)$$

Next consider the case $j \neq n$. Now all but two of the integrals can be performed by (C.75), and we obtain

$$\begin{aligned} & \int_A d^2r_1 \int_A d^2r_2 \cdots \int_A d^2r_N \text{pr}(\{\mathbf{r}_n\}|N) \delta(\mathbf{r}-\mathbf{r}_n) \delta(\mathbf{r}'-\mathbf{r}_j) \\ &= \int_A d^2r_n \int_A d^2r_j \text{pr}(\mathbf{r}_n, \mathbf{r}_j|N) \delta(\mathbf{r}-\mathbf{r}_n) \delta(\mathbf{r}'-\mathbf{r}_j) = \text{pr}(\mathbf{r}, \mathbf{r}'|N), \end{aligned} \quad (11.89)$$

where $\text{pr}(\mathbf{r}, \mathbf{r}'|N)$ is the joint density $\text{pr}(\mathbf{r}_n, \mathbf{r}_j|N)$ evaluated at $\mathbf{r}_n = \mathbf{r}$ and $\mathbf{r}_j = \mathbf{r}'$.

Since (11.89) is independent of j and n , the contribution to $E\{g(\mathbf{r})g(\mathbf{r}')|N\}$ from the $N^2 - N$ terms with $j \neq n$ is

$$[E\{g(\mathbf{r})g(\mathbf{r}')|N\}]_{j \neq n} = (N^2 - N) \text{pr}(\mathbf{r}, \mathbf{r}'|N). \quad (11.90)$$

The conditional autocorrelation function $\{g(\mathbf{r})g(\mathbf{r}')|N\}$ is obtained by adding (11.88) and (11.90). A subsequent average over N yields the general result,

$$R_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = E\{g(\mathbf{r})g(\mathbf{r}')\} = \langle N \text{pr}(\mathbf{r}|N) \rangle_N \delta(\mathbf{r} - \mathbf{r}') + \langle [N^2 - N] \text{pr}(\mathbf{r}, \mathbf{r}'|N) \rangle_N. \tag{11.91}$$

The autocovariance function for $g(\mathbf{r})$ is given by

$$\begin{aligned} K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') &= \langle \Delta g(\mathbf{r}) \Delta g(\mathbf{r}') \rangle = R_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') - E\{g(\mathbf{r})\} E\{g(\mathbf{r}')\} \\ &= \langle N \text{pr}(\mathbf{r}|N) \rangle_N \delta(\mathbf{r} - \mathbf{r}') + \langle [N^2 - N] \text{pr}(\mathbf{r}, \mathbf{r}'|N) \rangle_N - \langle N \text{pr}(\mathbf{r}|N) \rangle_N \langle N \text{pr}(\mathbf{r}'|N) \rangle_N, \end{aligned} \tag{11.92}$$

where $\Delta g(\mathbf{r}) = g(\mathbf{r}) - \langle g(\mathbf{r}) \rangle$.

Autocorrelation function of a Poisson point process We now specialize the general results (11.91) and (11.92) to the case of a Poisson process. Under that model, $\text{pr}(\mathbf{r}, \mathbf{r}'|N) = \text{pr}(\mathbf{r}) \text{pr}(\mathbf{r}')$ (independent of N) and $\text{pr}(\mathbf{r})$ is given by (11.83). Moreover, for Poisson random variables, $\langle N^2 - N \rangle_N = \overline{N}^2$, and \overline{N} is given by the denominator of (11.83). Thus,

$$R_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') + b(\mathbf{r}) b(\mathbf{r}'). \tag{11.93}$$

For the autocovariance function in the Poisson case, the second and third terms in the last form of (11.92) cancel, and we obtain

$$K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'). \tag{11.94}$$

Note that the variance, $K_{\mathbf{g}}(\mathbf{r}, \mathbf{r})$, is infinite; it could hardly be otherwise for a random process that takes on only the values zero and infinity. In Sec. 11.3.9 we shall see that this is not a worry in practice since a filtered Poisson random process always has finite variance.

Temporal Poisson processes We can easily transcribe the results of this section to the temporal case just by replacing $g(\mathbf{r})$ with $z(t)$ and $b(\mathbf{r})$ with $a(t)$. For a nonrandom but possibly time-varying rate $a(t)$, the mean of $z(t)$ is [cf. (11.84)]

$$E\{z(t)\} = a(t). \tag{11.95}$$

Similarly, the autocorrelation function is [cf. (11.93)]

$$R_z(t, t') = a(t) \delta(t - t') + a(t) a(t'). \tag{11.96}$$

The autocovariance function for $z(t)$ is [cf. (11.94)]

$$K_z(t, t') = a(t) \delta(t - t'). \tag{11.97}$$

We emphasize that these results hold only if the Poisson postulates are satisfied, which means that $a(t)$ is nonrandom and N is a Poisson random variable.

11.3.4 Relation between Poisson random vectors and processes

We have so far discussed Poisson random vectors and random processes separately. In this section we explore the connections between them.

From process to vector In Sec. 11.2.1 we discussed multivariate Poisson statistics, and especially the multivariate probability law (11.40). That law can also be derived another way, starting from what we know about Poisson random processes. Suppose we have a 2D detector array with uniformly spaced pixels of area ϵ^2 . Assume that the pattern of photons incident on the detector is described by the 2D Poisson random process $g(\mathbf{r})$ and that every photon incident on the area of the j^{th} pixel is detected and assigned to that pixel. Then the (random) number of counts in the j^{th} pixel is given by

$$g_j = \int_j d^2r g(\mathbf{r}), \quad (11.98)$$

where the integral is over the area of the j^{th} pixel. The mean number of counts in this pixel is given by

$$\bar{g}_j = \int_j d^2r b(\mathbf{r}). \quad (11.99)$$

The variance of g_j is given by

$$\begin{aligned} \text{Var}(g_j) &= \text{E}\{[g_j - \bar{g}_j]^2\} = \int_j d^2r \int_j d^2r' \langle \Delta g(\mathbf{r}) \Delta g(\mathbf{r}') \rangle \\ &= \int_j d^2r \int_j d^2r' K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = \int_j d^2r \int_j d^2r' b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') = \int_j d^2r b(\mathbf{r}) = \bar{g}_j, \end{aligned} \quad (11.100)$$

where $\Delta g(\mathbf{r}) = g(\mathbf{r}) - \langle g(\mathbf{r}) \rangle = g(\mathbf{r}) - b(\mathbf{r})$.

The covariance of the counts in two different pixels is computed similarly:

$$\begin{aligned} \text{E}\{(g_j - \bar{g}_j)(g_k - \bar{g}_k)\} &= \int_j d^2r \int_k d^2r' \langle \Delta g(\mathbf{r}) \Delta g(\mathbf{r}') \rangle \\ &= \int_j d^2r \int_k d^2r' K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = \int_j d^2r \int_k d^2r' b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'). \end{aligned} \quad (11.101)$$

Now, however, the double integral must be zero since \mathbf{r} cannot equal \mathbf{r}' if the former lies in the j^{th} pixel and the latter in the k^{th} . We can combine the cases $j = k$ and $j \neq k$ by writing

$$\text{E}\{(g_j - \bar{g}_j)(g_k - \bar{g}_k)\} = \bar{g}_j \delta_{jk}. \quad (11.102)$$

This result is in accord with (11.41).

We can also justify the multivariate Poisson form in (11.40). Again the key is the binomial selection theorem, with the probability of a photon being detected in the j^{th} pixel given by

$$P_j = \frac{\int_j d^2r b(\mathbf{r})}{\int_{\text{det}} d^2r b(\mathbf{r})}, \quad (11.103)$$

where the integral in the denominator is over the whole detector. Since binomial selection of a Poisson yields a Poisson, and since the events are independent, (11.40) follows.

From vector to process Having derived the probability law (11.40) from the properties of Poisson random processes, it is instructive to go in the other direction and derive the autocorrelation function of the random processes from the probability law (Metz, 1969). Since (11.40) implies (11.41), we start with the latter equation, rewriting it as

$$\mathbb{E} \left[\frac{\Delta g_j}{\epsilon^2} \frac{\Delta g_k}{\epsilon^2} \right] = \frac{\bar{g}_j}{\epsilon^2} \frac{\delta_{jk}}{\epsilon^2}, \quad (11.104)$$

where $\Delta g_k = g_k - \bar{g}_k$. Since ϵ^2 is the area of a pixel, \bar{g}_j/ϵ^2 is the mean number of counts per unit area in the j^{th} pixel. Similarly, g_j/ϵ^2 is the actual random number per unit area. If we pass to the limit $\epsilon \rightarrow 0$, then $g_j/\epsilon^2 \rightarrow g(\mathbf{r}_j)$ and $\bar{g}_j/\epsilon^2 \rightarrow b(\mathbf{r}_j)$. Furthermore,

$$\lim_{\epsilon \rightarrow 0} \frac{\delta_{jk}}{\epsilon^2} = \delta(\mathbf{r}_j - \mathbf{r}_k). \quad (11.105)$$

This result can be proved by integrating both sides over \mathbf{r}_j (or \mathbf{r}_k) and representing the integral on the left by a Riemann sum. Collecting results, we now have

$$\lim_{\epsilon \rightarrow 0} \mathbb{E} \left\{ \frac{\Delta g_j}{\epsilon^2} \frac{\Delta g_k}{\epsilon^2} \right\} = \mathbb{E} \{ \Delta g(\mathbf{r}_j) \Delta g(\mathbf{r}_k) \} = b(\mathbf{r}_j) \delta(\mathbf{r}_j - \mathbf{r}_k), \quad (11.106)$$

which is identical to (11.94).

11.3.5 Karhunen-Loève analysis of Poisson processes

In Sec. 8.2.7 we introduced the concept of Karhunen-Loève analysis, which is just eigenanalysis of the autocovariance operator. What are the eigenfunctions of the temporal autocovariance operator with kernel $K_{\mathbf{z}}(t, t')$ as given in (11.97)? The eigenvalue problem is

$$\int_{-\infty}^{\infty} dt' a(t') \delta(t - t') \phi(t') = \mu \phi(t). \quad (11.107)$$

The integral can be performed by means of the sifting property of delta functions, so the eigenvalue problem can also be stated as

$$a(t) \phi(t) = \mu \phi(t). \quad (11.108)$$

Since μ cannot be a function of t , we require a function which, when multiplied by an arbitrary $a(t)$, will yield a constant times the original function. The required function is

$$\phi(t) = \delta(t - t_0), \quad (11.109)$$

since, by (2.25),

$$a(t) \delta(t - t_0) = a(t_0) \delta(t - t_0) = \text{const} \cdot \delta(t - t_0). \quad (11.110)$$

Thus the eigenfunctions are the delta functions $\delta(t - t_0)$, indexed by the continuous variable t_0 , and the eigenvalues are just the rates $a(t_0)$. The continuous index arises because this particular correlation operator is not compact (see Sec. 8.2.7). The fact that the eigenfunctions are delta functions means that the Karhunen-Loève domain is the original time domain in this problem. An exactly parallel analysis holds for spatial Poisson random processes.

We are now up to four interpretations of the rate $a(t)$. It is (1) the mean number of counts per unit time; (2) when normalized, the probability density on the time of arrival of any individual count; (3) the expectation value of the random process $z(t)$, and now (4) an eigenvalue of the autocovariance operator. Just as the statistics of a Poisson random variable are fully determined by its mean, so too are the statistics of a Poisson random *process* fully determined by its mean *rate*. Similar conclusions hold for spatial Poisson processes, and the same set of four interpretations applies to the spatial density $b(\mathbf{r})$.

The reader may have noticed an anomaly. In Sec. 8.2.7 we learned that the Karhunen-Loève domain was the frequency domain for stationary random processes. Here we see that it is the time (or space) domain for Poisson random processes, which might in fact be stationary. How do we reconcile these apparently contradictory statements?

In order for $z(t)$ to be stationary, $a(t)$ must be constant. In that case, the stationary autocovariance function $K_{\mathbf{z}}(t)$ is $a\delta(t)$, so the autocovariance operator is a multiple of the unit operator. If we transform this operator to the frequency domain, we find

$$\Gamma(\nu_1, \nu_2) = \int_{-\infty}^{\infty} dt_1 \int_{-\infty}^{\infty} dt_2 a \delta(t_1 - t_2) \exp[-2\pi i(\nu_1 \cdot t_1 - \nu_2 \cdot t_2)] = a \delta(\nu_1 - \nu_2). \quad (11.111)$$

Thus the operator has exactly the same form in the frequency and time domains; unitary transformations leave the unit operator unchanged. It is therefore not surprising that both domains are Karhunen-Loève.

11.3.6 Doubly stochastic spatial Poisson random processes

In Sec. 11.1.4 we studied the effect of randomness in the rate $a(t)$ on the statistics of the total counts N , and in Sec. 11.2.2 we examined similar effects for random vectors, but so far in Sec. 11.3 $a(t)$ and its spatial counterpart $b(\mathbf{r})$ have been considered nonrandom. We now extend the treatment in Sec. 11.1.4 and compute the mean and autocorrelation function of a doubly stochastic spatial Poisson random process. The corresponding temporal case will be studied in Sec. 11.3.7.

Figure 11.3 illustrates the basic idea of a doubly stochastic Poisson process in 1D. Like a Poisson point process, each sample function $g(x)$ of this process is still a sum of delta functions, but now the density of the delta functions is controlled by the random process $b(x)$.

From (11.84) we know that the mean of $g(\mathbf{r})$ is $b(\mathbf{r})$ if that function is deterministic. We could equally well regard $b(\mathbf{r})$ as a sample function of a random process, however, and (11.84) would still be valid for a specific $b(\mathbf{r})$. The mean of a doubly stochastic Poisson random process is obtained simply by averaging (11.84) over all realizations of the process $b(\mathbf{r})$. All we need is some notation.

We now designate the kind of average we have been using in this chapter, where $b(\mathbf{r})$ is fixed, as a conditional average $E\{\cdot|\mathbf{b}\}$, where \mathbf{b} is the Hilbert-space vector corresponding to $b(\mathbf{r})$. With this notation, (11.84) can be written as

$$E\{g(\mathbf{r})|\mathbf{b}\} = b(\mathbf{r}). \quad (11.112)$$

A further average over realizations of $b(\mathbf{r})$ will be denoted by $E_{\mathbf{b}}\{\cdot\}$, so

$$E_{\mathbf{b}}\{E\{g(\mathbf{r})|\mathbf{b}\}\} = E_{\mathbf{b}}\{b(\mathbf{r})\} \equiv \bar{b}(\mathbf{r}). \quad (11.113)$$

If $b(\mathbf{r})$ is a stationary random process, then $\bar{b}(\mathbf{r})$ is a constant.

Now consider the same averaging process for the autocorrelation function. Averaging (11.93) over $b(\mathbf{r})$ yields

$$E_{\mathbf{b}}\{E\{g(\mathbf{r})g(\mathbf{r}')|\mathbf{b}\}\} = R_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = \bar{b}(\mathbf{r})\delta(\mathbf{r} - \mathbf{r}') + R_{\mathbf{b}}(\mathbf{r}, \mathbf{r}'), \quad (11.114)$$

where $R_{\mathbf{b}}(\mathbf{r}, \mathbf{r}')$ is the autocorrelation function of $b(\mathbf{r})$, defined by

$$R_{\mathbf{b}}(\mathbf{r}, \mathbf{r}') = E_{\mathbf{b}}\{b(\mathbf{r})b(\mathbf{r}')\}. \quad (11.115)$$

The corresponding autocovariance function is

$$\begin{aligned} K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') &= R_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') - \bar{b}(\mathbf{r})\bar{b}(\mathbf{r}') = \bar{b}(\mathbf{r})\delta(\mathbf{r} - \mathbf{r}') + R_{\mathbf{b}}(\mathbf{r}, \mathbf{r}') - \bar{b}(\mathbf{r})\bar{b}(\mathbf{r}') \\ &= \bar{b}(\mathbf{r})\delta(\mathbf{r} - \mathbf{r}') + K_{\mathbf{b}}(\mathbf{r}, \mathbf{r}'). \end{aligned} \quad (11.116)$$

Thus the autocovariance consists of two terms, a delta-correlated term $\bar{b}(\mathbf{r})\delta(\mathbf{r} - \mathbf{r}')$ which represents the average Poisson random process and a term $K_{\mathbf{b}}(\mathbf{r}, \mathbf{r}')$ which is just the autocovariance of the rate process $b(\mathbf{r})$. This result should be compared to (11.32) where the variance of a doubly stochastic Poisson random variable is similarly decomposed. Such decompositions will turn out to be very important when we consider the statistics of images where the fluctuations result from both Poisson noise and object variability.

Fig. 11.3 *Top:* Sample function from the doubly stochastic process $g(x)$.
Bottom: Corresponding sample function of the rate process $b(x)$.

11.3.7 Doubly stochastic temporal Poisson random processes

Next we examine the temporal counterparts of (11.113)–(11.116). For a doubly stochastic temporal random process where the rate is the random process $a(t)$, the overall mean of $z(t)$, averaged over both the Poisson process and the rate process, is given by

$$\langle z(t) \rangle = \bar{a}(t), \quad (11.117)$$

and the overall autocorrelation function is [cf. (11.114)]

$$R_{\mathbf{z}}(t, t + \tau) = \langle z(t)z(t + \tau) \rangle = \bar{a}(t)\delta(\tau) + R_{\mathbf{a}}(t, t + \tau), \quad (11.118)$$

where $R_{\mathbf{a}}(t, t + \tau)$ is the temporal autocorrelation function of the rate process $a(t)$.

The autocovariance function for $z(t)$ is

$$K_{\mathbf{z}}(t, t + \tau) = \langle [z(t) - \bar{a}(t)] [z(t + \tau) - \bar{a}(t + \tau)] \rangle = \bar{a}(t) \delta(\tau) + K_{\mathbf{a}}(t, t + \tau), \quad (11.119)$$

where $K_{\mathbf{a}}(t, t + \tau)$ is the autocovariance function of the rate process.

Statistics of the total count In Sec. 11.1.4 we considered a doubly stochastic random variable where the mean number of counts \bar{N} was itself a random variable with mean $\overline{\bar{N}}$ and variance $\text{Var}(\bar{N})$. In (11.32) we related the overall variance of N to these parameters. With what we have learned about doubly stochastic random processes, we are now in a position to relate $\overline{\bar{N}}$ and $\text{Var}(\bar{N})$ back to the statistics of $a(t)$.

We can immediately relate the (random) total number of counts N to $z(t)$ simply by integrating. From (11.64),

$$\int_0^T dt z(t) = \sum_{n=1}^N \int_0^T dt \delta(t - t_n) = \sum_{n=1}^N 1 = N. \quad (11.120)$$

The average of N over the Poisson process, conditional on $a(t)$, is

$$\bar{N} = \mathbf{E}\{N|\mathbf{a}\} = \int_0^T dt a(t), \quad (11.121)$$

where we have used (11.95). A second average $\mathbf{E}_{\mathbf{a}}\{\cdot\}$ over the rate process yields

$$\overline{\bar{N}} = \mathbf{E}_{\mathbf{a}}\{\mathbf{E}\{N|\mathbf{a}\}\} = \int_0^T dt \bar{a}(t). \quad (11.122)$$

If $a(t)$ is a stationary random process, $\bar{a}(t)$ is a constant and we find

$$\overline{\bar{N}} = \bar{a}T. \quad (11.123)$$

The overall variance of N is obtained by a similar double-averaging process. The definition is

$$\text{Var}(N) = \mathbf{E}_{\mathbf{a}}\{\mathbf{E}\{N^2|\mathbf{a}\}\} - \overline{\bar{N}}^2. \quad (11.124)$$

With a bit of algebra, we find

$$\text{Var}(N) = \overline{\bar{N}} + \int_0^T dt \int_0^T dt' K_{\mathbf{a}}(t, t'). \quad (11.125)$$

This equation has important physical consequences, most easily seen in the stationary case. If $K_{\mathbf{a}}(t, t') = K_{\mathbf{a}}(t - t')$, it is convenient to transform to center coordinate $t_0 = \frac{1}{2}(t + t')$ and difference coordinate $\Delta t = t' - t$ as in Sec. 8.2.4. If $a(t)$ fluctuates rapidly compared to the measurement time T , then $K_{\mathbf{a}}(\Delta t)$ is a sharply peaked function of Δt , and the limits on the Δt integral can be extended to infinity. Using $K_{\mathbf{a}}(\Delta t) = K_{\mathbf{a}}(-\Delta t)$, we can show that

$$\text{Var}(N) \approx \overline{\bar{N}} + T \int_{-\infty}^{\infty} d\Delta t K_{\mathbf{a}}(\Delta t). \quad (11.126)$$

We can define a correlation time $\tau_{\mathbf{a}}$ for the process $a(t)$ by

$$\tau_{\mathbf{a}} = \frac{\int_{-\infty}^{\infty} d\Delta t K_{\mathbf{a}}(\Delta t)}{K_{\mathbf{a}}(0)} = \frac{\int_{-\infty}^{\infty} d\Delta t K_{\mathbf{a}}(\Delta t)}{\text{Var}(a)}. \quad (11.127)$$

With (11.123) and (11.127), $\text{Var}(N)$ is given by

$$\text{Var}(N) \approx \overline{N} + \overline{N}^2 \frac{\tau_{\mathbf{a}}}{T} \frac{\text{Var}(a)}{\overline{a}^2}. \quad (11.128)$$

This equation reveals several situations under which N would behave as a Poisson random variable, at least in the sense that $\text{Var}(N) \approx \overline{N}$. First, if $a(t)$ is nonrandom, $\text{Var}(a) = 0$ and $\text{Var}(N) = \overline{N} = \overline{N}$. Second, if \overline{N} is very small compared to one (events are rare on the time scale T), then $\overline{N}^2 \ll \overline{N}$ and again $\text{Var}(N) \approx \overline{N}$. Finally, in the limit of short correlation time or long measurement time, *i.e.*, $\tau_{\mathbf{a}}/T \rightarrow 0$, then $\text{Var}(N) \rightarrow \overline{N}$ regardless of the statistics of $a(t)$. This last condition comes into play with white light, where $\tau_{\mathbf{a}}$ is of order 10^{-15} sec and $\text{Var}(a)/\overline{a}^2 = 1$.

11.3.8 Point processes in other domains

We have discussed spatial and temporal point processes separately, but of course it is possible that both spatial and temporal aspects are important in the same problem. In that case we must be concerned with spatio-temporal point processes, with sample functions of the form,

$$g(\mathbf{r}, t) = \sum_{n=1}^N \delta(t - t_n) \delta(\mathbf{r} - \mathbf{r}_n). \quad (11.129)$$

Now the rate process can depend on both space and time, so we denote it as $b(\mathbf{r}, t)$. We shall say that the events are fully statistically independent if \mathbf{r}_j and \mathbf{r}_k ($j \neq k$) are independent, t_j and t_k are independent, and \mathbf{r}_j is independent of t_j . Full statistical independence will occur only if $b(\mathbf{r}, t)$ is nonrandom.

For the fully independent case, both the spatial and temporal Poisson postulates are satisfied, and it is easy to show that

$$\langle g(\mathbf{r}, t) \rangle = b(\mathbf{r}, t); \quad (11.130)$$

$$K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}'; t, t') \equiv \langle g(\mathbf{r}, t) g(\mathbf{r}', t') \rangle - \langle g(\mathbf{r}, t) \rangle \langle g(\mathbf{r}', t') \rangle = b(\mathbf{r}, t) \delta(\mathbf{r} - \mathbf{r}') \delta(t - t'). \quad (11.131)$$

For the general doubly stochastic case where $b(\mathbf{r}, t)$ is a spatio-temporal random process, (11.131) becomes

$$K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}'; t, t') = \overline{b}(\mathbf{r}, t) \delta(\mathbf{r} - \mathbf{r}') \delta(t - t') + K_{\mathbf{b}}(\mathbf{r}, \mathbf{r}'; t, t'). \quad (11.132)$$

Other point processes are also important in imaging applications. For example, in Chap. 10 we introduced the concept of radiance L in a deterministic sense, but it can also be regarded as the mean of a 4D point process. We can define

$$g(\mathbf{r}, \hat{\mathbf{n}}) = \sum_j \delta(\mathbf{r} - \mathbf{r}_j) \delta(\hat{\mathbf{n}} - \hat{\mathbf{n}}_j), \quad (11.133)$$

where the second delta function is an angular one, satisfying the sifting property (2.155). The mean of this process is the mean number of photons per unit area per unit solid angle, which we called the photon radiance in Chap. 10. Thus,

$$\langle g(\mathbf{r}, \hat{\mathbf{n}}) \rangle = L_{phot}(\mathbf{r}, \hat{\mathbf{n}}). \quad (11.134)$$

If $g(\mathbf{r}, \hat{\mathbf{n}})$ is a Poisson point process, then its statistics are fully determined by its mean and hence by the photon radiance. This is a useful result since there are many ways of determining the radiance in imaging systems. For example, if we consider film illuminated with collimated light, then the output radiance is proportional to the bidirectional transmittance distribution function or BTDF (see Sec. 10.2.4).

One last kind of point process worth mentioning because of its radiological applications is the spatio-spectral process,

$$g(\mathbf{r}, \mathcal{E}) = \sum_j \delta(\mathbf{r} - \mathbf{r}_j) \delta(\mathcal{E} - \mathcal{E}_j), \quad (11.135)$$

where \mathcal{E} denotes a photon energy. As we shall see in Chap. 12, certain types of gamma-ray cameras estimate position and energy of each gamma ray, and the output of such cameras can be described by (11.135).

11.3.9 Filtered point processes

The general topic of filtered random processes was introduced in Sec. 8.2.6. We saw there that each sample function of the random process goes through a linear filter just as any deterministic function would. If the random process $g(\mathbf{r})$ is the input to a general shift-variant filter with impulse response $h(\mathbf{r}, \mathbf{r}')$, the output random process is given by

$$g_o(\mathbf{r}) = \int_{\infty} d^q r' h(\mathbf{r}, \mathbf{r}') g(\mathbf{r}'). \quad (11.136)$$

For a point process, where $g(\mathbf{r})$ is given by (11.72), the filter output becomes

$$g_o(\mathbf{r}) = \int_{\infty} d^q r' h(\mathbf{r}, \mathbf{r}') \sum_{n=1}^N \delta(\mathbf{r}' - \mathbf{r}_n) = \sum_{n=1}^N h(\mathbf{r}, \mathbf{r}_n), \quad (11.137)$$

so the output is just a sum of randomly displaced impulse responses. If the filter is shift-invariant, we have

$$g_o(\mathbf{r}) = \sum_{n=1}^N h(\mathbf{r} - \mathbf{r}_n), \quad (11.138)$$

which is a sum of identical, randomly displaced replicas of $h(\mathbf{r})$. The expressions in (11.137) and (11.138) are illustrated in Fig. 11.4.

Fig. 11.4 Illustration in one dimension of the output of a linear filter when the input is a random point process. (a) Input; (b) Output of shift-variant filter; (c) Output of shift-invariant filter.

Mean value of the filter output Calculation of the expectation of $g_o(\mathbf{r})$ is straightforward. For the case of a general shift-variant filter and a doubly stochastic Poisson process, we have

$$\langle g_o(\mathbf{r}) \rangle = \int_{\infty} d^q r' h(\mathbf{r}, \mathbf{r}') \langle g(\mathbf{r}') \rangle = \int_{\infty} d^q r' h(\mathbf{r}, \mathbf{r}') \bar{b}(\mathbf{r}'). \quad (11.139)$$

Various special cases are easily derived from this general result. If we consider a Poisson point process rather than a doubly stochastic one, all we have to do is delete the overbar on $\bar{b}(\mathbf{r}')$. If the filter is shift-invariant, $h(\mathbf{r}, \mathbf{r}')$ can be replaced with $h(\mathbf{r} - \mathbf{r}')$. And if the input process is stationary, $\langle g(\mathbf{r}') \rangle$ is a constant and can be removed from the integral.

The autocorrelation is a bit more complicated; it will be discussed separately for Poisson processes and doubly stochastic ones.

Autocovariance of filtered Poisson point processes In Sec. 8.2.6 we investigated filtering of delta-correlated processes. By (11.94), a Poisson point process $g(\mathbf{r})$ has a delta-function autocovariance. Equivalently, the zero-mean process $\Delta g(\mathbf{r}) = g(\mathbf{r}) - \bar{g}(\mathbf{r})$ has a delta-function autocorrelation, and the results in Sec. 8.2.6 can be applied immediately. From (11.94) we have

$$K_{g_o}(\mathbf{r}, \mathbf{r} + \Delta\mathbf{r}) = R_{\Delta g_o}(\mathbf{r}, \mathbf{r} + \Delta\mathbf{r}) = \int_{\infty} d^q r' h(\mathbf{r}, \mathbf{r}') b(\mathbf{r}') h^*(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}'). \quad (11.140)$$

For shift-invariant filters, this equation reduces to

$$\begin{aligned} K_{g_o}(\mathbf{r}, \mathbf{r} + \Delta\mathbf{r}) &= \int_{\infty} d^q r' h(\mathbf{r} - \mathbf{r}') b(\mathbf{r}') h^*(\mathbf{r} + \Delta\mathbf{r} - \mathbf{r}') \\ &= b(\mathbf{r}) * [h(\mathbf{r}) h^*(\mathbf{r} + \Delta\mathbf{r})]. \end{aligned} \quad (11.141)$$

Thus, in order to compute the autocovariance of a filtered Poisson point process, all we have to do is convolve the mean of the input, $b(\mathbf{r})$, with the function $[h(\mathbf{r}) h^*(\mathbf{r} + \Delta\mathbf{r})]$. As discussed in Sec. 8.2.6, this induces a correlation width determined by the impulse response.

The variance can be easily derived from the autocovariance. For a shift-variant filter with a Poisson process on the input, we have

$$\text{Var}\{g_o(\mathbf{r})\} = K_{g_o}(\mathbf{r}, \mathbf{r}) = \int_{\infty} d^q r' |h(\mathbf{r}, \mathbf{r}')|^2 b(\mathbf{r}'), \quad (11.142)$$

and when the filter is shift-invariant,

$$\text{Var}\{g_o(\mathbf{r})\} = b(\mathbf{r}) * |h(\mathbf{r})|^2. \quad (11.143)$$

In the literature on shot noise (*e.g.*, Davenport and Root, 1958), (11.143) is called *Campbell's theorem*.

It is interesting to compare (11.142) and (11.143) to the corresponding expressions for the mean of $g_o(\mathbf{r})$, as obtained from (11.139):

$$\text{E}\{g_o(\mathbf{r})\} = \int_{\infty} d^q r' h(\mathbf{r}, \mathbf{r}') b(\mathbf{r}'), \quad (\text{shift-variant}); \quad (11.144)$$

$$\text{E}\{g_o(\mathbf{r})\} = b(\mathbf{r}) * h(\mathbf{r}), \quad (\text{shift-invariant}). \quad (11.145)$$

Thus the expression for the variance of $g_o(\mathbf{r})$ has the same form as for the mean, save only that the squared modulus of the filter kernel appears in place of the filter kernel itself. We emphasize, however, that this neat result holds only when the input is a Poisson (delta-correlated) random process.

Another important result follows from (11.142) and (11.143). We saw in (11.94) that the variance of a Poisson process was infinite, but (11.142) shows that the variance on the filter output is finite any time either $|h(\mathbf{r}, \mathbf{r}')|^2$ or $b(\mathbf{r}')$ has finite spatial support. To be mathematically precise, we should also require that neither $|h(\mathbf{r}, \mathbf{r}')|^2$ nor $b(\mathbf{r}')$ can go to infinity anywhere, but physically that doesn't happen anyway. For any real-world filter, a filtered Poisson random process will have finite variance.

For a stationary random process, $b(\mathbf{r})$ is a constant b_0 , and (11.142) shows that the variance is

$$\text{Var}\{g_o(\mathbf{r})\} = K_{g_o}(\mathbf{r}, \mathbf{r}) = b_0 \int_{\infty} d^q r' |h(\mathbf{r}, \mathbf{r}')|^2. \quad (11.146)$$

Note that this variance can still be a function of \mathbf{r} if the filter is shift-variant. For a shift-invariant filter, however,

$$\text{Var}\{g_o(\mathbf{r})\} = b_0 \int_{\infty} d^q r' |h(\mathbf{r} - \mathbf{r}')|^2 = b_0 \int_{\infty} d^q r' |h(\mathbf{r}')|^2 = \text{const}. \quad (11.147)$$

If a stationary random process is filtered with a shift-invariant filter, then neither the input nor the filter imposes any preferred origin and hence the output is also stationary.

Autocovariance of filtered doubly stochastic Poisson processes In Sec. 11.3.6 we derived the autocovariance of a doubly stochastic Poisson random process. These expressions can be substituted into the formulas from Sec. 8.2.6 to find the effects of filtering. We consider explicitly the case of a nonstationary process but a shift-invariant filter; the computation for a shift-variant filter is similar but messier.

From (8.146) and (8.147), we find

$$\begin{aligned}
 & K_{g_o}(\mathbf{r}, \mathbf{r} + \Delta\mathbf{r}) \\
 &= \int_{\infty} d^q r' h(\mathbf{r}') \int_{\infty} d^q r'' h^*(\mathbf{r}'') [\bar{b}(\mathbf{r} - \mathbf{r}') \delta(\mathbf{r}' + \Delta\mathbf{r} - \mathbf{r}'') + K_{\mathbf{b}}(\mathbf{r} - \mathbf{r}', \mathbf{r} + \Delta\mathbf{r} - \mathbf{r}'')] \\
 &= \bar{b}(\mathbf{r}) * [h(\mathbf{r}) h^*(\mathbf{r} + \Delta\mathbf{r})] + \int_{\infty} d^q r' h(\mathbf{r}') \int_{\infty} d^q r'' h^*(\mathbf{r}'') K_{\mathbf{b}}(\mathbf{r} - \mathbf{r}', \mathbf{r} + \Delta\mathbf{r} - \mathbf{r}'') \\
 &= \bar{b}(\mathbf{r}) * [h(\mathbf{r}) h^*(\mathbf{r} + \Delta\mathbf{r})] + [\mathcal{H}\mathcal{K}_{\mathbf{b}}\mathcal{H}^\dagger](\mathbf{r}, \mathbf{r} + \Delta\mathbf{r}), \tag{11.148}
 \end{aligned}$$

where \mathcal{H} is the integral operator corresponding to convolution with $h(\mathbf{r})$, \mathcal{H}^\dagger is its adjoint (see Sec. 1.3.5) and $\mathcal{K}_{\mathbf{b}}$ is the integral operator for which the kernel is the autocovariance function of $b(\mathbf{r})$ (see Sec. 8.2.7).

The first term in (11.148) is identical to (11.141) except for the overbar on $\bar{b}(\mathbf{r})$; it represents the average Poisson random process as seen through the filter. The second term is just what we would get by filtering the process $b(\mathbf{r})$ without regard to the fact that it is the mean of a Poisson process [*cf.* (11.129)].

11.3.10 Characteristic functionals of filtered point processes

The discussion above of filtered point processes is incomplete since it does not give the full PDF of the output process. This PDF would have several applications. For example, it would describe the output of a photon-counting detector with high spatial resolution but post-detection smoothing. Also, as we saw in Sec. 8.4.4, a filtered Poisson process called a lumpy background is a useful model for background inhomogeneities in objects.

It is not possible to get the PDF in its full infinite-dimensional generality, but we can compute the characteristic functional, from which all other statistical properties can be derived (see Sec. 8.2.3). We shall carry out this computation first for an unfiltered Poisson random process, and then we shall consider the effects of filtering and show how various marginal PDFs can be derived. We shall also make contact with Sec. 8.4.4 and discuss the statistics of lumpy-background texture models.

As defined in (8.94), the characteristic functional involves an \mathbb{L}_2 scalar product between the random process and the function $s(\mathbf{r})$ in the argument of the functional. To apply this definition to a Poisson process, we must either take $s(\mathbf{r})$ as a test function or treat $\delta(\mathbf{r} - \mathbf{r}_n)$ as the limit of a sequence of \mathbb{L}_2 functions; with either approach, we can substitute the definition of the point process from (11.72) into (8.94) and obtain

$$\Psi_{\mathbf{g}}(\mathbf{s}) = \left\langle \exp \left[-2\pi i \int_A d^2 r s(\mathbf{r}) \sum_{n=1}^N \delta(\mathbf{r} - \mathbf{r}_n) \right] \right\rangle = \left\langle \exp \left[-2\pi i \sum_{n=1}^N s(\mathbf{r}_n) \right] \right\rangle. \tag{11.149}$$

The expectation is performed in two steps, first over the set of random variables $\{\mathbf{r}_n\}$ for fixed N , then over N . By using Poisson assumptions and the methods of Sec. 11.3.3 [or by peeking at the derivation below (11.160)], the reader can show that

$$\Psi_{\mathbf{g}}(\mathbf{s}) = \exp \left\{ -\bar{N} + \int_A d^2 r_n b(\mathbf{r}_n) e^{-2\pi i \mathbf{s}(\mathbf{r}_n)} \right\}, \quad (11.150)$$

where $b(\mathbf{r})$ is the usual photon fluence (which must be nonrandom for this expression to hold). For a stationary Poisson random process where $b(\mathbf{r})$ is constant over an area A , the fluence is \bar{N}/A , and we have

$$\Psi_{\mathbf{g}}(\mathbf{s}) = \exp \left\{ -\bar{N} \left[1 + \frac{1}{A} \int_A d^2 r_n e^{-2\pi i \mathbf{s}(\mathbf{r}_n)} \right] \right\}. \quad (11.151)$$

Effect of filtering Though similar in form to the characteristic function of a Poisson random variable [see (C.171)], the expressions in (11.150) and (11.151) are not very useful as they stand. In particular, we know that the variance and higher moments of a Poisson random process are infinite, so there is little point in trying to compute them from the characteristic functionals. We can, however, go immediately from (11.150) to the characteristic functional for a filtered Poisson process.

If we consider a general nonstationary Poisson random process and a general linear filter \mathcal{H} as defined in (11.136), then from (11.150) and (8.96) we see that

$$\Psi_{\mathbf{g}_o}(\mathbf{s}) = \Psi_{\mathbf{g}}(\mathcal{H}^\dagger \mathbf{s}) = \exp \left\{ -\bar{N} + \int_A d^2 r_n b(\mathbf{r}_n) \exp \left[-2\pi i \int_A d^2 r' s(\mathbf{r}') h(\mathbf{r}', \mathbf{r}_n) \right] \right\}. \quad (11.152)$$

This expression, the full characteristic function for the output process, is equivalent to the full infinite-dimensional density of the process. To relate it to familiar single-point or multiple-point characteristic functions and densities, we need to make additional linear transformations.

For example, to get the univariate characteristic function on the scalar random variable $g_o(\mathbf{r})$ for some fixed point $\mathbf{r} = \mathbf{R}$, we define a sampling operator $\mathcal{S}_{\mathbf{R}}$ (see Sec. 3.5) such that $\mathcal{S}_{\mathbf{R}} \mathbf{g}_o = g_o(\mathbf{R})$. The kernel of this operator is $\delta(\mathbf{r} - \mathbf{R})$, and the characteristic function (not functional this time) is given by (8.96) as

$$\psi_{g_o(\mathbf{R})}(\xi) = \Psi_{\mathbf{g}_o}(\mathcal{S}_{\mathbf{R}}^\dagger \xi). \quad (11.153)$$

Since $\mathcal{S}_{\mathbf{R}}^\dagger \xi = \xi \delta(\mathbf{r} - \mathbf{R})$, we see from (11.152) that

$$\psi_{g_o(\mathbf{R})}(\xi) = \exp \left\{ -\bar{N} + \int_A d^2 r_n b(\mathbf{r}_n) \exp[-2\pi i \xi h(\mathbf{R}, \mathbf{r}_n)] \right\}. \quad (11.154)$$

To instill some confidence in this formalism, we can use (11.154) to compute the mean and variance of $g_o(\mathbf{R})$. With (C.55) and a little algebra, we find that

$$\langle g_o(\mathbf{R}) \rangle = \int_A d^2 r h(\mathbf{R}, \mathbf{r}) b(\mathbf{r}), \quad \text{Var} \{g_o(\mathbf{R})\} = \int_A d^2 r |h(\mathbf{R}, \mathbf{r})|^2 b(\mathbf{r}), \quad (11.155)$$

in agreement with (11.139) and (11.142).

Single-point density The single-point (univariate) PDF on $g_o(\mathbf{R})$ can be obtained by performing an inverse Fourier transform on (11.154), but usually this computation will have to be performed numerically. The Fourier integral is one-dimensional (with ξ as the variable of integration), but each point in the integrand requires another two-dimensional integral (the one over \mathbf{r}_n), so the overall computational effort is equivalent to a three-dimensional numerical integration — no great problem on modern computers.

To gain some insight into the problem without doing numerical integrals, let us consider a stationary problem with constant fluence b_0 and a shift-invariant filter such that $h(\mathbf{R}, \mathbf{r}_n) = \text{rect}[(\mathbf{R} - \mathbf{r}_n)/\epsilon]$. This filter function is either 0 or 1, so the inner integral in (11.154) simplifies to

$$\int_A d^2r_n b(\mathbf{r}_n) \exp[-2\pi i \xi h(\mathbf{R}, \mathbf{r}_n)] = [A - \epsilon^2 + \epsilon^2 \exp(-2\pi i \xi)] b_0, \quad (11.156)$$

provided \mathbf{R} is not within ϵ of the border. Since $b_0 A = \bar{N}$, (11.154) becomes

$$\psi_{g_o(\mathbf{R})}(\xi) = \exp\{-\epsilon^2 b_0 [1 - \exp(-2\pi i \xi)]\}. \quad (11.157)$$

This expression will be recognized as the characteristic function for a Poisson, (C.171), with mean given by $\epsilon^2 b_0$.

The corresponding single-point PDF is essentially also a Poisson, but now as a density rather than a probability; specifically [cf. (C.24)],

$$\text{pr}[g_o(\mathbf{R})] = \sum_{N=0}^{\infty} \frac{(\epsilon^2 b_0)^N}{N!} \exp(-\epsilon^2 b_0) \delta[g_o(\mathbf{R}) - N]. \quad (11.158)$$

The delta functions at integer values arise since (11.157) is periodic with period 1.

The characteristic functional can, of course, be used also to compute various multivariate densities, such as $\text{pr}[g_o(\mathbf{R}_1), g_o(\mathbf{R}_2)]$. In that case it is necessary to define a sampling operator that maps the function $g_o(\mathbf{r})$ to a 2D vector, the components of which are the scalars $g_o(\mathbf{R}_1)$ and $g_o(\mathbf{R}_2)$. Because of the filtering operation, the bivariate density will not factor into two univariate densities if \mathbf{R}_1 is within a filter width of \mathbf{R}_2 .

Generalized lumpy backgrounds In Sec. 8.4.4 we discussed the concept of a lumpy background as a model for random texture fields. The simplest definition was given in (8.303) as

$$f(\mathbf{r}) = \sum_{n=1}^N l(\mathbf{r} - \mathbf{r}_n), \quad (11.159)$$

where $l(\mathbf{r})$ is the lump profile, taken as nonrandom in the initial formulation by Rolland and Barrett (1992). If the lump positions are independent and N is a Poisson random variable, then this $f(\mathbf{r})$ is a filtered Poisson random process, and its statistics can be analyzed as discussed above. We also mentioned in Sec. 8.4.4, however, that it can be very useful to take the lump profile as random. We shall now extend the theory of filtered random processes to allow for random lump profile (or filter function). Our tool will again be the characteristic functional.

We consider a random process $f(\mathbf{r})$ that is composed of a sum of N statistically independent and identically distributed realizations of some other random process

$l(\mathbf{r})$, where N is a Poisson random variable. Denoting the n^{th} realization by $l_n(\mathbf{r})$, we write

$$f(\mathbf{r}) = \sum_{n=1}^N l_n(\mathbf{r}). \tag{11.160}$$

The original lumpy background of (11.159) fits this mold if the only randomness is in the location, but (11.160) is much more general.

To find the characteristic functional, we start with the basic definition (8.94) and write [cf. (11.149)]

$$\Psi_{\mathbf{f}}(\mathbf{s}) = \left\langle \exp \left[-2\pi i \sum_{n=1}^N \int_A d^2r s(\mathbf{r}) l_n(\mathbf{r}) \right] \right\rangle. \tag{11.161}$$

As usual in this chapter, we perform the expectation in two steps, first over the randomness of each member of the set $\{l_n(\mathbf{r}), n = 1, \dots, N\}$ for fixed N , then over N itself. We therefore have

$$\Psi_{\mathbf{f}}(\mathbf{s}) = \left\langle \left\langle \prod_{n=1}^N \exp \left[-2\pi i \int_A d^2r s(\mathbf{r}) l_n(\mathbf{r}) \right] \right\rangle_{\{l_n(\mathbf{r})\}_N} \right\rangle_N. \tag{11.162}$$

Since the realizations are independent, the expectation of the product is the product of the expectations, and each factor is the same since the realizations are identically distributed; hence

$$\Psi_{\mathbf{f}}(\mathbf{s}) = \left\langle \prod_{n=1}^N \left\langle \exp \left[-2\pi i \int_A d^2r s(\mathbf{r}) l_n(\mathbf{r}) \right] \right\rangle_{\{l_n(\mathbf{r})\}_N} \right\rangle_N = \left\langle [\Psi_{\mathbf{I}}(\mathbf{s})]^N \right\rangle_N, \tag{11.163}$$

where $\Psi_{\mathbf{I}}(\mathbf{s})$ is the characteristic functional of the individual random process $l_n(\mathbf{r})$.

To perform the remaining expectation, we temporarily define N_0 by

$$N_0 = \bar{N} \Psi_{\mathbf{I}}(\mathbf{s}), \tag{11.164}$$

so that

$$\Psi_{\mathbf{f}}(\mathbf{s}) = \sum_{N=0}^{\infty} \exp(-\bar{N}) \frac{\bar{N}^N}{N!} [\Psi_{\mathbf{I}}(\mathbf{s})]^N = \exp(-\bar{N} + N_0) \sum_{N=0}^{\infty} \exp(-N_0) \frac{N_0^N}{N!}. \tag{11.165}$$

The sum is unity (since Poisson probabilities are normalized), and we have, finally,

$$\Psi_{\mathbf{f}}(\mathbf{s}) = \exp(-\bar{N} + N_0) = \exp[-\bar{N} + \bar{N} \Psi_{\mathbf{I}}(\mathbf{s})]. \tag{11.166}$$

From this characteristic functional, we can in principle compute any desired statistical properties of this generalized lumpy background, just as we discussed above for the simple filtered Poisson process. Moreover, various special cases can be treated by making different assumptions about the randomness inherent in $l(\mathbf{r})$. The reader should, for example, be able to go from (11.166) to (11.154).

Another useful exercise is to let \bar{N} get large and show that (11.166) approaches the characteristic functional for a normal random process, (8.216). Thus, no matter the statistics of $l(\mathbf{r})$, a random process created by adding a large number of i.i.d. realizations of it approaches normality.

Characteristic functionals of other kinds of point processes have been derived by Ramirez-Perez and Serfling (2001). Statistical properties of other kinds of lumpy backgrounds can be obtained by modifying their results to include the filtering operation as above.

11.3.11 Spectral properties of point processes

As we have seen in Chap. 8, Fourier analysis is often a useful tool for studying random processes. In this section we use the Fourier domain to study Poisson point processes and their relatives.

Fourier transform of a sample function In Chap. 3 we discussed the Fourier properties of generalized functions at some length. We can apply these methods directly to random point processes. For example, the Fourier transform of a sample function of the q D point process $g(\mathbf{r})$, as defined in (11.72), is

$$G(\boldsymbol{\rho}) = \mathcal{F}_q\{g(\mathbf{r})\} = \sum_{n=1}^N \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}_n). \quad (11.167)$$

Thus $G(\boldsymbol{\rho})$ is a sum of a random number of plane waves with random *frequencies* \mathbf{r}_n .

Power spectral density of stationary Poisson processes The power spectral density (see Sec. 8.2.5) is an important way of specifying the frequency content of a stationary random process. By the Wiener-Khinchin theorem, the power spectral density $S_{\mathbf{g}}(\boldsymbol{\rho})$ is the Fourier transform of the autocorrelation function $R_{\mathbf{g}}(\Delta\mathbf{r})$. For a stationary Poisson point process, $R_{\mathbf{g}}(\Delta\mathbf{r})$ is obtained from (11.93) by setting $b(\mathbf{r}) = b_0 = \text{constant}$ and $\Delta\mathbf{r} = \mathbf{r}' - \mathbf{r}$. We then obtain for the spectral density,

$$S_{\mathbf{g}}(\boldsymbol{\rho}) = \mathcal{F}_q\{b_0 \delta(\Delta\mathbf{r}) + b_0^2\} = b_0 + b_0^2 \delta(\boldsymbol{\rho}). \quad (11.168)$$

The term $b_0^2 \delta(\boldsymbol{\rho})$ is a result of the nonzero mean of $g(\mathbf{r})$. If we define a zero-mean process $\Delta g(\mathbf{r}) = g(\mathbf{r}) - b_0$, its power spectral density is

$$S_{\Delta g}(\boldsymbol{\rho}) = \mathcal{F}_q\{b_0 \delta(\Delta\mathbf{r})\} = b_0. \quad (11.169)$$

Thus a stationary Poisson random process is *white*; its power spectral density is a constant, namely the mean photon fluence.

Filtered Poisson processes Suppose a stationary Poisson process is passed through a filter with shift-invariant impulse response $h(\mathbf{r})$, and hence transfer function $H(\boldsymbol{\rho})$. Let the output of the filter be denoted $g_o(\mathbf{r})$ and define $\Delta g_o(\mathbf{r}) = g_o(\mathbf{r}) - \langle g_o(\mathbf{r}) \rangle$. Then, by (8.156), the power spectral density of $\Delta g(\mathbf{r})$ is given by

$$S_{\Delta g_o}(\boldsymbol{\rho}) = b_0 |H(\boldsymbol{\rho})|^2. \quad (11.170)$$

Thus the output spectrum is a direct measure of $|H(\boldsymbol{\rho})|^2$, but of course only because we know that the input is white.

If the poisson process is not stationary, we cannot use the power spectral density to describe its frequency content, but we can use the stochastic Wigner distribution function defined in Sec. 8.2.5. As an exercise, the reader can show that $W_{\Delta g_o}(\mathbf{r}, \boldsymbol{\rho}) = b(\mathbf{r}) * W_h(\mathbf{r}, \boldsymbol{\rho})$ and that this expression reduces to (11.170) when the fluence is constant.

Stationary doubly stochastic processes The autocovariance function of a doubly stochastic Poisson process is given by (11.116). The process is (wide-sense) stationary if $\bar{b}(\mathbf{r}) = \bar{b} = \text{constant}$ and $K_{\mathbf{b}}(\mathbf{r}, \mathbf{r}') = K_{\mathbf{b}}(\mathbf{r} - \mathbf{r}')$. In that case, the power

spectral density of $\Delta g(\mathbf{r})$ is given by

$$S_{\Delta g}(\boldsymbol{\rho}) = \mathcal{F}_q\{K_{\mathbf{g}}(\Delta\mathbf{r})\} = \bar{b} + S_{\Delta b}(\boldsymbol{\rho}). \quad (11.171)$$

In contrast to (11.169), this spectrum is not white; in addition to the constant term \bar{b} , there is also a term $S_{\Delta b}(\boldsymbol{\rho})$ arising from the rate process. The presence of these two terms can, perhaps, be appreciated from the sample functions shown in Fig. 11.3. These images were constructed with a rate process having a low-pass character, and the low spatial frequencies are evident in the images if the fine structure arising from the white-noise component is ignored. The same low frequencies are also seen in the sample functions of $b(\mathbf{r})$ shown in the figure.

11.4 RANDOM AMPLIFICATION

Many detectors and other imaging devices include a built-in gain mechanism. Examples include photomultipliers, avalanche photodiodes, fluorescent screens, image intensifiers and photographic film. In this section we develop the basic statistical tools for the analysis of such devices.

The basic principles of random amplification are introduced in Sec. 11.4.1 in the context of single-element detectors. Such devices are analyzed again in Sec. 11.4.2 in order to introduce the useful mathematical technique of generating functions. In Sec. 11.4.3 we study the spatial and temporal dependence of amplified point processes, and the same topics are treated in the frequency domain in Sec. 11.4.4. These sections build heavily on the discussion of random point processes in Sec. 11.3. Finally, in Sec. 11.4.5, we apply the formalism of generating functions to imaging arrays with gain.

11.4.1 Random amplification in single-element detectors

We begin by considering a simple nonimaging detector such as a photomultiplier or avalanche photodiode in which the input is photons and the output is electrons. All we need to know about the mechanism of the detector for now is that it puts out some random number of electrons for each input photon it absorbs. Since the same mathematics will apply to detectors with other inputs (*e.g.*, electrons or ions) and/or other outputs (especially photons), we refer to the input events as *primaries* and the output events as *secondaries*.

If N primaries are absorbed in time T and the n^{th} primary produces k_n secondaries, then the total number of secondaries is

$$K = \sum_{n=1}^N k_n. \quad (11.172)$$

There are $N + 1$ random variables in this problem: each of the k_n and N itself. The objective of the problem is to determine the statistics of K from those of N and the set $\{k_n\}$.

Conditional probabilities The statistics of k_n are governed by a probability law $\text{Pr}(k_n = k)$. Since the primaries are indistinguishable, the gain mechanism must be the same for all primaries. Hence $\text{Pr}(k_n = k)$ has the same form for all n , and we

shall denote it as $\gamma(k)$. If $N = 1$, this same probability law also governs the total number of output secondaries K , *i.e.*,

$$\Pr(K|N = 1) = \gamma(K). \quad (11.173)$$

The conditional mean and variance of K are given by

$$E\{K|N = 1\} = \sum_{K=0}^{\infty} K \Pr(K|N = 1) = \sum_{k=0}^{\infty} k \gamma(k) = m_1; \quad (11.174)$$

$$\text{Var}\{K|N = 1\} = \sum_{k=0}^{\infty} k^2 \gamma(k) - m_1^2 = m_2 - m_1^2, \quad (11.175)$$

where m_j is the j^{th} moment of $\gamma(k)$. The first moment m_1 is the average gain \bar{k}_n , *i.e.*, the mean number of output secondaries per input primary.

If we assume that all input primaries are amplified independently, then the mean and variance for N primaries are given by

$$E\{K|N\} = Nm_1, \quad (11.176)$$

$$\text{Var}\{K|N\} = N(m_2 - m_1^2). \quad (11.177)$$

From these results it follows that the conditional second moment of K is

$$E\{K^2|N\} = N(m_2 - m_1^2) + N^2 m_1^2. \quad (11.178)$$

The overall first and second moments of K can now be calculated by averaging over N :

$$E\{K\} = \bar{N}m_1, \quad (11.179)$$

$$E\{K^2\} = \bar{N}(m_2 - m_1^2) + [\text{Var}(N) + \bar{N}^2] m_1^2. \quad (11.180)$$

The overall variance of K is not obtained just by replacing N with \bar{N} in (11.177). Instead, we must write

$$\text{Var}(K) = E\{K^2\} - [E\{K\}]^2 = \bar{N}(m_2 - m_1^2) + m_1^2 \text{Var}(N). \quad (11.181)$$

Since $m_2 - m_1^2$ is the variance of k_n (for one input primary) and m_1 is the corresponding mean, we can also write

$$\text{Var}(K) = \bar{N} \text{Var}(k_n) + \bar{k}_n^2 \text{Var}(N). \quad (11.182)$$

This result is often referred to as the *Burgess variance theorem* (Burgess, 1959), but it has been rederived many times in the literature; see Shockley and Pierce (1938), Mandel (1959) and Zwieg (1965).

For a Poisson input, $\text{Var}(N) = \bar{N}$, so (11.182) becomes

$$\text{Var}(K) = \bar{N} [\text{Var}(k_n) + \bar{k}_n^2] = \bar{N}m_2, \quad (11.183)$$

showing that in this case the variance of the output is the mean number of input primaries times the second moment of the gain distribution. We can also express

this result in terms of an output signal-to-noise ratio, defined as the mean of K divided by its standard deviation:

$$\text{SNR}_{\text{out}} \equiv \frac{\overline{K}}{\sqrt{\text{Var}(K)}} = \overline{N}^{\frac{1}{2}} \frac{m_1}{\sqrt{m_2}}. \quad (11.184)$$

For a Poisson random variable, the SNR is the square root of the mean, so we also have

$$[\text{SNR}_{\text{out}}]^2 = [\text{SNR}_{\text{in}}]^2 \frac{m_1^2}{m_2}. \quad (11.185)$$

By the Schwarz inequality, $m_1^2 \leq m_2$ for any probability law, so SNR_{out} is always less than or equal to SNR_{in} . The gain mechanism gives us a stronger signal, but it cannot improve the SNR beyond that inherent in the Poisson statistics of the input. In the radiology literature (see *e.g.*, Barrett and Swindell, 1981, 1996), the ratio m_1^2/m_2 is known as the *Swank factor* since R. K. Swank (1973) derived it in the course of analyzing fluorescent screens for x-ray imaging.

If $m_2 = m_1^2$, then the Swank factor is unity, the variance of k_n is zero and the gain mechanism is noise-free, so $\text{SNR}_{\text{out}} = \text{SNR}_{\text{in}}$ for a Poisson input N . This does not mean, however, that the output K is also Poisson. Instead, from (11.179) and (11.183), $\text{Var}(K) = m_1 \overline{K} = \overline{k_n}^2 \overline{N}$, so the variance is increased in absolute terms by the square of the gain, while the mean is increased only linearly. Rarity begets Poissonicity, but amplification (even noise-free amplification) inevitably destroys it. Since the secondaries come in bursts, they are not independent.

11.4.2 Random amplification and generating functions

Discussions of random amplification in the literature often make use of probability-generating functions (or generating functions for short). In order to give the reader the necessary background to follow this literature, we shall now rederive all of the results in Sec. 11.4.1 with generating functions. There is no loss of continuity in skipping this section and going directly to Sec. 11.4.3, but the material here will be needed in Sec. 11.4.5 when we discuss random amplification in arrays.

Sums of a random number of random variables By its definition (11.172), K is a sum of a random number of integer-valued random variables. A natural tool for dealing with integer-valued random variables is the generating function $\Phi(\zeta)$ defined in Sec. C.3.3. Here we have three separate integer-valued random variables, K , k_n and N , so we distinguish their generating functions with appropriate subscripts. If the individual k_n are i.i.d., there is a compact expression for the generating function $\Phi_K(\zeta)$ (see Sec. C.3.3) for the total output K in terms of the generating function $\Phi_N(\zeta)$ for the random number of terms N and the (common) generating function $\Phi_k(\zeta)$ for each of the k_n .

The generating function for K is defined by

$$\Phi_K(\zeta) = \langle \zeta^K \rangle = \sum_{K=0}^{\infty} \zeta^K \text{Pr}(K), \quad (11.186)$$

and $\Phi_k(\zeta)$ and $\Phi_N(\zeta)$ are defined similarly. With the usual probability calculus, we can write

$$\Phi_K(\zeta) = \sum_{N=0}^{\infty} \sum_{K=0}^{\infty} \zeta^K \Pr(K|N) \Pr(N). \tag{11.187}$$

The sum over K is the *conditional* generating function for K given a fixed N ; in light of the assumed independence of the k_n , it can be written as

$$\sum_{K=0}^{\infty} \zeta^K \Pr(K|N) = E \{ \zeta^K | N \} = \prod_{n=1}^N E \{ \zeta^{k_n} \} = \prod_{n=1}^N \Phi_k(\zeta) = [\Phi_k(\zeta)]^N. \tag{11.188}$$

Plugging this result back into (11.187), we find

$$\Phi_K(\zeta) = \sum_{N=0}^{\infty} \Pr(N) [\Phi_k(\zeta)]^N. \tag{11.189}$$

But this expression has the same form as $\Phi_N(\zeta)$ [*cf.* (11.186)] except that $\Phi_k(\zeta)$ appears in place of ζ ; we can therefore write

$$\Phi_K(\zeta) = \Phi_N[\Phi_k(\zeta)]. \tag{11.190}$$

Hence the generating function for the total number of secondaries K is a compound generating function (function of a function) involving the separate generating functions for number of primaries N and number of secondaries per primary k_n . If there are many stages of gain, the compounding can be repeated for each stage (Lombard and Martin, 1961).

One limit in which we can verify (11.190) is when N is not really random. Then $\Pr(N) = \delta_{NN_0}$, $\Phi_N(\zeta) = \zeta^{N_0}$ and $\Phi_K(\zeta) = [\Phi_k(\zeta)]^{N_0}$, just as we would expect for the sum of a *fixed* number of independent random variables.

Moments From (C.63) we know that $\Phi_K(\zeta)$ is essentially the z -transform of the probability law for K , so we can in principle go from (11.190) to $\Pr(K)$, though it requires a model for $\Pr(k)$ or $\Phi_k(\zeta)$. As we shall see in later chapters, however, many practical figures of merit for image quality require only the first- and second-order statistics, so we turn now to computation of moments of K . The reader who is interested in $\Pr(K)$ is referred to Saleh (1978) and Saleh and Teich (1982).

To compute moments of K , we must compute derivatives of the compound function $\Phi_K(\zeta)$ (see Sec. C.3.3). For the first derivative, we have

$$\frac{d}{d\zeta} [\Phi_K(\zeta)] = \frac{d}{d\zeta} \{ \Phi_N[\Phi_k(\zeta)] \} = \frac{d}{d\Phi_k} [\Phi_N(\Phi_k)] \frac{d}{d\zeta} [\Phi_k(\zeta)] = \Phi'_N(\Phi_k) \Phi'_k(\zeta), \tag{11.191}$$

where prime denotes the derivative of a function with respect to its argument. For the second derivative, we obtain

$$\frac{d^2}{d\zeta^2} [\Phi_K(\zeta)] = \Phi'_N(\Phi_k) \Phi''_k(\zeta) + \Phi''_N(\Phi_k) [\Phi'_k(\zeta)]^2. \tag{11.192}$$

Note the asymmetry in this result; the functional compounding takes place in a specific order.

We can now use the results in (11.191) and (11.192) to obtain the first two moments of K . From (C.65) we know how to compute factorial moments c_k from derivatives of the generating function. The first factorial moment c_1 is simply the mean m_1 , and the second factorial moment is related to the mean and variance by (C.43). Thus we can write

$$\langle N \rangle = \Phi'_N(1), \quad \text{Var}(N) = \Phi''_N(1) - [\Phi'_N(1)]^2 + \Phi'_N(1). \quad (11.193)$$

Similarly, the mean and variance of each of k_n is given by

$$\langle k_n \rangle = \Phi'_k(1), \quad \text{Var}(k_n) = \Phi''_k(1) - [\Phi'_k(1)]^2 + \Phi'_k(1). \quad (11.194)$$

For the total output K , we obtain

$$\langle K \rangle = \Phi'_N[\Phi_k(1)] \Phi'_k(1) = \Phi'_N(1) \Phi'_k(1) = \langle N \rangle \langle k_n \rangle, \quad (11.195)$$

$$\text{Var}(K) = \Phi'_N(1) \Phi''_k(1) + \Phi''_N(1) [\Phi'_k(1)]^2 - [\Phi'_N(1) \Phi'_k(1)]^2 + \Phi'_N(1) \Phi'_k(1). \quad (11.196)$$

The variance of the compound process can be expressed in terms of the means and variances of the component processes by adding and subtracting $\Phi'_N(1)[\Phi'_k(1)]^2$ on the righthand side of (11.196):

$$\begin{aligned} \text{Var}(K) &= \Phi'_N(1) \left\{ \Phi''_k(1) - [\Phi'_k(1)]^2 + \Phi'_k(1) \right\} \\ &\quad + [\Phi'_k(1)]^2 \left\{ \Phi''_N(1) - [\Phi'_N(1)]^2 + \Phi'_N(1) \right\}. \end{aligned} \quad (11.197)$$

With the use of (11.193) and (11.194), we now have

$$\text{Var}(K) = \langle N \rangle \text{Var}(k_n) + \langle k_n \rangle^2 \text{Var}(N), \quad (11.198)$$

in agreement with (11.182).

These results have been used in the literature to analyze nonimaging detectors with gain, most notably photomultipliers (Lombard and Martin, 1961). In Sec. 11.4.5 we shall learn how to extend the method to imaging arrays.

11.4.3 Random amplification of point processes

In Sec. 11.4.1 we considered the statistics of the total number of output secondaries in a detector with gain, but we did not look at the random output process itself. If we describe each secondary as a delta function in time, then a sample function of the temporal random process on the detector output can be written as

$$y(t) = \sum_{n=1}^N \sum_{k=1}^{k_n} \delta(t - t_{nk}) = \sum_{n=1}^N \sum_{k=1}^{k_n} \delta(t - t_n - \Delta t_{nk}), \quad (11.199)$$

where t_n is the time at which the n^{th} primary is absorbed, t_{nk} is the time at which the k^{th} secondary (of those resulting from the n^{th} primary) is produced, and Δt_{nk} is the random time delay from absorption of the n^{th} primary to production of its k^{th} secondary. The total number of output secondaries $K = \sum_{n=1}^N k_n$.

If the spatial distribution is of interest, a sample function of the amplified point process is given by

$$y(\mathbf{r}) = \sum_{n=1}^N \sum_{k=1}^{k_n} \delta(\mathbf{r} - \mathbf{r}_{nk}) = \sum_{n=1}^N \sum_{k=1}^{k_n} \delta(\mathbf{r} - \mathbf{R}_n - \Delta\mathbf{r}_{nk}), \quad (11.200)$$

where \mathbf{R}_n is the location at which the n^{th} primary is absorbed, \mathbf{r}_{nk} is the location for the k^{th} secondary produced by that primary, and $\Delta\mathbf{r}_{nk}$ is the random displacement. The only essential difference in the spatial and temporal cases is that Δt_{nk} must be positive since the secondary cannot be produced before the primary is absorbed, while the components of $\Delta\mathbf{r}_{nk}$ can have either sign.

We shall apply the procedures of Sec. 11.3.3 to calculate the mean and autocorrelation function of $y(\mathbf{r})$, and the results can be readily transcribed for the temporal case. For definiteness, we assume that \mathbf{r} , \mathbf{R}_n and $\Delta\mathbf{r}_{nk}$ are 2D vectors, but that restriction too is easily lifted.

Specification of the probability laws The random quantities in $y(\mathbf{r})$ are the sets $\{\Delta\mathbf{r}_{nk}\}$, $\{\mathbf{R}_n\}$ and $\{k_n\}$ plus the random number of primaries N and, for a doubly stochastic source, the primary fluence $b(\mathbf{r})$. In order to decide how to average over all of these quantities, we must know how each affects the probability laws on the others.

Consider first the displacements $\{\Delta\mathbf{r}_{nk}\}$ of the secondaries from the primary positions. The secondaries from different primaries are generated independently since the devices in question have no memory from one primary to the next. Thus $\Delta\mathbf{r}_{nk}$ must be independent of $\Delta\mathbf{r}_{n'k'}$ for $n \neq n'$. Moreover, even for the same primary ($n = n'$), it is reasonable to assume that $\Delta\mathbf{r}_{nk}$ is independent of $\Delta\mathbf{r}_{nk'}$ for $k \neq k'$ unless there is some specific mechanism (perhaps space charge) coupling the secondaries. We can thus assume that the multivariate density on $\{\Delta\mathbf{r}_{nk}\}$ is a product of univariate densities on each of the $\Delta\mathbf{r}_{nk}$. Similarly, the *conditional* multivariate density $\text{pr}(\{\mathbf{r}_{nk}\}|\mathbf{R}_n)$ is a product of conditional univariate densities $\text{pr}(\mathbf{r}_{nk}|\mathbf{R}_n)$. Notice, however, that the statistical independence of the \mathbf{r}_{nk} is lost when we consider the randomness in \mathbf{R}_n ; then \mathbf{r}_{nk} and $\mathbf{r}_{nk'}$ ($k \neq k'$) are not independent because of the common term \mathbf{R}_n . It remains quite reasonable to assume that $\Delta\mathbf{r}_{nk}$ and $\Delta\mathbf{r}_{nk'}$ ($k \neq k'$) are independent even with random \mathbf{R}_n , and this is one advantage of working with $\Delta\mathbf{r}_{nk}$ rather than \mathbf{r}_{nk} .

In principle the univariate density on $\Delta\mathbf{r}_{nk}$ could depend on N , k_n or $b(\mathbf{r})$, but such dependence is ruled out if we consider only linear detectors where the mean spatial pattern on the output is independent of the input fluence. (With this assumption we ignore an effect called *blooming*, where an image is blurred more at high fluences than at lower ones.) On the other hand, we should allow the spatial pattern of secondaries to depend on the position of the primary interaction, since the blur in the amplification process is shift-variant in many detectors. Thus the density on $\Delta\mathbf{r}_{nk}$ can depend on \mathbf{R}_n (though not on $\mathbf{R}_{n'}$ for $(n' \neq n)$, and the relevant univariate density describing the displacement is denoted $\text{pr}_{\Delta\mathbf{r}}(\Delta\mathbf{r}_{nk}|\mathbf{R}_n)$.

The specific form of $\text{pr}_{\Delta\mathbf{r}}(\Delta\mathbf{r}_{nk}|\mathbf{R}_n)$ can be deduced by an argument similar to the one used to obtain (11.70) or (11.76). Let $p_d(\mathbf{r}, \mathbf{R})$ be the shift-variant point spread function of the gain mechanism, defined as the mean number of secondaries per unit area at \mathbf{r} from one primary absorbed at \mathbf{R} . By analogy to (11.66), the probability of one secondary falling in a vanishingly small area $\Delta A(\mathbf{r})$ centered at

\mathbf{r} is given by

$$\Pr(1 \text{ sec in } \Delta A(\mathbf{r}) | 1 \text{ pri at } \mathbf{R}) = p_d(\mathbf{r}, \mathbf{R}) \Delta A(\mathbf{r}). \quad (11.201)$$

Another way of computing the probability of one secondary in $\Delta A(\mathbf{r})$ is to consider a specific secondary, say the k^{th} secondary produced by the n^{th} primary. If exactly k_n indistinguishable secondaries are produced by the n^{th} primary, the probability that one of them falls in $\Delta A(\mathbf{r})$ is k_n times the probability that specifically the k^{th} secondary falls in that area. Thus

$$\begin{aligned} & \Pr(1 \text{ sec in } \Delta A(\mathbf{r}) | 1 \text{ pri at } \mathbf{R}_n, k_n \text{ secs produced}) \\ &= k_n \Pr(\mathbf{r}_{nk} \text{ in } \Delta A(\mathbf{r}) | 1 \text{ pri at } \mathbf{R}_n, k_n \text{ secs produced}) \\ &= k_n \Delta A(\mathbf{r}) \text{pr}_{\Delta \mathbf{r}}(\Delta \mathbf{r}_{nk} | \mathbf{R}_n) |_{\Delta \mathbf{r}_{nk} = \mathbf{r} - \mathbf{R}_n}, \end{aligned} \quad (11.202)$$

where $\text{pr}_{\Delta \mathbf{r}}(\Delta \mathbf{r}_{nk} | \mathbf{R}_n)$ is the probability density function on $\Delta \mathbf{r}_{nk}$ given that the k^{th} secondary was produced by the n^{th} primary at \mathbf{R}_n . Averaging over k_n yields

$$\Pr(1 \text{ sec in } \Delta A(\mathbf{r}) | 1 \text{ pri at } \mathbf{R}_n) = \bar{k}_n(\mathbf{R}_n) \Delta A(\mathbf{r}) \text{pr}_{\Delta \mathbf{r}}(\Delta \mathbf{r}_{nk} | \mathbf{R}_n) |_{\Delta \mathbf{r}_{nk} = \mathbf{r} - \mathbf{R}_n}, \quad (11.203)$$

where

$$\bar{k}_n(\mathbf{R}_n) = \int_{\infty} d^2 r p_d(\mathbf{r}, \mathbf{R}_n). \quad (11.204)$$

Comparison of (11.201) and (11.203) shows that

$$\text{pr}_{\Delta \mathbf{r}}(\Delta \mathbf{r}_{nk} | \mathbf{R}_n) = [\bar{k}_n(\mathbf{R}_n)]^{-1} p_d(\Delta \mathbf{r}_{nk} + \mathbf{R}_n, \mathbf{R}_n). \quad (11.205)$$

We shall also need the probability density function on \mathbf{R}_n . For a given photon fluence function $b(\mathbf{r})$ (or Hilbert-space vector \mathbf{b}), this density is given by (11.76), written here as

$$\text{pr}_{pri}(\mathbf{R}_n | \mathbf{b}) = \frac{b(\mathbf{R}_n)}{\bar{N}(\mathbf{b})}, \quad (11.206)$$

where $\bar{N}(\mathbf{b})$ is the mean total number of counts for fixed \mathbf{b} .

We still need probability laws on N and $\{k_n\}$. Since the mechanisms of generating primaries and secondaries are unrelated, and since the secondaries produced by one primary have no effect on those produced by another primary, it is reasonable to assume that

$$\Pr(N, \{k_n\} | \mathbf{b}) = \Pr(N | \mathbf{b}) \Pr(\{k_n\} | N) = \Pr(N | \mathbf{b}) \prod_{n=1}^N \Pr(k_n). \quad (11.207)$$

As we saw in Sec. 11.1.1, a fixed \mathbf{b} implies a Poisson law for N , but by treating the probability on N as conditional on \mathbf{b} , we can later average over \mathbf{b} and get a more general doubly stochastic model.

To summarize, averaging any function of the point process $y(\mathbf{r})$ requires the following steps, in sequence:

- (a) Average over displacements $\{\Delta \mathbf{r}_{nk}\}$ for fixed \mathbf{R}_n with density (11.205);
- (b) Average over number of secondaries k_n for fixed \mathbf{R}_n ;

- (c) Average over \mathbf{R}_n for fixed \mathbf{b} with density (11.206);
- (d) Average over total number of primaries N for fixed \mathbf{b} ;
- (e) Average over \mathbf{b} if the primaries are doubly stochastic.

Calculation of the mean With the recipe given above, calculation of the mean of $y(\mathbf{r})$ is straightforward. Step (a), the average over $\{\Delta\mathbf{r}_{nk}\}$, yields

$$\begin{aligned} \langle y(\mathbf{r}) \rangle_{\{\Delta\mathbf{r}_{nk}\}} &= \sum_{n=1}^N \sum_{k=1}^{k_n} \int_{\infty} d^2 \Delta r_{nk} \delta(\mathbf{r} - \mathbf{R}_n - \Delta\mathbf{r}_{nk}) [\bar{k}_n(\mathbf{R}_n)]^{-1} p_d(\Delta\mathbf{r}_{nk} + \mathbf{R}_n, \mathbf{R}_n) \\ &= \sum_{n=1}^N \sum_{k=1}^{k_n} [\bar{k}_n(\mathbf{R}_n)]^{-1} p_d(\mathbf{r}, \mathbf{R}_n) = \sum_{n=1}^N k_n [\bar{k}_n(\mathbf{R}_n)]^{-1} p_d(\mathbf{r}, \mathbf{R}_n), \end{aligned} \quad (11.208)$$

where the last form follows from the observation that the summand is independent of k and that there are k_n terms in the sum over k . Step (b), the average over all k_n for fixed \mathbf{R}_n simply replaces k_n by $\bar{k}(\mathbf{R}_n)$, so

$$\langle \langle y(\mathbf{r}) \rangle_{\{\Delta\mathbf{r}_{nk}\}} \rangle_{\{k_n\}} = \sum_{n=1}^N p_d(\mathbf{r}, \mathbf{R}_n). \quad (11.209)$$

Step (c) involves integration against the density $\text{pr}_{pri}(\mathbf{R}_n|\mathbf{b})$ from (11.206), yielding

$$\begin{aligned} \langle \langle \langle y(\mathbf{r}) \rangle_{\{\Delta\mathbf{r}_{nk}\}} \rangle_{\{k_n\}} \rangle_{\{\mathbf{R}_n\}} &= \sum_{n=1}^N [\bar{N}(\mathbf{b})]^{-1} \int_{\infty} d^2 R_n p_d(\mathbf{r}, \mathbf{R}_n) b(\mathbf{R}_n) \\ &= N [\bar{N}(\mathbf{b})]^{-1} \int_{\infty} d^2 R p_d(\mathbf{r}, \mathbf{R}) b(\mathbf{R}), \end{aligned} \quad (11.210)$$

where the last line follows since all N terms in the sum are independent of n once the dummy variable of integration \mathbf{R}_n is renamed \mathbf{R} .

Steps (d) and (e) are now easy. An average over N conditional on \mathbf{b} replaces N with $\bar{N}(\mathbf{b})$, so

$$\mathbb{E}\{y(\mathbf{r})|\mathbf{b}\} = \int_{\infty} d^2 R p_d(\mathbf{r}, \mathbf{R}) b(\mathbf{R}). \quad (11.211)$$

Step (e), the average over \mathbf{b} , replaces $b(\mathbf{R})$ with $\bar{b}(\mathbf{R})$, yielding, finally,

$$\langle y(\mathbf{r}) \rangle = \int_{\infty} d^2 R p_d(\mathbf{r}, \mathbf{R}) \bar{b}(\mathbf{R}) = \int_{\infty} d^2 R \text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{R}|\mathbf{R}) \bar{k}_n(\mathbf{R}) \bar{b}(\mathbf{R}), \quad (11.212)$$

where the second form has incorporated (11.205).

For later convenience, we now define a linear operator \mathcal{H}_1 such that

$$[\mathcal{H}_1 \mathbf{b}](\mathbf{r}) = \int_{\infty} d^2 R p_d(\mathbf{r}, \mathbf{R}) b(\mathbf{R}), \quad (11.213)$$

where \mathbf{b} is the Hilbert-space vector corresponding to the function $b(\mathbf{R})$. The operator \mathcal{H}_1 maps a function of \mathbf{R} to a function of \mathbf{r} . Comparison with (11.212) shows that the kernel of the operator is $\text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{R}|\mathbf{R}) \bar{k}_n(\mathbf{R})$. With this notation, we have

$$\langle y(\mathbf{r}) \rangle = [\mathcal{H}_1 \bar{\mathbf{b}}](\mathbf{r}). \quad (11.214)$$

Discussion The expressions for the mean in (11.212) may be anticlimactic; the first form, at least, could have been written down at once by someone conversant with shift-variant imaging systems (see Sec. 7.2.1) but ignorant of the statistics of point processes. The second form is also fairly obvious since it says merely that the input fluence pattern is first multiplied by the space-variant gain and then subjected to a space-variant blurring process.

Several limits of (11.212) are worth examining. If the system is really shift-invariant, then $p_d(\mathbf{r}, \mathbf{R}) = p_d(\mathbf{r} - \mathbf{R})$ and $\langle y(\mathbf{r}) \rangle$ is just the convolution of the mean input fluence $\bar{b}(\mathbf{R})$ with the point spread function. If the system is shift-variant but $\bar{b}(\mathbf{R})$ is slowly varying compared to the blur width, then $\bar{b}(\mathbf{R})$ can be approximated by $\bar{b}(\mathbf{r})$ and removed from the integral. The integral can then be evaluated via (11.205), giving

$$\langle y(\mathbf{r}) \rangle \approx \bar{b}(\mathbf{r}) \bar{k}_n(\mathbf{r}), \quad (11.215)$$

which is just the mean input fluence times the position-dependent gain. If the image amplifier is ideal in the sense that the blur width is negligible and the gain is independent of position, then $\langle y(\mathbf{r}) \rangle$ is the mean input fluence times a constant gain factor.

The final average over \mathbf{b} may not be appropriate in all cases. Often we want to know the statistics of the image for *one* object, which implies one fluence pattern $b(\mathbf{r})$, so the conditional expectation $E\{y(\mathbf{r})|\mathbf{b}\}$ is the important quantity; it is recovered from (11.212) just by deleting the overbar.

Calculation of the autocorrelation function The autocorrelation function of $y(\mathbf{r})$ is defined by

$$R_{\mathbf{y}}(\mathbf{r}, \mathbf{r}') = \langle y(\mathbf{r}) y(\mathbf{r}') \rangle = \left\langle \sum_{n=1}^N \sum_{k=1}^{k_n} \delta(\mathbf{r} - \mathbf{R}_n - \Delta \mathbf{r}_{nk}) \sum_{n'=1}^N \sum_{k'=1}^{k_{n'}} \delta(\mathbf{r}' - \mathbf{R}_{n'} - \Delta \mathbf{r}_{n'k'}) \right\rangle, \quad (11.216)$$

where the angle brackets imply the five-step recipe outlined above. Executing the recipe is a bit tedious because of the four sums. As in Sec. 11.3.3, various special cases must be considered separately.

In the double sum over n and n' , there are N terms with $n = n'$ (each term being itself a double sum over k and k') and $N^2 - N$ terms with $n \neq n'$. For $n = n'$, there are k_n terms with $k = k'$ in the double sum over k and k' , and there are $k_n^2 - k_n$ terms with $k \neq k'$. For $n \neq n'$, it is irrelevant whether $k = k'$, so there are three cases to consider.

Case 1: $n = n'$ and $k = k'$

The calculation in this case parallels the derivation of (11.88), with the additional step of averaging over \mathbf{R}_n . From steps (a)–(d) in the recipe, the total contribution from all terms with $n = n'$ and $k = k'$ is

$$[E\{y(\mathbf{r}) y(\mathbf{r}')|\mathbf{b}\}]_{n=n', k=k'} = \left[\int_{\infty} d^2 R p_d(\mathbf{r}, \mathbf{R}) b(\mathbf{R}) \right] \delta(\mathbf{r} - \mathbf{r}') = [\mathcal{H}_1 \mathbf{b}](\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'). \quad (11.217)$$

Step (e) in this case just replaces $b(\mathbf{R})$ with $\bar{b}(\mathbf{R})$, but we shall postpone this step for a while.

Case 2: $n = n'$ and $k \neq k'$

Now step (a) in the recipe requires averaging $\delta(\mathbf{r} - \mathbf{R}_n - \Delta\mathbf{r}_{nk}) \delta(\mathbf{r}' - \mathbf{R}_n - \Delta\mathbf{r}_{nk'})$ over $\Delta\mathbf{r}_{nk}$ and $\Delta\mathbf{r}_{nk'}$ for fixed \mathbf{R}_n . Since $\Delta\mathbf{r}_{nk}$ and $\Delta\mathbf{r}_{nk'}$ are independent, this average is $\text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{R}_n | \mathbf{R}_n) \text{pr}_{\Delta\mathbf{r}}(\mathbf{r}' - \mathbf{R}_n | \mathbf{R}_n)$. Each of the $k_n^2 - k_n$ terms with $k \neq k'$ gives this same form, so the result of averaging over displacements and summing over k and k' for fixed n is

$$\begin{aligned} & \sum_{k=1}^{k_n} \sum_{k'=1}^{k_n} (1 - \delta_{kk'}) \text{E}_{\{\Delta\mathbf{r}_{nk}\}} \left\{ \delta(\mathbf{r} - \mathbf{R}_n - \Delta\mathbf{r}_{nk}) \delta(\mathbf{r}' - \mathbf{R}_n - \Delta\mathbf{r}_{nk'}) | \mathbf{R}_n \right\} \\ & = (k_n^2 - k_n) \text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{R}_n | \mathbf{R}_n) \text{pr}_{\Delta\mathbf{r}}(\mathbf{r}' - \mathbf{R}_n | \mathbf{R}_n). \end{aligned} \quad (11.218)$$

Note that the factor $k_n^2 - k_n$ eliminates primary interactions for which $k_n = 0$ or 1; there must be at least two secondaries for this expression to be nonzero since we are considering $k \neq k'$.

The average over k_n required in step (b) yields

$$\text{E}\{k_n^2 - k_n | \mathbf{R}_n\} = \text{Var}(k_n | \mathbf{R}_n) + [\text{E}\{k_n | \mathbf{R}_n\}]^2 - \text{E}\{k_n | \mathbf{R}_n\} \equiv s(\mathbf{R}_n), \quad (11.219)$$

where we have introduced $s(\mathbf{R}_n)$ as a shorthand for the indicated combination of conditional mean and variance. The mnemonic is that $s(\mathbf{R})$ is related to the statistical spread of the gain mechanism at point \mathbf{R} .

Steps (c) and (d) now give

$$[\text{E}\{y(\mathbf{r}) y(\mathbf{r}') | \mathbf{b}\}]_{n=n', k \neq k'} = \int_{\infty} d^2 R \text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{R}) \text{pr}_{\Delta\mathbf{r}}(\mathbf{r}' - \mathbf{R} | \mathbf{R}) b(\mathbf{R}) s(\mathbf{R}). \quad (11.220)$$

We can express this term more compactly by defining a linear operator \mathcal{H}_2 that maps a function of \mathbf{R} to a function of \mathbf{r} and \mathbf{r}' . The definition is

$$[\mathcal{H}_2 \mathbf{b}](\mathbf{r}, \mathbf{r}') = \int_{\infty} d^2 R \text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{R} | \mathbf{R}) \text{pr}_{\Delta\mathbf{r}}(\mathbf{r}' - \mathbf{R} | \mathbf{R}) b(\mathbf{R}) s(\mathbf{R}). \quad (11.221)$$

Case 3: $n \neq n'$

If $n \neq n'$, $\Delta\mathbf{r}_{nk}$ and $\Delta\mathbf{r}_{n'k'}$ are independent, and there is no correlation between \mathbf{R}_n and $\mathbf{R}_{n'}$ except possibly that induced by randomness in the fluence $b(\mathbf{r})$. For fixed fluence, then,

$$\begin{aligned} & [\text{E}\{y(\mathbf{r}) y(\mathbf{r}') | \mathbf{b}\}]_{n \neq n'} \\ & = \text{E}\{N^2 - N | \mathbf{b}\} \text{E}\{k_n \delta(\mathbf{r} - \mathbf{R}_n - \Delta\mathbf{r}_{nk}) | \mathbf{b}\} \text{E}\{k_{n'} \delta(\mathbf{r}' - \mathbf{R}_{n'} - \Delta\mathbf{r}_{n'k'}) | \mathbf{b}\}. \end{aligned} \quad (11.222)$$

Since N is a Poisson random variable if the fluence is fixed, we know that

$$\text{E}\{N^2 - N | \mathbf{b}\} = \text{Var}(N | \mathbf{b}) + [\text{E}\{N | \mathbf{b}\}]^2 - \text{E}\{N | \mathbf{b}\} = [\text{E}\{N | \mathbf{b}\}]^2 = [\overline{N}(\mathbf{b})]^2. \quad (11.223)$$

The remaining two expectations in (11.222) were calculated in (11.211), and we have

$$\begin{aligned} [\text{E}\{y(\mathbf{r}) y(\mathbf{r}') | \mathbf{b}\}]_{n \neq n'} & = \int_{\infty} d^2 R p_d(\mathbf{r}, \mathbf{R}) b(\mathbf{R}) \int_{\infty} d^2 R' p_d(\mathbf{r}', \mathbf{R}') b(\mathbf{R}') \\ & = [\mathcal{H}_1 \mathbf{b}](\mathbf{r}) [\mathcal{H}_1 \mathbf{b}](\mathbf{r}'), \end{aligned} \quad (11.224)$$

where \mathcal{H}_1 is the operator defined in (11.213).

Conditional autocorrelation and autocovariance Adding (11.217), (11.220) and (11.224), we find

$$R_y(\mathbf{r}, \mathbf{r}' | \mathbf{b}) = E\{y(\mathbf{r})y(\mathbf{r}') | \mathbf{b}\} = [\mathcal{H}_1 \mathbf{b}](\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') + [\mathcal{H}_2 \mathbf{b}](\mathbf{r}, \mathbf{r}') + [\mathcal{H}_1 \mathbf{b}](\mathbf{r}) [\mathcal{H}_1 \mathbf{b}](\mathbf{r}'). \quad (11.225)$$

This expression is the conditional autocorrelation function (for fixed \mathbf{b}) of the amplified point process $y(\mathbf{r})$. The corresponding conditional autocovariance function is obtained by subtracting off the product of the conditional means; comparison of (11.225) and (11.211) shows that the term to be subtracted off is just the third term in (11.225), so the conditional autocovariance is

$$\begin{aligned} K_y(\mathbf{r}, \mathbf{r}' | \mathbf{b}) &= E\{y(\mathbf{r})y(\mathbf{r}') | \mathbf{b}\} - E\{y(\mathbf{r}) | \mathbf{b}\}E\{y(\mathbf{r}') | \mathbf{b}\} \\ &= \left[\int_{-\infty}^{\infty} d^2 R p_d(\mathbf{r}, \mathbf{R}) b(\mathbf{R}) \right] \delta(\mathbf{r} - \mathbf{r}') + \int_{-\infty}^{\infty} d^2 R \text{pr}_{\Delta \mathbf{r}}(\mathbf{r} - \mathbf{R} | \mathbf{R}) \text{pr}_{\Delta \mathbf{r}}(\mathbf{r}' - \mathbf{R} | \mathbf{R}) b(\mathbf{R}) s(\mathbf{R}) \\ &= [\mathcal{H}_1 \mathbf{b}](\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') + [\mathcal{H}_2 \mathbf{b}](\mathbf{r}, \mathbf{r}'). \end{aligned} \quad (11.226)$$

This expression contains a delta-correlated part, which comes from the fact that each sample function of the amplified random process is a sum of delta functions, and it also has a term with a finite correlation range. The factor $\text{pr}_{\Delta \mathbf{r}}(\mathbf{r} - \mathbf{R} | \mathbf{R}) \text{pr}_{\Delta \mathbf{r}}(\mathbf{r}' - \mathbf{R} | \mathbf{R})$ in the kernel of \mathcal{H}_2 drops to zero when $|\mathbf{r} - \mathbf{r}'|$ is approximately equal to the width of $\text{pr}_{\Delta \mathbf{r}}(\mathbf{r} | \mathbf{R})$.

The similarity of the second term in $K_y(\mathbf{r}, \mathbf{r}' | \mathbf{b})$ to (11.140) should be noted (see also the discussion in Sec. 8.2.6). The randomness in $\Delta \mathbf{r}_{nk}$ induces a correlation in $y(\mathbf{r})$ of the same form as that induced by filtering. A key difference, however, is that there is no delta-correlated term in the autocorrelation or autocovariance function of a filtered point process. An amplified point process is still a point process, but a filtered point process is not. Instead, each input delta function produces a shifted replica of the filter spread function, so there is no longer a delta-correlated component.

A possible simplifying assumption at this point would be that the gain process obeys Poisson statistics, so that $\text{Var}(k_n | \mathbf{R}_n) = \bar{k}_n(\mathbf{R}_n)$. In fact, a Poisson law for detectors with gain is rarely valid (see Sec. 11.4.2), but if it is, then $s(\mathbf{R})$ is just the square of the gain $E\{k_n | \mathbf{R}_n\}$. In that case, the second term in (11.226) is identical to (11.140), with the effective filter spread function $h(\mathbf{r}, \mathbf{R})$ given by the product of the gain and the probability density function $\text{pr}_{\Delta \mathbf{r}}(\mathbf{r} - \mathbf{R} | \mathbf{R})$ that controls the blur.

Amplification without blur Another interesting limit is where the gain process has no significant blur associated with it, so that $\text{pr}_{\Delta \mathbf{r}}(\mathbf{r} - \mathbf{R} | \mathbf{R})$ is well approximated by $\delta(\mathbf{r} - \mathbf{R})$. Then,

$$[\mathcal{H}_2 \mathbf{b}](\mathbf{r}, \mathbf{r}') \approx \int_{-\infty}^{\infty} d^2 R \delta(\mathbf{r} - \mathbf{R}) \delta(\mathbf{r}' - \mathbf{R}) b(\mathbf{R}) s(\mathbf{R}) = b(\mathbf{r}) s(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'). \quad (11.227)$$

Under this approximation, both terms are delta-correlated, and the conditional autocovariance is given by

$$\begin{aligned} K_y(\mathbf{r}, \mathbf{r}' | \mathbf{b}) &= \bar{k}_n(\mathbf{r}) b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') + s(\mathbf{r}) b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') \\ &= \{\text{Var}(k_n | \mathbf{r}) + \bar{k}_n^2(\mathbf{r})\} b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'), \end{aligned} \quad (11.228)$$

where we have used (11.219). We recall from (11.94) that the autocovariance of a Poisson random process is just $b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}')$, and by computing the autocovariance of $y(\mathbf{r})$ conditional on \mathbf{b} , we are, in effect, assuming that the input to the amplifier is a Poisson random process. For an amplifier without blur, (11.228) shows that the autocovariance is increased by a factor of $\text{Var}(k_n|\mathbf{r}) + \bar{k}_n^2(\mathbf{r})$. For a noise-free, blur-free amplifier, the factor would be $\bar{k}_n^2(\mathbf{r})$, but noise in the amplification process imparts a random amplitude to the impulses.

Since $\text{Var}(k_n|\mathbf{r}) + \bar{k}_n^2(\mathbf{r})$ is just the second moment m_2 of the number of secondaries, the autocovariance is increased by m_2/m_1^2 , which is the reciprocal of the Swank factor discussed in Sec. 11.4.1. Here the factor refers to the relative strength of an autocorrelation function rather than a variance, so it can be a function of position.

Mislocation without gain Some imaging detectors do not amplify the point process but rather estimate (with some error) the location of each impulse; an example is the Anger scintillation camera to be introduced in Sec. 12.3. In such devices, k_n is identically one but $\Delta\mathbf{r}_{n1}$ is still a random variable. The derivation just given still applies if we set $\text{Var}(k_n) = 0$ and $\bar{k}_n(\mathbf{R}) = 1$. Then $s(\mathbf{R}) = 0$ and the conditional autocovariance function (11.226) becomes

$$K_y(\mathbf{r}, \mathbf{r}'|\mathbf{b}) = \left[\int_{\infty} d^2R \text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{R}|\mathbf{R}) b(\mathbf{R}) \right] \delta(\mathbf{r} - \mathbf{r}'), \quad (11.229)$$

which is just what we would have for a Poisson random process and an ideal detector, except that the mean fluence pattern is blurred with the spread function $\text{pr}_{\Delta\mathbf{r}}(\mathbf{r}|\mathbf{R})$. With no gain and no randomness in \mathbf{b} , only the delta-correlated term appears.

Random fluence If the fluence pattern is random, the overall autocorrelation function is obtained by averaging (11.225) over \mathbf{b} . The first two terms, both linear in \mathbf{b} , are easily averaged just by adding an overbar. The final term becomes

$$\begin{aligned} E_{\mathbf{b}}\{[\mathcal{H}_1\mathbf{b}](\mathbf{r}) [\mathcal{H}_1\mathbf{b}](\mathbf{r}')\} &= \int_{\infty} d^2R p_d(\mathbf{r}, \mathbf{R}) \int_{\infty} d^2R' p_d(\mathbf{r}', \mathbf{R}') E_{\mathbf{b}}\{b(\mathbf{R}) b(\mathbf{R}')\} \\ &= \int_{\infty} d^2R p_d(\mathbf{r}, \mathbf{R}) \int_{\infty} d^2R' p_d(\mathbf{r}', \mathbf{R}') R_{\mathbf{b}}(\mathbf{R}, \mathbf{R}'), \end{aligned} \quad (11.230)$$

where $R_{\mathbf{b}}(\mathbf{r}, \mathbf{r}')$ is the autocorrelation function of $b(\mathbf{r})$. The integral in (11.230) can be interpreted as the autocorrelation of $b(\mathbf{r})$ as transformed by \mathcal{H}_1 ; we denote it as $[\mathcal{H}_1 R_{\mathbf{b}} \mathcal{H}_1^\dagger](\mathbf{r}, \mathbf{r}')$. The final expression for R_y is

$$R_y(\mathbf{r}, \mathbf{r}') = E\{y(\mathbf{r}) y(\mathbf{r}')\} = [\mathcal{H}_1 \bar{\mathbf{b}}](\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') + [\mathcal{H}_2 \bar{\mathbf{b}}](\mathbf{r}, \mathbf{r}') + [\mathcal{H}_1 R_{\mathbf{b}} \mathcal{H}_1^\dagger](\mathbf{r}, \mathbf{r}'). \quad (11.231)$$

To get the autocovariance, we must subtract the product of the means, now including the average over \mathbf{b} . The result is

$$\begin{aligned} K_y(\mathbf{r}, \mathbf{r}') &= E\{y(\mathbf{r}) y(\mathbf{r}')\} - E\{y(\mathbf{r})\} E\{y(\mathbf{r}')\} \\ &= [\mathcal{H}_1 \bar{\mathbf{b}}](\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') + [\mathcal{H}_2 \bar{\mathbf{b}}](\mathbf{r}, \mathbf{r}') + [\mathcal{H}_1 R_{\mathbf{b}} \mathcal{H}_1^\dagger](\mathbf{r}, \mathbf{r}') - [\mathcal{H}_1 \bar{\mathbf{b}}](\mathbf{r}) [\mathcal{H}_1 \bar{\mathbf{b}}](\mathbf{r}'). \end{aligned} \quad (11.232)$$

The third and fourth terms comprise the autocovariance function $K_{\mathbf{b}}(\mathbf{r}, \mathbf{r}')$ transformed by the operator \mathcal{H}_1 , so we can write, finally,

$$K_{\mathbf{y}}(\mathbf{r}, \mathbf{r}') = [\mathcal{H}_1 \bar{\mathbf{b}}](\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') + [\mathcal{H}_2 \bar{\mathbf{b}}](\mathbf{r}, \mathbf{r}') + [\mathcal{H}_1 K_{\mathbf{b}} \mathcal{H}_1^\dagger](\mathbf{r}, \mathbf{r}'). \quad (11.233)$$

As in the case of nonrandom fluence, the delta-correlated term arises because the amplified point process is still a sum of delta functions. The second term arises from the amplification process, and the third is the contribution from the doubly stochastic nature of the source, as in (11.116).

11.4.4 Spectral analysis

As we saw in Sec. 11.2, stationary random processes are usefully described in the frequency domain by their power spectral densities. There are, however, many reasons why the amplified point process $y(\mathbf{r})$ might not be stationary. We shall enumerate these reasons here along with the assumptions needed for stationarity; then we shall compute the power spectral density of $y(\mathbf{r})$ under these assumptions.

For a random process to be stationary in the wide sense, its mean must be constant and its autocorrelation function must depend only on $\mathbf{r} - \mathbf{r}'$. From (11.212), the mean is constant if the blurring process $\text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{R} | \mathbf{R})$ is shift-invariant, meaning that it can be written as $\text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{R})$, and the mean gain $\bar{k}_n(\mathbf{R})$ and mean input fluence $\bar{b}(\mathbf{R})$ are independent of position \mathbf{R} . One way to achieve a constant input fluence is to illuminate the detector with a uniform flood source of radiation. In that case, $b(\mathbf{R})$ is nonrandom and independent of \mathbf{R} .

One additional condition for stationarity that is impossible to satisfy in practice is that the detector and the input fluence must both extend to infinity so that the limits of integration in (11.212) are infinite. As discussed in Sec. 8.2.4, boundary effects require a modified definition of stationarity. For present purposes we simply ignore the boundaries and use infinite limits.

If all of these conditions — constant gain and fluence, shift-invariant blurring and infinite field of view — are satisfied, (11.212) is the convolution of $\text{pr}_{\Delta\mathbf{r}}(\mathbf{r})$ with a constant, which gives a constant.

To achieve stationarity for the conditional autocovariance (11.226), we must impose the additional condition that $s(\mathbf{R})$ is constant, which requires that the variance of the amplification process as well as its mean be constant. If we set $s(\mathbf{R}) = s_0$ and $b(\mathbf{R}) = b_0$ and make the change of variables $\mathbf{R}' = \mathbf{r} - \mathbf{R}$, we can rewrite the second term in (11.226) as

$$\begin{aligned} [\mathcal{H}_2 \mathbf{b}](\mathbf{r}, \mathbf{r}') &= s_0 b_0 \int_{\infty} d^2 R' \text{pr}_{\Delta\mathbf{r}}(\mathbf{R}') \text{pr}_{\Delta\mathbf{r}}(\mathbf{r}' - \mathbf{r} + \mathbf{R}') \\ &= s_0 b_0 [\text{pr}_{\Delta\mathbf{r}} \star \text{pr}_{\Delta\mathbf{r}}](\mathbf{r}' - \mathbf{r}), \end{aligned} \quad (11.234)$$

where \star denotes the spatial (not statistical) autocorrelation function as defined in (3.115). The conditional autocovariance under the accumulated assumptions is thus

$$K_{\mathbf{y}}(\mathbf{r}, \mathbf{r}' | \mathbf{b}) = \bar{k} b_0 \delta(\mathbf{r} - \mathbf{r}') + s_0 b_0 [\text{pr}_{\Delta\mathbf{r}} \star \text{pr}_{\Delta\mathbf{r}}](\mathbf{r} - \mathbf{r}'), \quad (11.235)$$

where \bar{k} is the constant mean gain, and we have used the normalization of $\text{pr}_{\Delta\mathbf{r}}(\mathbf{r})$.

Since this expression is manifestly a function of only $\mathbf{r} - \mathbf{r}'$, it describes a wide-sense stationary random process. The conditional power spectral density of the

zero-mean process $\Delta y(\mathbf{r})$ is the Fourier transform of the autocovariance function $K_{\mathbf{y}}$ (see Sec. 8.2.5). An easy transform leads to

$$S_{\Delta \mathbf{y}}(\boldsymbol{\rho}|\mathbf{b}) = \bar{k}b_0 + s_0b_0|\psi_{\Delta \mathbf{r}}(\boldsymbol{\rho})|^2, \quad (11.236)$$

where $\psi_{\Delta \mathbf{r}}(\boldsymbol{\rho})$ is the Fourier transform of $\text{pr}_{\Delta \mathbf{r}}(\mathbf{r})$ (*i.e.*, the characteristic function for $\Delta \mathbf{r}$), and we have used (3.245).

The first term in (11.236) represents white noise with power spectral density $\bar{k}b_0$ equal to the mean number of secondaries per unit area. Since $\text{pr}_{\Delta \mathbf{r}}(\mathbf{r})$ is the point spread function of the amplifier, $\psi_{\Delta \mathbf{r}}(\boldsymbol{\rho})$ is its transfer function, and the second term in (11.236) is proportional to the squared modulus of the transfer function. This term has a low-pass characteristic since $\text{pr}_{\Delta \mathbf{r}}(\mathbf{r})$ is a blurring filter.

If the fluence pattern is a random process, then the autocovariance function has another term as seen in (11.233). In order for $y(\mathbf{r})$ to be stationary, $b(\mathbf{r})$ must be stationary as well. Under that assumption, the third term in (11.233) is just a double convolution, and we obtain

$$S_{\Delta \mathbf{y}}(\boldsymbol{\rho}) = \bar{k}\bar{b} + \left[s_0\bar{b} + \bar{k}^2 S_{\Delta \mathbf{b}}(\boldsymbol{\rho}) \right] |\psi_{\Delta \mathbf{r}}(\boldsymbol{\rho})|^2. \quad (11.237)$$

Now we have a superposition of three distinctly different spectral functions: a white-noise term $\bar{k}\bar{b}$, a term $s_0\bar{b}|\psi_{\Delta \mathbf{r}}(\boldsymbol{\rho})|^2$ proportional to the squared modulus of the transfer function, and a term $\bar{k}^2 S_{\Delta \mathbf{b}}(\boldsymbol{\rho})|\psi_{\Delta \mathbf{r}}(\boldsymbol{\rho})|^2$. The first of these arises since $y(\mathbf{r})$ is still a sum of impulses, the second arises from the spread of the gain mechanism, and the third represents the fluence spectrum as amplified and filtered by the transfer function.

11.4.5 Random amplification in arrays

If a detector with gain is to be used as part of a digital imaging system, the output must be binned into discrete pixels. The binned output is then a random vector rather than a random process, and a second-order statistical analysis must give the mean vector and the covariance matrix. There are three basic ways in which we can compute these quantities, corresponding to three different descriptions of imaging systems. As we saw in Chap. 7, an imaging system can be modeled as a continuous-to-continuous (CC), continuous-to-discrete (CD) or discrete-to-discrete (DD) mapping. The discussion in Secs. 11.3.3 and 11.3.4 was based on a stochastic CC model, where both input and output of the detector are random processes. However, we showed in Sec. 11.3.4 how to convert mean and autocovariance function of a random process to mean vector and covariance matrix by integrating over pixels. Applying this procedure to (11.226), we obtain immediately the conditional (fixed-fluence) covariance matrix,

$$[\mathbf{K}_{\mathbf{y}}(\mathbf{b})]_{mm'} = \delta_{mm'} \int_m d^2r [\mathcal{H}_1 \mathbf{b}](\mathbf{r}) + \int_{\infty} d^2R p_m(\mathbf{R}) p_{m'}(\mathbf{R}) b(\mathbf{R}) s(\mathbf{R}), \quad (11.238)$$

where

$$p_m(\mathbf{R}) = \int_m d^2r \text{pr}_{\Delta r}(\mathbf{r} - \mathbf{R}|\mathbf{R}). \quad (11.239)$$

The second approach is to model the detector from the outset as a CD mapping and to modify the derivation given in Sec. 11.4.3 so that it uses probabilities rather

than probability density functions. For example, instead of the conditional density $\text{pr}(\mathbf{r}_{nk}|\mathbf{R}_n)$, we would consider the probability that a secondary produced by a primary at the continuous position \mathbf{R} will fall in the j^{th} output pixel. This approach will also lead to (11.238).

The third approach is to imagine that the position of the primary interaction is described not by a continuous variable \mathbf{R} , but by another discrete pixel index. In this approach we are interested in the probability that a secondary will fall in pixel j given that it was produced by a primary in pixel i . Few real detectors are accurately described by this DD model, just as few real imaging systems are accurately described by deterministic DD models. Nevertheless, such models are deeply entrenched in the literature, and it is worthwhile learning how to analyze them. Furthermore, the stochastic DD model affords a chance to gain more fluency with the useful technique of generating functions. For these reasons, we sketch here an analysis of amplifying detectors based on multivariate generating functions and a DD model, an approach used by Rabbani *et al.* (1987).

Multivariate generating functions We denote the random number of primaries absorbed on the j^{th} input pixel by g_j , $j = 1, \dots, J$, and the random number of secondaries on the m^{th} output pixel by y_m , $m = 1, \dots, M$. The set $\{g_j\}$ can be regarded as the components of a $J \times 1$ vector \mathbf{g} , while the set $\{y_m\}$ forms an $M \times 1$ vector \mathbf{y} . Note that the number of input pixels need not be the same as the number of output pixels, and in fact J can be allowed to go to infinity to get results for the CD case.

The multivariate generating function (more specifically, the probability-generating function) is a generalization of the univariate generating function discussed in Sec. C.3.3. For the output vector \mathbf{y} , the generating function is defined by

$$\Phi_{\mathbf{y}}(\zeta_1, \zeta_2, \dots, \zeta_M) = \Phi_{\mathbf{y}}(\boldsymbol{\zeta}) = E_{\mathbf{y}} \left\{ \prod_{m=1}^M (\zeta_m)^{y_m} \right\}, \quad (11.240)$$

where $\boldsymbol{\zeta}$ is an $M \times 1$ vector with components $\{\zeta_m\}$. The generating function for the input vector \mathbf{g} is defined similarly:

$$\Phi_{\mathbf{g}}(\xi_1, \xi_2, \dots, \xi_J) = \Phi_{\mathbf{g}}(\boldsymbol{\xi}) = E_{\mathbf{g}} \left\{ \prod_{j=1}^J (\xi_j)^{g_j} \right\}, \quad (11.241)$$

where $\boldsymbol{\xi}$ is a $J \times 1$ vector.

It will also be useful to consider various conditional generating functions, defined like (11.240) or (11.241) but with conditional expectations. Consider first the conditional generating function $\Phi_{\mathbf{y}}(\boldsymbol{\zeta}|1 \text{ pri in } j, 1 \text{ sec})$ where one primary is absorbed in the j^{th} input pixel and exactly one secondary is produced. Since there is only one secondary, the sample space for each of the y_m is just $(0, 1)$. The conditional probability that $y_m = 1$, given that one secondary was produced in input pixel j , will be denoted p_{jm} . If a particular y_m (say the one with $m = n$) equals one, all others must be zero since there is only one secondary. When that event occurs, the M -fold product in (11.240) consists of one factor given by $(\zeta_n)^1 = \zeta_n$ and $M - 1$ factors of $(\zeta_m)^0 = 1$. This event has probability p_{jn} , and it is mutually exclusive of the similar events for other m values, so the corresponding probabilities

add. The conditional generating function is thus

$$\Phi_{\mathbf{y}}(\zeta|1 \text{ pri in } j, 1 \text{ sec}) = \sum_{m=1}^M p_{jm} \zeta_m. \tag{11.242}$$

The righthand side of (11.242) has the form of a scalar product in an M -dimensional space, so we define an $M \times 1$ vector \mathbf{p}_j with components p_{jm} and write

$$\Phi_{\mathbf{y}}(\zeta|1 \text{ pri in } j, 1 \text{ sec}) = \mathbf{p}_j^t \zeta. \tag{11.243}$$

We have assumed throughout that secondaries are independent, so if exactly k_j secondaries are produced at input pixel j , they are distributed independently among the output pixels. We thus have

$$\Phi_{\mathbf{y}}(\zeta|1 \text{ pri in } j, k_j \text{ secs}) = (\mathbf{p}_j^t \zeta)^{k_j}. \tag{11.244}$$

Averaging over k_j yields

$$\Phi_{\mathbf{y}}(\zeta|1 \text{ pri in } j) = \sum_{k_j=0}^{\infty} (\mathbf{p}_j^t \zeta)^{k_j} \text{Pr}(k_j) = \Phi_{k_j}(\mathbf{p}_j^t \zeta), \tag{11.245}$$

where we have used the definition of the generating function, (11.186).

We can also take advantage of the fact that secondaries produced by different primaries are independent. If one primary is absorbed in pixel i and another in pixel j , the conditional expectations factor, and we find

$$\Phi_{\mathbf{y}}(\zeta|1 \text{ pri in } i \text{ and } 1 \text{ pri in } j) = \Phi_{k_i}(\mathbf{p}_i^t \zeta) \Phi_{k_j}(\mathbf{p}_j^t \zeta). \tag{11.246}$$

By extension, given a specific realization of the random primary vector \mathbf{g} (each component of which is an integer), we have

$$\Phi_{\mathbf{y}}(\zeta|\mathbf{g}) = \prod_{j=1}^J [\Phi_{k_j}(\mathbf{p}_j^t \zeta)]^{g_j}. \tag{11.247}$$

Averaging over \mathbf{g} yields

$$\Phi_{\mathbf{y}}(\zeta) = E_{\mathbf{g}}\{\Phi_{\mathbf{y}}(\zeta|\mathbf{g})\} = E_{\mathbf{g}} \left\{ \prod_{j=1}^J [\Phi_{k_j}(\mathbf{p}_j^t \zeta)]^{g_j} \right\}. \tag{11.248}$$

Comparison with (11.241) shows that

$$\Phi_{\mathbf{y}}(\zeta) = \Phi_{\mathbf{g}} [\Phi_{k_1}(\mathbf{p}_1^t \zeta), \Phi_{k_2}(\mathbf{p}_2^t \zeta), \dots, \Phi_{k_J}(\mathbf{p}_J^t \zeta)]. \tag{11.249}$$

Mean and covariance We can derive the mean vector and covariance matrix for \mathbf{y} by differentiating (11.249) in a manner similar to (11.195)–(11.198). Chain-rule differentiation gives

$$\frac{\partial \Phi_{\mathbf{y}}(\zeta)}{\partial \zeta_m} = \sum_{j=1}^J \frac{\partial \Phi_{\mathbf{g}} [\Phi_{k_1}(\mathbf{p}_1^t \zeta), \dots, \Phi_{k_J}(\mathbf{p}_J^t \zeta)]}{\partial \Phi_{k_j}(\mathbf{p}_j^t \zeta)} \frac{\partial \Phi_{k_j}(\mathbf{p}_j^t \zeta)}{\partial \mathbf{p}_j^t \zeta} \frac{\partial \mathbf{p}_j^t \zeta}{\partial \zeta_m}. \tag{11.250}$$

The mean of y_m is found by evaluating (11.250) with $\zeta_j = 1$ for all j (or $\boldsymbol{\zeta} = \mathbf{1}$, where $\mathbf{1}$ is a vector with all elements equal to one). The last factor in the summand, $\partial \mathbf{p}_j^t \boldsymbol{\zeta} / \partial \zeta_m$, is simply p_{jm} , independent of $\boldsymbol{\zeta}$, so no evaluation is needed. The middle factor evaluates to

$$\frac{\partial \Phi_{k_j}(\mathbf{p}_j^t \boldsymbol{\zeta})}{\partial \mathbf{p}_j^t \boldsymbol{\zeta}} \Big|_{\boldsymbol{\zeta}=\mathbf{1}} = \frac{\partial \Phi_{k_j}(\nu)}{\partial \nu} \Big|_{\nu=\sum_m p_{jm}=1} = \bar{k}_j, \tag{11.251}$$

where the middle step makes use of the normalization of probability, from which it follows that setting $\boldsymbol{\zeta} = \mathbf{1}$ is the same thing as setting $\mathbf{p}_j^t \boldsymbol{\zeta} = 1$.

The first factor in (11.251) evaluates to

$$\frac{\partial \Phi_{\mathbf{g}}[\Phi_{k_1}(\mathbf{p}_1^t \boldsymbol{\zeta}), \dots, \Phi_{k_J}(\mathbf{p}_J^t \boldsymbol{\zeta})]}{\partial \Phi_{k_j}(\mathbf{p}_j^t \boldsymbol{\zeta})} \Big|_{\boldsymbol{\zeta}=\mathbf{1}} = \frac{\partial \Phi_{\mathbf{g}}(\xi_1, \dots, \xi_J)}{\partial \xi_j} \Big|_{\boldsymbol{\xi}=\mathbf{1}} = \bar{g}_j, \tag{11.252}$$

where in this step we have used the fact that $\Phi_{k_j}(\mathbf{p}_j^t \mathbf{1}) = \Phi_{k_j}(1) = 1$ since the zeroth moment of any random variable is unity.

Collecting results, we find

$$\langle y_m \rangle = \sum_{j=1}^J \bar{g}_j \bar{k}_j p_{jm}. \tag{11.253}$$

A similar analysis shows that

$$\begin{aligned} & \frac{\partial^2 \Phi_{\mathbf{y}}(\boldsymbol{\zeta})}{\partial \zeta_m \partial \zeta_n} \Big|_{\boldsymbol{\zeta}=\mathbf{1}} = \langle y_m y_n \rangle \\ & = \sum_{j=1}^J \bar{g}_j \bar{k}_j p_{jm} \sum_{l=1}^J \bar{g}_l \bar{k}_l p_{lm} + \sum_{j=1}^J \bar{g}_j p_{jm} p_{jn} \langle k_j(k_j - 1) \rangle, \quad (m \neq n). \end{aligned} \tag{11.254}$$

For the special case $m = n$ we find

$$\begin{aligned} & \frac{\partial^2 \Phi_{\mathbf{y}}(\boldsymbol{\zeta})}{\partial \zeta_m^2} \Big|_{\boldsymbol{\zeta}=\mathbf{1}} = \langle y_m(y_m - 1) \rangle \\ & = \sum_{j=1}^J \bar{g}_j \bar{k}_j p_{jm} \sum_{l=1}^J \bar{g}_l \bar{k}_l p_{lm} + \sum_{j=1}^J \bar{g}_j p_{jm}^2 \langle k_j(k_j - 1) \rangle. \end{aligned} \tag{11.255}$$

From these expressions, the covariance matrix of \mathbf{y} (for fixed fluence) is found to be

$$\begin{aligned} [\mathbf{K}_{\mathbf{y}}(\mathbf{b})]_{mn} & = [\langle y_m y_n \rangle - \langle y_m \rangle \langle y_n \rangle] (1 - \delta_{mn}) + [\langle y_m(y_m - 1) \rangle + \langle y_m \rangle - \langle y_m \rangle^2] \delta_{mn} \\ & = \sum_{j=1}^J \bar{g}_j p_{jm} p_{jn} \langle k_j(k_j - 1) \rangle + \left[\sum_{j=1}^J \bar{g}_j p_{jm} \bar{k}_j \right] \delta_{mn}. \end{aligned} \tag{11.256}$$

This expression is the discrete counterpart of (11.226). The latter can be derived from (11.256) by sprinkling in factors of $1/\epsilon^2$, where ϵ is the pixel width, and passing to the limit $\epsilon \rightarrow 0$ [*cf.* (11.106)]. In carrying out this procedure, note that $\langle k_j(k_j - 1) \rangle$ corresponds to $s(\mathbf{R})$, which appears in (11.226) in the guise of \mathcal{H}_2 [see (11.219) and (11.221)].

The covariance matrix in the CD case can also be derived by letting $J \rightarrow \infty$ in (11.256) but keeping the output pixel size constant. In this case the Kronecker delta function remains instead of limiting to a Dirac delta as in (11.105). This procedure will reproduce (11.238).

11.5 QUANTUM MECHANICS OF PHOTON COUNTING

In this section we examine the role of quantum electrodynamics (QED) in the analysis of photon-counting experiments. Much of the groundwork for this discussion was laid in Chap. 10, where we introduced the concepts of modes of the radiation field, number operators and photons, along with the elements of photodetection theory. The reader is presumed to be familiar with these ideas and with the basic principles of quantum mechanics, including the concept of a state vector and its relation to a wavefunction. Dirac notation is used freely, and quantum-mechanical operators are denoted with a caret.

11.5.1 Coherent states

Since this chapter is mainly about Poisson statistics, we begin our discussion of QED and photon counting by considering a set of quantum states where the Poisson distribution is of central importance. These states, introduced briefly in Sec. 10.1.3, are called variously *coherent states*, *canonical coherent states*, *Glauber states* or *minimum uncertainty states*. They are states of a harmonic oscillator, but we saw in Chap. 10 that a single mode of the radiation field is in fact described by a harmonic oscillator.

The fundamental reference on coherent states is Glauber (1963), and excellent discussions are found in Meystre and Sargent (1990), Mandel and Wolf (1995) and Cohen-Tannoudji *et al.* (1989). Here we summarize, without derivation, the main properties needed to better understand the role of Poisson statistics in imaging. Along the way, we shall note some interesting connections with local Fourier transforms, wavelets and other mathematical concepts introduced earlier in this book.

Eigenstates of the annihilation operator We saw in Sec. 10.1.3 that the electric field operator for the j^{th} mode of the radiation field is [cf. (10.22)]

$$\hat{\mathbf{e}}_j(\mathbf{r}, t) = i\gamma_j N_j \left[\exp(i\mathbf{k}_j \cdot \mathbf{r}) \hat{a}_j - \exp(-i\mathbf{k}_j \cdot \mathbf{r}) \hat{a}_j^\dagger \right], \quad (11.257)$$

where γ_j is a unit vector in the direction of the field, N_j is a constant defined in (10.13), and \hat{a}_j^\dagger and \hat{a}_j are, respectively, the creation and annihilation operators. As shown in (10.27), the creation operator increases the number of photons in the field by one and the annihilation operator decreases the number by one.

In Sec. 10.1.3 we discussed mainly the number states, eigenstates of the Hamiltonian. Another very useful set of states consists of the eigenstates of the annihilation operator. The annihilation operator is especially important since (as stated more precisely in Sec. 10.1.4) photodetection takes place by annihilating photons.

We now drop the index j designating a particular mode of the field. Then the annihilation operator is denoted by \hat{a} , and its eigenstate $|\alpha\rangle$ is defined by

$$\hat{a}|\alpha\rangle = \alpha|\alpha\rangle. \quad (11.258)$$

Since \hat{a} is not Hermitian, its eigenvalue α need not be real, and in fact it can take on any value in the complex plane.

The state $|\alpha\rangle$ can be expressed in terms of number states as

$$|\alpha\rangle = \sum_{n=0}^{\infty} |n\rangle \langle n|\alpha\rangle, \quad (11.259)$$

where (Glauber, 1963)

$$\langle n|\alpha\rangle = \exp(-\frac{1}{2}|\alpha|^2) \frac{\alpha^n}{\sqrt{n!}}. \quad (11.260)$$

As noted in Sec. 10.1.3, the probability that the state $|\alpha\rangle$ contains n photons is given by

$$|c_n|^2 = |\langle n|\alpha\rangle|^2 = \exp(-|\alpha|^2) \frac{|\alpha|^{2n}}{n!}, \quad (11.261)$$

which is a Poisson distribution with mean $|\alpha|^2$.

Orthogonality and completeness The states $|\alpha\rangle$ are not orthogonal; instead they satisfy (Glauber, 1963)

$$\langle\alpha|\alpha'\rangle = \exp(-|\alpha - \alpha'|^2). \quad (11.262)$$

In spite of the lack of orthogonality, the coherent states form a complete set in terms of which any state of the mode can be expanded. The set is overcomplete in the sense that some subset of it would also span the state space; the state space is an \mathbb{L}_2 space and can therefore be spanned by a denumerable basis (see Sec. 1.1.5).

The closure relation (resolution of the unit operator) is

$$\hat{I} = \frac{1}{\pi} \int_{\infty} d^2\alpha |\alpha\rangle\langle\alpha|, \quad (11.263)$$

where $d^2\alpha$ is an area element in the complex α plane. The factor of $1/\pi$ is a measure of overcompleteness of the states; for a complete, orthonormal set, the sum of outer products is \hat{I} rather than $\pi\hat{I}$. Equation (11.263) is reminiscent of closure relations for other overcomplete sets or extended representations introduced in Chap. 5; see, in particular, (5.39) and (5.85). We shall explore this connection further below.

One use of the closure relation is to express a number state as

$$|n\rangle = \frac{1}{\pi} \int_{\infty} d^2\alpha |\alpha\rangle\langle\alpha|n\rangle, \quad (11.264)$$

where $\langle\alpha|n\rangle$ is the complex conjugate of (11.260).

Displacement operator As discussed by Glauber (1963), the coherent state $|\alpha\rangle$ can be generated by the *Weyl displacement operator* $\hat{D}(\alpha)$ acting on the harmonic-oscillator ground state (or vacuum state):

$$|\alpha\rangle = \hat{D}(\alpha)|0\rangle. \quad (11.265)$$

Explicitly, $\hat{D}(\alpha)$ is given by

$$\hat{D}(\alpha) = \exp(\alpha\hat{a}^\dagger - \alpha^*\hat{a}) = \exp(-\frac{1}{2}|\alpha|^2) \exp(\alpha\hat{a}^\dagger). \quad (11.266)$$

The exponential operator is defined in the same way as a matrix exponential and obeys the same manipulation rules (see Sec. A.7.1). Note that $\hat{D}(\alpha)$ reduces to the unit operator when $\alpha \rightarrow 0$. Thus the vacuum state corresponds to both $n = 0$ and $\alpha = 0$, and the ambiguity of the notation $|0\rangle$ causes no problem.

We can also express $\hat{D}(\alpha)$ in terms of position and momentum operators. Following (10.16), we define these operators by

$$\hat{Q} = \sqrt{\frac{\hbar}{2\omega}} (\hat{a}^\dagger + \hat{a}), \quad \hat{P} = i\sqrt{\frac{\hbar\omega}{2}} (\hat{a}^\dagger - \hat{a}), \quad (11.267)$$

and we also define real scalars q and p by

$$q = \sqrt{\frac{\hbar}{2\omega}} (\alpha^* + \alpha), \quad p = i\sqrt{\frac{\hbar\omega}{2}} (\alpha^* - \alpha), \quad (11.268)$$

respectively. With these definitions,

$$\hat{D}(\alpha) = \exp\left[\frac{i}{\hbar}(p\hat{Q} - q\hat{P})\right] \equiv \hat{D}(q, p). \quad (11.269)$$

To discover the reason for the term *displacement operator*, we use the coordinate representation where

$$\hat{Q}|q'\rangle = q'|q'\rangle. \quad (11.270)$$

In this representation, the matrix elements of \hat{Q} are given by (Messiah, 1961)

$$\langle q'|\hat{Q}|q''\rangle = q'\delta(q' - q''), \quad (11.271)$$

and those of \hat{P} are given by

$$\langle q'|\hat{P}|q''\rangle = -i\hbar\frac{\partial}{\partial q'}\delta(q' - q''). \quad (11.272)$$

With (11.270), it follows that

$$\langle q'|\hat{D}(q, p)|q''\rangle = \exp\left(\frac{i}{\hbar}pq' - q\frac{\partial}{\partial q'}\right)\delta(q' - q''). \quad (11.273)$$

In the coordinate representation, the stationary-state wavefunctions $\psi_n(q') = \langle q'|n\rangle$ are Hermite-Gauss functions, and in particular the vacuum state is represented by (Messiah, 1961)

$$\langle q'|0\rangle = \left(\frac{\omega}{\pi\hbar}\right)^{\frac{1}{4}} \exp\left(-\frac{\omega}{2\hbar}q'^2\right). \quad (11.274)$$

Thus

$$\langle q'|\alpha\rangle = \int dq'' \langle q'|\hat{D}(p, q)|q''\rangle \langle q''|0\rangle = \left(\frac{\omega}{\pi\hbar}\right)^{\frac{1}{4}} \exp\left(\frac{i}{\hbar}pq' - q\frac{\partial}{\partial q'}\right) \exp\left(-\frac{\omega}{2\hbar}q'^2\right). \quad (11.275)$$

We recognize $\exp(-q\frac{\partial}{\partial q'})$ as the displacement operator defined in Sec. A.10.1 of App. A. From (A.177) and (11.275), it follows that

$$\langle q'|\alpha\rangle = \int dq'' \langle q'|\hat{D}(p, q)|q''\rangle \langle q''|0\rangle = \left(\frac{\omega}{\pi\hbar}\right)^{\frac{1}{4}} \exp\left(\frac{i}{\hbar}pq'\right) \exp\left[-\frac{\omega}{2\hbar}(q' - q)^2\right]. \quad (11.276)$$

Thus the effect of $\hat{D}(q, p)$ on the vacuum wavefunction $\langle q'|0\rangle$ is to displace it from the origin by an amount q and to multiply it by the linear phase factor $\exp(ipq'/\hbar)$.

Uncertainty We showed in Sec. 5.1.2 that the uncertainty product $\sigma_q\sigma_p$ is minimized when the wavefunction is a Gaussian. Thus the uncertainty is minimal for a harmonic oscillator when it is in its ground state. The same uncertainty product is, however, obtained for all coherent states. The phase factor in (11.276) vanishes

when we compute the probability density $|\langle q'|\alpha\rangle|^2$, and a shift of a probability density function does not affect its variance. In fact, the phase factor is merely a shift in the momentum wavefunction, which is the Fourier transform of $\langle q'|\alpha\rangle$, and the squared modulus of the momentum wavefunction is the probability density function on the momentum. Hence both σ_q and σ_p are independent of α by the observation that variance is independent of shift.

Thus the coherent states comprise a family of states, all of which have the smallest possible uncertainty. Recall also that the coherent states are quantum states of a single mode of the radiation field and that the mode is a plane wave. A perfectly monochromatic classical plane wave would have constant amplitude, but in quantum mechanics the real and imaginary parts of the amplitude are operators subject to the uncertainty relation. The coherent state is the best quantum-mechanical counterpart of a classical monochromatic plane wave in the sense of minimizing that uncertainty.

Local Fourier transforms In Sec. 5.1 we defined a local Fourier transform by windowing a function with, say, a Gaussian, multiplying it by a linear phase factor (or Fourier kernel), and then integrating. The local Fourier transform (5.1) is then a function of the shift of the window function and the spatial frequency, which is essentially the slope of the linear phase. Equivalently, the local Fourier transform is a scalar product with a kernel of the form $b(x - x_0) \exp(2\pi i \xi x)$. Exactly the same operations—shifting and multiplying by a linear phase factor—occur in (11.276), so we can think of the coherent-state wavefunction as a kernel in a local Fourier transform.

This analogy sheds some light on the orthogonality and completeness properties of the coherent states. We saw in Sec. 5.1 that the local Fourier transform was always invertible without any requirement that the kernels be orthogonal. As seen in (5.40), inversion of the local Fourier transform requires integration over both the shift variable and the spatial frequency. The closure relation (5.39) is, in fact, identical to (11.263) since the integral over the complex α plane can be expressed in terms of integrals over p and q . The reader should fill in the details of this assertion as an exercise.

Coherent states and group theory In Chap. 5 we saw the similarities between the local Fourier transform and the wavelet transform, and in Chap. 6 we investigated the relation between wavelets and group theory. There is also an intimate connection between coherent states and group theory (Klauder, 1985; Daubechies, 1992).

As we saw in Sec. 6.8.5, wavelets are derived from the affine group, a Lie group that involves shifting and scaling a function. Coherent states and the local Fourier transform are related to the *Weyl-Heisenberg group*, a group of functional transformations of the form, $f(x) \rightarrow \exp(2\pi i \xi x) f(x - x_0)$. This group is sometimes referred to as the *translate-modulate* group while the affine group is the *translate-scale* group.

There are many similarities between the Weyl-Heisenberg and affine groups. Both are multiparameter Lie groups, both are non-Abelian and both have only infinite-dimensional irreducible representations (see Sec. 6.8.5). A minor difference is that the affine group has two parameters, the shift and the scale, but the Weyl-Heisenberg group actually has three; we must include multiplication by a constant phase factor $e^{i\phi}$ in order for the functional transformations to form a group. An

element of the group is then specified by x_0 , ξ and ϕ (or q , p and ϕ in quantum language).

Klauder (1985) has shown how *any* Lie group can be used to define generalized coherent states. Consider a Lie group \mathbf{G} represented by a set of unitary operators $\{\hat{T}_\theta\}$ on some Hilbert space. (In Chap. 6 such an operator would have been denoted by \mathcal{T}_θ , but here we use the caret to suggest a quantum-mechanical operator.) A set of vectors in the Hilbert space can be defined by

$$|\theta\rangle = \hat{T}_\theta|0\rangle, \quad (11.277)$$

where $|0\rangle$ is an arbitrary reference state, called the *fiducial state*. Klauder calls $|\theta\rangle$ a generalized coherent state if it satisfies two conditions:

Continuity: The vector $|\theta\rangle$ is a strongly continuous function of the label θ .

Completeness: There exists a positive measure $\delta\theta$ on the Hilbert space such that the unit operator can be expressed as

$$\hat{I} = \int \delta\theta |\theta\rangle\langle\theta|. \quad (11.278)$$

These conditions are satisfied by Glauber's coherent states (which Klauder refers to as the *canonical coherent states*); in that case, the fiducial state is the vacuum state of a harmonic oscillator, and the resolution of unity is given in (11.263).

Note that the continuity condition rules out discrete orthogonal vectors or δ -normalized continuum orthogonal vectors such as delta functions and plane waves. Moreover, the vectors $|\theta\rangle$ are not orthogonal in general, so $|\theta\rangle$ cannot be an eigenstate of a Hermitian operator.

11.5.2 Density operators

According to the basic axioms of quantum mechanics, any physical observable Ω is represented by a Hermitian operator $\hat{\Omega}$, and the expectation value of the observable in any pure quantum state $|\psi\rangle$ is

$$\langle\hat{\Omega}\rangle = \langle\psi|\hat{\Omega}|\psi\rangle. \quad (11.279)$$

This expectation can be computed in any convenient basis. For example, in the basis formed by the number states,

$$\langle\hat{\Omega}\rangle = \sum_{n,m} \langle\psi|n\rangle \langle n|\hat{\Omega}|m\rangle \langle m|\psi\rangle, \quad (11.280)$$

and in the coordinate basis,

$$\langle\hat{\Omega}\rangle = \int_{-\infty}^{\infty} dq' \int_{-\infty}^{\infty} dq'' \langle\psi|q'\rangle \langle q'|\hat{\Omega}|q''\rangle \langle q''|\psi\rangle. \quad (11.281)$$

It is useful to define an operator, called the *density operator*, by

$$\hat{\rho} = |\psi\rangle\langle\psi|. \quad (11.282)$$

The matrix elements of this operator in the number-state representation are given by

$$\rho_{mn} = \langle m|\psi\rangle\langle\psi|n\rangle, \quad (11.283)$$

and the matrix with these elements is called the *density matrix*.

In terms of the density operator, (11.280) becomes

$$\langle\hat{\Omega}\rangle = \sum_m \left[\sum_n \rho_{mn} \langle n|\hat{\Omega}|m\rangle \right] = \text{tr} \left\{ \hat{\rho} \hat{\Omega} \right\}, \quad (11.284)$$

where $\text{tr}\{\cdot\}$ denotes the trace or sum of diagonal elements.

Since the trace is invariant to unitary transformations, the final form of (11.284) applies also in the coordinate representation where

$$\langle q'|\hat{\rho}|q''\rangle = \langle q'|\psi\rangle\langle\psi|q''\rangle = \psi(q')\psi^*(q''), \quad (11.285)$$

and $\psi(q')$ is the usual Schrödinger wavefunction. In this representation, the counterpart of (11.284) is

$$\langle\hat{\Omega}\rangle = \int_{-\infty}^{\infty} dq' \int_{-\infty}^{\infty} dq'' \langle q'|\hat{\rho}|q''\rangle \langle q''|\hat{\Omega}|q'\rangle = \int_{-\infty}^{\infty} dq' \langle q'|\hat{\rho}\hat{\Omega}|q'\rangle, \quad (11.286)$$

where the last step follows from the closure relation,

$$\int_{-\infty}^{\infty} dq'' |q''\rangle\langle q''| = \hat{I}. \quad (11.287)$$

The single integral in the last form of (11.286) can be interpreted as a trace, but with the discrete indices replaced with continuous variables and the sum replaced by an integral.

Mixed or doubly stochastic states As we have just seen, the density operator, in any representation, is sufficient for computing the expectation value of any physical observable; knowledge of $\hat{\rho}$ is equivalent to knowledge of the wavefunction or state vector. Often, however, we do not know that the system is in a particular state. Perhaps we can say only that it is in state $|\psi_k\rangle$ with probability $\text{Pr}(k)$. In the quantum-mechanics literature, such a system is often said to be in a *mixed state*, though this may be misleading since we are really just saying that we do not know what state it is in. In a frequentist interpretation of probability, the system is in state $|\psi_k\rangle$ with relative frequency $\text{Pr}(k)$ (over repeated experiments), and in an ensemble interpretation a fraction $\text{Pr}(k)$ of the systems are described by state vector $|\psi_k\rangle$. In either case, $\text{Pr}(k)$ is a classical probability satisfying the Kolmogorov axioms (see Sec. C.1.4), not a quantum-mechanical probability amplitude.

In a mixed state, the expectation must be computed by a double averaging process: first the quantum-mechanical expectation for a particular state, then a classical averaging over states. The resulting expression is

$$\langle\hat{\Omega}\rangle = \sum_k \text{Pr}(k) \langle\psi_k|\hat{\Omega}|\psi_k\rangle. \quad (11.288)$$

In Sec. 11.1.4, we defined a doubly stochastic random variable as one for which a parameter of the probability law is itself random. That definition applies here if

we think of the index k as the random parameter. Thus the averaging process in (11.288) is the same sort of doubly stochastic averaging we have used often in this chapter.

We can still use the concept of a density operator if we now define it as

$$\hat{\rho} = \sum_k \text{Pr}(k) |\psi_k\rangle \langle \psi_k|. \quad (11.289)$$

The density matrix in the number-state representation (or any other denumerable basis) is given by

$$\rho_{nm} = \langle n | \rho | m \rangle = \sum_k \text{Pr}(k) \langle n | \psi_k \rangle \langle \psi_k | m \rangle, \quad (11.290)$$

and we can still write the overall, doubly averaged, expectation of $\hat{\Omega}$ as

$$\langle \hat{\Omega} \rangle = \text{tr} \{ \hat{\rho} \hat{\Omega} \}. \quad (11.291)$$

Density operator in the coherent-state representation The density operator can be expressed in terms of coherent states as (Glauber, 1963)

$$\hat{\rho} = \int d^2\alpha P(\alpha) |\alpha\rangle \langle \alpha|. \quad (11.292)$$

The function $P(\alpha)$ appears to play the same role as $\text{Pr}(k)$ in (11.290), but it cannot be interpreted as a classical probability or probability density function. In (11.290), the states $|\psi_k\rangle$ are distinct (orthogonal), and the system is in state k with probability $\text{Pr}(k)$. If the system is in a particular $|\psi_k\rangle$, say $k = k_0$, with probability one, then by the Kolmogorov axioms (see Sec. C.1.4), its probability of being in some other state must be zero. Because of the lack of orthogonality, however, the states $|\alpha\rangle$ are not distinct. If the system is described exactly by $|\psi\rangle = |\alpha_0\rangle$, then its probability $|\langle \alpha_1 | \psi \rangle|^2$ of being in some other coherent state $|\alpha_1\rangle$ is not zero. This problem causes $P(\alpha)$ to have some properties that are not allowed in classical probability theory. As we shall see in some examples below, $P(\alpha)$ can go negative, and it can be more singular than a delta function; that is, it does not integrate to a finite value and hence it cannot be normalized as a probability density function.

Nevertheless, $P(\alpha)$ is quite useful for computing expectation values of functions of the operators \hat{a} and \hat{a}^\dagger . Suppose we have a classical complex random variable $z = x + iy$, and we want to compute the expectation of some function $f(x, y)$. Since x and y can be expressed in terms of z and z^* , we can define $f(x, y) = f'(z^*, z)$ and write the expectation as

$$\langle f'(z^*, z) \rangle = \int_{\infty} d^2z \text{pr}(z) f'(z^*, z), \quad (11.293)$$

where the notation $\text{pr}(z)$ is used as a shorthand for the joint density of z and z^* . One might think that a similar formula would hold for an operator function $f(\hat{a}^\dagger, \hat{a})$, but \hat{a}^\dagger and \hat{a} do not commute, so any expectation must depend on the order in which the operators are written.

One important way of ordering operators is *normal ordering*, where all creation operators appear to the left of all annihilation operators; an example is $[a^\dagger]^3 a^2$.

Another possibility is *antinormal ordering* where the annihilation operators appear to the left, as in $a^2[a^\dagger]^3$. There are also several ways of defining a *symmetrical ordering* (Tatarskii, 1983). Since the commutation relations are known, it is straightforward to convert from one ordering to another. Normal ordering is important in optics since, as we saw in Sec. 10.1.4, the photodetection rate is proportional to an expectation value of a normally ordered operator.

The function $P(\alpha)$ plays the role of a probability for normally ordered operators. The quantum-mechanical counterpart of (11.293) is

$$\langle \{f(\hat{a}^\dagger, \hat{a})\}_{nor} \rangle = \int_{\infty} d^2\alpha P(\alpha) f(\alpha^*, \alpha), \quad (11.294)$$

where $\{\cdot\}_{nor}$ indicates a normal ordering. Since it appears where a true probability density function would appear in this formula, $P(\alpha)$ is called a *quasiprobability*.

Other quasiprobabilities Equations analogous to (11.294) can be given for other ordering schemes. The quasiprobability for antinormal ordering is usually denoted $Q(\alpha)$. If $P(\alpha)$ is known, $Q(\alpha)$ can be found by convolving it with a Gaussian of the form $\exp(-|\alpha|^2)$ (Cohen-Tannoudji *et al.*, 1989). As a result of the smoothing action of this convolution, $Q(\alpha)$ is much better behaved than $P(\alpha)$; it is never negative and it can always be normalized as a probability density function.

For a certain kind of symmetric ordering (called *Weyl ordering*), the appropriate quasiprobability is the Wigner distribution function or WDF (Tatarskii, 1983). The WDF is also a smoothed version of $P(\alpha)$, but the convolution is with $\exp(-\frac{1}{2}|\alpha|^2)$ rather than $\exp(-|\alpha|^2)$. The WDF is intermediate between P and Q in terms of its mathematical behavior; it can go negative but nevertheless it obeys the normalization rules of a true joint probability density function.

From $P(\alpha)$ to the density matrix In terms of $P(\alpha)$, the number-state matrix elements of the density operator are given by

$$\rho_{nm} = \langle n|\hat{\rho}|m \rangle = \int_{\infty} d^2\alpha P(\alpha) \langle n|\alpha \rangle \langle \alpha|m \rangle, \quad (11.295)$$

where $\langle n|\alpha \rangle$ is given by (11.260). The diagonal element ρ_{nn} is the probability of having n photons in the mode; it is given by

$$\rho_{nn} = \langle n|\hat{\rho}|n \rangle = \frac{1}{n!} \int_{\infty} d^2\alpha |\alpha|^{2n} \exp(-|\alpha|^2) P(\alpha). \quad (11.296)$$

This integral is formally identical to the Poisson transform defined in (11.25), and it might appear that we have just rederived the classical result. Since $P(\alpha)$ does not behave like a true probability density function, however, some strange and distinctly nonclassical behavior can occur. To illustrate, let us look at a few forms for $P(\alpha)$ and the resulting ρ_{nn} .

Example 1: Coherent state Consider first the coherent state $|\alpha_0\rangle$. For this state, $P(\alpha) = \delta(\alpha - \alpha_0)$, and ρ_{nn} is given from (11.296) as

$$\rho_{nn} = \frac{1}{n!} \int_{\infty} d^2\alpha |\alpha|^{2n} \exp(-|\alpha|^2) \delta(\alpha - \alpha_0) = \frac{|\alpha_0|^{2n}}{n!} \exp(-|\alpha_0|^2), \quad (11.297)$$

which is a Poisson probability of mean $|\alpha_0|^2$. One consequence is that the variance of the number of photons is equal to its mean.

Recall that in Sec. 11.1 we considered a source where the rate of photon emission was constant and the photons were independent, and we showed that the probability law on the number of photons was Poisson. Here we see that a coherent state satisfies the assumptions of that calculation. A classical steady wave gives rise to a Poisson distribution of counts, and the coherent state is the best quantum-mechanical approximation to a classical steady wave.

Example 2: Thermal equilibrium If the system is in thermal equilibrium, $P(\alpha)$ is a Gaussian centered at the origin (Glauber, 1963):

$$P(\alpha) = \frac{1}{\pi \langle n \rangle} \exp \left[-\frac{|\alpha|^2}{\langle n \rangle} \right]. \quad (11.298)$$

This $P(\alpha)$ can be interpreted as a classical probability density function. In fact, it is just the circular Gaussian density discussed in Sec. 8.3.6. The real and imaginary parts of α are independent and identically distributed.

The diagonal elements of the density matrix are now given by

$$\rho_{nn} = \frac{1}{\pi \langle n \rangle n!} \int_{\infty} d^2\alpha |\alpha|^{2n} \exp(-|\alpha|^2) \exp \left[-\frac{|\alpha|^2}{\langle n \rangle} \right]. \quad (11.299)$$

The integral is easily performed in polar coordinates. If we set $\alpha = Re^{i\theta}$, then $d^2\alpha = R dR d\theta$, and the θ integral yields a factor of 2π . A further change of variables, $u = R^2 = |\alpha|^2$, converts the integral to

$$\rho_{nn} = \frac{1}{\langle n \rangle} \int_0^{\infty} du \frac{u^n}{n!} e^{-u} \exp \left[-\frac{u}{\langle n \rangle} \right]. \quad (11.300)$$

Recalling (11.25), we recognize this form as the Poisson transform of an exponential probability law. From the definition of the gamma or factorial function and some algebra, we find (Saleh, 1978)

$$\rho_{nn} = \frac{\langle n \rangle^n}{[\langle n \rangle + 1]^{n+1}}, \quad (11.301)$$

which can also be written as

$$\rho_{nn} = \frac{1}{\langle n \rangle + 1} \exp \left[-n \ln \left(\frac{\langle n \rangle + 1}{\langle n \rangle} \right) \right]. \quad (11.302)$$

This is the *Bose-Einstein* distribution of photons in a single mode.

This Bose-Einstein distribution should not be confused with another function often given the same designation. The latter function specifies the variation of $\langle n \rangle$ with the frequency ω of the mode and the absolute temperature T :

$$\langle n \rangle = \frac{1}{\exp \left(\frac{\hbar\omega}{k_B T} \right) - 1}, \quad (11.303)$$

where k_B is Boltzmann's constant. The Bose-Einstein distribution in (11.301) gives the *probability* distribution of photons, but (11.303) gives their distribution over

frequency; it would better be called a spectrum, but the term distribution is almost universal for it. Both (11.301) and (11.303) are needed for a complete statistical description of the statistics of photons in multiple modes, but we concentrate here on a single mode, where the statistics in thermal equilibrium are fully determined by the single number $\langle n \rangle$.

The (single-mode) Bose-Einstein distribution ρ_{nn} is plotted in Fig. 11.5. As seen from (11.302), ρ_{nn} is a simple exponential sampled at integer values; the most probable value of n in thermal equilibrium is always zero.

Fig. 11.5 Plot of the Bose-Einstein probability distribution of photons in a single mode, as given by the expression for ρ_{nn} in (11.301).

The variance associated with this distribution is given by (C.187) as

$$\text{Var}(n) = \langle n \rangle + \langle n \rangle^2. \quad (11.304)$$

This value is necessarily greater than $\langle n \rangle$ (unless $\langle n \rangle = 0$), so there is an excess variance (see Sec. 11.1.4), beyond the variance associated with a Poisson distribution of the same mean.

Example 3: Number state Finally, consider a particular number state $|N\rangle$. The density operator for this state is $\hat{\rho} = |N\rangle\langle N|$, and the matrix elements of this operator in the number-state representation are given by

$$\rho_{mn} = \langle m|N\rangle\langle N|n\rangle = \delta_{Nm} \delta_{Nn}. \quad (11.305)$$

Hence the probability of finding n photons is

$$\rho_{nn} = \delta_{Nn}, \quad (11.306)$$

so the state contains exactly N photons.

Since n can take on only the single value N , the mean of n is N and the variance of n is zero in the number state $|N\rangle$. Since 0 is less than N , the variance of the number of photons in this state is less than the value predicted for a Poisson with the same mean, and the statistics of n are said to be *sub-Poisson*. The classical expression (11.32) says that sub-Poisson statistics cannot occur, so the number state is an example of nonclassical light.

The density operator for a number state can also be expressed in the coherent-state representation. The relevant $P(\alpha)$ is given by Glauber (1963) as

$$P(\alpha) = \frac{1}{\pi} (-1)^N e^{|\alpha|^2} \delta^{(N)}(|\alpha|^2), \quad (11.307)$$

where $\delta^{(N)}(\cdot)$ denotes the N^{th} derivative of a delta function as defined in Sec. 2.2.4. This $P(\alpha)$ is unbounded and takes on negative values, which is another indication that we are dealing with nonclassical light. It is a nontrivial exercise in delta functions to go from (11.307) to (11.306).

11.5.3 Counting statistics

So far we have discussed the statistics of photons in a single mode of the radiation field, but the number of photons is not directly observable. All we can ever do is use some photoelectric detector and study the statistics of the number of photoelectrons.

For a single mode, Scully and Lamb (1969) did a quantum mechanical calculation of the probability of counting k photoelectrons in a certain time τ . They considered first the probability of getting one photoelectron in τ when the mode contained exactly one photon, so the state was $|1\rangle$. Denoting this probability as p , they then showed that the probability of getting k photoelectrons in τ is given by

$$\text{Pr}(k) = \sum_{n=k}^{\infty} \binom{n}{k} p^k (1-p)^{n-k} \rho_{nn}. \quad (11.308)$$

This result is exactly like the classical expression (11.23), but now we know that ρ_{nn} is given by (11.296), so

$$\text{Pr}(k) = \sum_{n=k}^{\infty} \binom{n}{k} p^k (1-p)^{n-k} \int_{\infty} d^2\alpha P(\alpha) \exp(-|\alpha|^2) \frac{|\alpha|^{2n}}{n!}. \quad (11.309)$$

The same algebra as used in deriving the Poisson transform, (11.25), shows that

$$\text{Pr}(k) = \frac{1}{k!} \int_{\infty} d^2\alpha P(\alpha) \exp(-p|\alpha|^2) (p|\alpha|^2)^k. \quad (11.310)$$

This expression looks just like (11.296) except that the number of photons n is replaced with the number of photoelectrons k and $|\alpha|^2$ is replaced with $p|\alpha|^2$. Thus the photoelectron statistics reflect the photon statistics as modified by the properties of the detector, including its quantum efficiency η and the exposure time τ . To understand better the nature of this modification, we shall revisit the examples used in Sec. 11.4.2.

Example 1: Coherent state For the coherent state $|\alpha_0\rangle$, $P(\alpha) = \delta(\alpha - \alpha_0)$, and (11.310) becomes

$$\begin{aligned} \text{Pr}(k) &= \frac{1}{k!} \int_{\infty} d^2\alpha \delta(\alpha - \alpha_0) \exp(-p|\alpha|^2) (p|\alpha|^2)^k \\ &= \exp(-p|\alpha_0|^2) \frac{(p|\alpha_0|^2)^k}{k!}. \end{aligned} \quad (11.311)$$

This is a Poisson probability law, so the photoelectrons always obey Poisson statistics if the incident light is in a coherent state.

The mean number of photoelectrons is $p|\alpha_0|^2$, and p was defined as the probability of one photoelectron in the observation time if there is exactly one photon in the mode. In the coherent state $|\alpha_0\rangle$, the mean number of photons in the mode is $|\alpha_0|^2$ [see (11.297)], so we see that the mean number of photoelectrons is just the mean number of photons times the probability of one photoelectron from one photon. In other words, we have recovered the binomial selection theorem (11.24), but now in a quantum-mechanical context. The coherent state is the correct quantum-mechanical description of a source that produces a Poisson-distributed photon stream on a detector.

Example 2: Thermal state For a single mode in thermal equilibrium, $P(\alpha)$ is given by (11.298), and the distribution of photoelectrons is given by

$$\Pr(k) = \frac{1}{\pi \langle n \rangle k!} \int_{\infty} d^2\alpha \exp\left[-\frac{|\alpha|^2}{\langle n \rangle}\right] \exp(-p|\alpha|^2) (p|\alpha|^2)^k. \quad (11.312)$$

This integral has the same form as (11.299), and similar manipulations show that [cf. (11.301)]

$$\Pr(k) = \frac{\langle k \rangle^k}{[\langle k \rangle + 1]^{k+1}}, \quad (11.313)$$

where $\langle k \rangle = p\langle n \rangle$. Thus the distribution of photoelectrons is also a Bose-Einstein, and it follows that

$$\text{Var}(k) = \langle k \rangle + \langle k \rangle^2. \quad (11.314)$$

These results might lead the unwary to think that it would be rather easy to observe a Bose-Einstein distribution of photocounts in the laboratory, but we must remember that we are considering only a single mode of the radiation field here. Since the modes are characterized by their frequency and the direction of their wavevector, (11.313) and (11.314) apply only to highly directional and essentially monochromatic thermal light. To get the directionality in the laboratory, we might place a small thermal source at the rear focal plane of a lens, and to get a nearly monochromatic source we might use a narrowband optical filter. The resulting light would become more directional as the source size got smaller and more nearly monochromatic as the bandwidth of the filter got smaller, but both of these measures result in loss of light (unless we somehow let the temperature of the thermal source get correspondingly larger). In practice, the thermal light we can produce in the laboratory is not well described by a single mode of the radiation field. To analyze the photoelectron distribution with practical thermal sources, we must consider multiple modes.

Actually, we have already analyzed the case of nonmonochromatic thermal light, though we did not use that language. In Sec. 11.3.7, we considered a doubly stochastic temporal random process where the rate is the random process $a(t)$. If modes of different frequencies and random phases are present, the rate of photoemission is a temporal random process, and the variance of the number of counts is given by (11.128) rather than (11.314). (Note that N in (11.128) is the same thing as k in this section.) We can regard (11.314) as the (hypothetical) photocount variance for a single-mode thermal source, while (11.128) describes the actual multimode variance for a practical source. Though derived classically in Sec. 11.3.7,

(11.128) would also result from a multimode generalization of the calculation by Scully and Lamb.

We can get a rough idea of the differences between (11.128) and (11.314) by considering thermal light that is somehow perfectly directional but which has a finite bandwidth $\Delta\nu$ imposed by a narrowband filter. The rate process $a(t)$ in Sec. 11.3.7 has correlation time τ_a of approximately $1/\Delta\nu$. Achievable filter bandwidths in the optical region are of order 10^{11} Hz, and a typical observation time T might be $1 \mu\text{sec}$, so the factor τ_a/T in (11.128) is of order 10^{-5} , and the factor $\text{Var}(a)/\bar{a}^2$ is unity for a thermal source since \bar{a} is exponentially distributed (Sec. C.5.3). Thus the excess variance is reduced by a factor of about 10^{-5} . Any deviation from perfect directionality would reduce the excess variance still further (Goodman, 1985). In other words, it is very difficult to discern any deviation between the photocount variance produced by a practical thermal source and that produced by a coherent state.

Example 3: Number state Now consider our prime example of nonclassical light, the single-mode number state. Substituting (11.306) into (11.308) yields

$$\text{Pr}(k) = \binom{N}{k} p^k (1-p)^{N-k}, \quad k \leq N. \quad (11.315)$$

This is the binomial law (C.161). From (C.163), the mean of k is pN and the variance is

$$\text{Var}(k) = pN - p^2N = \langle k \rangle - p\langle k \rangle. \quad (11.316)$$

The excess variance $-p\langle k \rangle$ is negative, again reflecting the nonclassical nature of the light, but we note that $\text{Var}(k) \rightarrow \langle k \rangle$ as $p \rightarrow 0$. As we saw several times in Sec. 11.1, rare events tend to a Poisson law. In the present context, rare means that the probability of getting one photocount when there is one photon in the mode is small.

12

Noise in Detectors

The physical principles underlying photodetection were introduced in Secs. 10.1.4 and 10.1.5, but there we discussed only the mean response. In Chap. 11 we developed the tools needed to discuss fluctuations about this mean, and in this chapter we use these tools to analyze the noise properties of a variety of practical photodetectors.

We begin the discussion in Sec. 12.1 with a specific class of detectors called photodiodes. These devices are important in their own right, but they also serve as a useful pedagogical device for discussing the discrete nature of photoelectric interactions and the consequent fundamental limits to optical detection. In Sec. 12.2 we discuss a variety of other noise sources that afflict practical optical detectors.

Finally, Sec. 12.3 addresses detectors for x rays and gamma rays, with particular attention to photon-counting detectors. The interesting new feature of these devices is that we can do more than detect the presence or absence of a photon interaction; we can also estimate the energy of the photon, the depth in the detector at which it interacts and other attributes.

12.1 PHOTON NOISE AND SHOT NOISE IN PHOTODIODES

The terms *Poisson noise*, *shot noise*, and *photon noise* occur frequently in the literature on radiation detectors, and they are often used interchangeably. The simplest description of shot noise is that it is the noise associated with the random arrival of discrete electrons, and photon noise is often similarly ascribed to the random arrival of discrete photons. As noted in Chaps. 10 and 11, however, we seldom have to consider the quantum properties of the electromagnetic field, so it is not really relevant whether light consists of photons. On the other hand, photoelectric interactions are discrete events, and the electrons produced in these events result in shot noise just as any other free electrons do. Thus so-called photon noise is just shot noise with photoelectrons.

The term Poisson noise is somewhat more problematic since certain conditions, discussed in detail in Chap. 11, must be satisfied for photoelectrons to obey Poisson statistics. In this section we shall generally assume that these conditions are satisfied, so shot noise (or photon noise) will be well described by Poisson random processes.

In Section 12.1.1 we discuss a simple device called a vacuum photodiode. Though rarely used in practice, the vacuum photodiode provides a convenient way of understanding the role of Poisson random processes in photodetection.

Section 12.1.2 is a digression from the main theme of Sec. 12.1. It is included to ensure that readers are familiar with some basic concepts and terminology of semiconductor physics. Many readers will be able to skip this section with impunity. In particular, Sec. 12.1.2 deals entirely with average quantities such as mean carrier concentrations and conductivities; fluctuations about these means and their effects on observable noise are taken up later, beginning in Sec. 12.1.3.

Section 12.1.3 discusses P-N junctions as detectors of electromagnetic radiation, especially in the visible and infrared portions of the spectrum. The treatment parallels the discussion of vacuum photodiodes in Sec. 12.1.1, with considerable emphasis on the role of Poisson statistics.

12.1.1 Vacuum photodiodes

A vacuum photodiode is illustrated in Fig. 12.1. To fix the geometry, assume that the light is propagating in the $+z$ direction, that the photocathode lies in the plane $z = 0$, and that the anode lies in $z = L_z$. Assume also that the lateral dimensions L_x and L_y are large compared to L_z .

Fig. 12.1 Basic geometry for a vacuum photodiode.

The light falls on the photocathode and liberates photoelectrons into the vacuum gap with a quantum efficiency η . The electrons are accelerated across the vacuum gap by an applied potential V_b , producing a current in the anode circuit. In addition, electrons may also be liberated from the photocathode by thermal excitation; to distinguish these two mechanisms, we refer to current arising from thermal excitation as *dark current* and that arising from the incident radiation as *photocurrent*. Once liberated, however, all electrons produce the same effect in the output current.

To understand the noise properties of the anode current, we must first determine the form of the current pulse $i_0(t)$ produced by a single electron emitted from the photocathode at time $t = 0$. We assume that the electron has very little kinetic energy when it leaves the photocathode, but the electric field $E_0 = -V_b/L_z$ in the vacuum gap accelerates it towards the anode. By Newton's second law, the

z -component of the electron velocity at time t is given by

$$v_z(t) = \frac{eV_b}{mL_z}t, \quad (12.1)$$

where $-e$ and m are, respectively, the charge and mass of the electron.

The work done by the field on the electron when it moves a distance dz is $dW = -eE_0dz$, and the power delivered to the electron is $P(t) = dW/dt = -eE_0v_z(t) = +eV_bv_z(t)/L_z$. By conservation of energy, this power must be delivered to the photodiode by the external circuit, so the power flow in the circuit is $-P(t)$. If the circuit maintains the potential across the diode at V_b (e.g., with an operational amplifier, as discussed below), then the current during the time the electron is moving across the gap is

$$i_0(t) = -\frac{P(t)}{V_b} = -\frac{e}{L_z}v_z(t) = -\frac{e^2V_b}{mL_z^2}t, \quad 0 \leq t < T_{tr}, \quad (12.2)$$

where T_{tr} is the transit time, given by

$$T_{tr} = L_z \sqrt{\frac{2m}{eV_b}}. \quad (12.3)$$

Note that it is not necessary for the electron actually to reach the anode to induce a current in the external circuit. We see from (12.2) that this current has the form of a triangular pulse, with the current beginning as soon as the electron is liberated from the cathode and then increasing in magnitude linearly with time as the electron accelerates.

Delta-function approximation With practical values for V_b and L_z , it often turns out that the induced current pulse is very narrow compared to the response time of the circuit. For example, if $V_b = 10$ Volts and $L_z = 1$ mm, then $T_{tr} \simeq 10^{-9}$ sec. If the circuit bandwidth is small compared to 1 GHz, we can approximate the triangular pulse by a delta function. As an exercise, the reader should show that the approximation takes the form

$$i_0(t) \simeq -e\delta(t). \quad (12.4)$$

That the coefficient is $-e$ should not be surprising; the time integral of the current is the charge on the electron. The units are also worthy of note: current is measured in amperes or Coulombs per second, which is dimensionally consistent with the right-hand side of (12.4) since e is measured in Coulombs and a temporal delta function has units of sec^{-1} (see Sec. 2.4.3).

RC filtering Suppose the photodiode output is filtered by a simple RC circuit as shown in Fig. 12.2a or the slightly more complicated circuit of Fig. 12.2b. In both cases, the input to the filter is the current from the photodiode, and the output of the filter is the voltage drop across the RC network. The circuit in Fig. 12.2b has the advantage that the voltage on the output plate of the photodiode is held very near zero potential. Because an operational amplifier has very high gain, the voltage across its input terminals remains very small; it is often said that the input port of an operational amplifier is a *virtual ground*. Thus the potential difference

between the two plates of the diode remains essentially at the fixed potential V_b regardless of how much current flows. In the circuit of Fig. 12.2a, on the other hand, the potential difference between the plates is $V_b - V_{out}(t)$, so there can be a change in the field inside the diode if V_{out} is significant compared to V_b . We shall neglect this so-called *debias* effect here, either by using Fig. 12.2b or by keeping $V_{out}(t) \ll V_b$.

Fig. 12.2 Two circuits for filtering the output of a vacuum photodiode. In (a), the output current flows through a simple parallel RC circuit, and the voltage across this circuit is the filter output. In (b), an operational amplifier with very high gain is used to maintain the anode of the photodiode at ground potential, and the output voltage of the amplifier is the filter output.

With this assumption, the current from the photodiode is equal to the current through the parallel RC combination, which is the sum of the current through the capacitor and the current through the resistor. From elementary circuit theory,

$$i(t) = C \frac{dV_{out}(t)}{dt} + \frac{V_{out}(t)}{R}. \quad (12.5)$$

If we let $i(t)$ be the impulsive current (12.4) produced by a single electron, then the corresponding $V_{out}(t)$ is the impulse response of the filter, denoted $h(t)$, which must then satisfy

$$C \frac{dh(t)}{dt} + \frac{h(t)}{R} = -e \delta(t). \quad (12.6)$$

The solution of this differential equation is

$$h(t) = -\frac{e}{C} \exp\left(-\frac{t}{RC}\right) \text{step}(t). \quad (12.7)$$

Verification of this solution requires some properties of delta functions, including (2.73) and (2.25).

Filtering a photoelectron stream So far we have computed the filter output for a single photoelectron. Now suppose the photocathode is illuminated with steady radiation satisfying the Poisson postulates. From the discussion in Sec. 11.1, we know that the photoelectrons are statistically independent in this case, and we assume that the dark-current electrons are also independent (of each other and of the photoelectrons). Then, with approximation (12.4), the total output current from the photodiode has the form [see also (11.62)]

$$i(t) = \sum_{n=1}^N i_0(t - t_n) = -ez(t), \quad (12.8)$$

where $z(t)$ is a stationary Poisson process of rate a . With this input, the filter output is a stationary random process given by

$$V_{out}(t) = h(t) * z(t). \quad (12.9)$$

Note that the input to the filter is $z(t)$, not $i(t)$; we have included the constant $-e$ in the definition of $h(t)$. Thus $h(t)$ has dimensions of voltage, and the dimensions of $z(t)$ (namely sec^{-1}) cancel those of the asterisk (the time integral in the convolution) in (12.9).

The statistical properties of filtered Poisson point processes were discussed in Sec. (11.3.9). From the temporal counterpart of (11.139), we know that the mean of $V_{out}(t)$ is

$$\langle V_{out}(t) \rangle = h(t) * \langle z(t) \rangle = h(t) * a = -\frac{ea}{C} \int_0^\infty dt' \exp(-t'/RC) = -eaR. \quad (12.10)$$

This result is really just a statement of Ohm's law since $-ea$ is the mean current. Note that the mean filter output is proportional to the rate of the input process; for this reason an RC filter is sometimes called a *ratemeter*.

The variance of the output is given by the temporal counterpart of (11.143),

$$\text{Var}\{V_{out}(t)\} = [h(t)]^2 * \langle z(t) \rangle = \frac{e^2 a}{C^2} \int_0^\infty dt' \exp(-2t'/RC) = \frac{e^2 a R}{2C}. \quad (12.11)$$

The ratio of the square of the mean voltage to its variance is

$$\frac{[\langle V_{out}(t) \rangle]^2}{\text{Var}\{V_{out}(t)\}} = 2aRC. \quad (12.12)$$

One way to interpret this ratio is to compare it to the corresponding expression for a perfect counter which observes a Poisson source for a time T . For this counter, we know from Chap. 11 that the number of counts N in time T is Poisson and the variance is equal to the mean; specifically, $\text{Var}(N) = \bar{N} = aT$. Thus the ratio of squared mean to variance is also aT for the counter. The expression in (12.12) shows that the filter output has the same ratio if $T = 2RC$; the effective averaging time of the filter is thus $2RC$.

Once one knows that the effective averaging time T_{eff} is $2RC$, the expressions above for the mean and variance of $V_{out}(t)$ can be deduced from Poisson statistics. Suppose N electrons occur in time T_{eff} . These electrons carry a charge $-Ne$, so the effective current is $-Ne/T_{eff}$ and the resulting voltage drop across the load resistor is $-RNe/T_{eff}$. Thus the factor $-Re/T_{eff}$ converts number of electrons to voltage. The mean voltage is obtained by replacing the random number N by its mean aT_{eff} , reproducing (12.10). The variance of the voltage is the variance in N times the *square* of the conversion factor $-Re/T_{eff}$. Since $\text{Var}(N) = aT_{eff}$, (12.11) follows readily.

Power spectral density and effective noise bandwidth Since we are assuming that the photoelectron stream is a stationary temporal random process, we can also discuss the noise properties in the frequency domain. If we subtract off the mean of all random processes, the input to our filter is the random process $\Delta z(t)$, and we have

seen in Sec. 11.3.11 that its power spectral density is the constant rate a , so the input is white noise. The power spectral density of the current is

$$S_{\Delta i}(\nu) = e^2 a = e|\langle i(t) \rangle|. \quad (12.13)$$

By the temporal counterpart of (11.170), the power spectral density on the output of the filter is

$$S_{\Delta V_{out}}(\nu) = a|H(\nu)|^2, \quad (12.14)$$

where $H(\nu)$ is the Fourier transform of the impulse response $h(t)$. Hence this power spectral density has the same functional form as the squared modulus of the filter transfer function. A straightforward transform of (12.7) shows that, for the problem at hand,

$$|H(\nu)|^2 = \frac{e^2 R^2}{1 + (2\pi\nu RC)^2}. \quad (12.15)$$

The variance of $V_{out}(t)$ is the autocovariance function at zero lag, or

$$\begin{aligned} \text{Var}\{V_{out}(t)\} &= R_{\Delta V_{out}}(0) = \int_{-\infty}^{\infty} d\nu S_{\Delta V_{out}}(\nu) \\ &= \int_{-\infty}^{\infty} d\nu \frac{e^2 R^2 a}{1 + (2\pi\nu RC)^2}, \end{aligned} \quad (12.16)$$

where we have used the Wiener-Khinchin theorem (8.133). The integral in (12.16) is elementary, and we find

$$\text{Var}\{V_{out}(t)\} = \frac{e^2 a R}{2C}, \quad (12.17)$$

in agreement with (12.11).

Another way of viewing this result is to define an *effective noise bandwidth* B by

$$B \equiv \frac{1}{|H(0)|^2} \int_0^{\infty} d\nu |H(\nu)|^2. \quad (12.18)$$

Note that the integral runs from 0 to ∞ in accord with the common practice in electrical engineering of defining bandwidth over positive frequencies only.

For our RC filter,

$$B = \int_0^{\infty} d\nu \frac{1}{1 + (2\pi\nu RC)^2} = \frac{1}{4RC}, \quad (12.19)$$

so (12.17) can be written as

$$\text{Var}\{V_{out}(t)\} = 2Be^2 a R^2 = 2BeR^2|\langle i(t) \rangle|, \quad (12.20)$$

which is a familiar formula in the literature on electronic shot noise. The appearance of $2B$ rather than just B often confuses students, but in fact $2B$ is the total bandwidth, including negative frequencies. Note that $2B$ is the reciprocal of the effective averaging time $2RC$.

SNR and DQE The rate a that appears in (12.10) and (12.11) is the total rate of emission of photoelectrons from the photocathode. If we consider the radiation to be made up of photons and assume that each incident photon produces a single photoelectron with probability η (the quantum efficiency), then a can be written as

$$a = \eta a_{phot} + a_{dark}, \quad (12.21)$$

where a_{phot} is the rate of arrival of photons and a_{dark} is the rate associated with dark current or thermionic emission. The first term, ηa_{phot} , can be considered a *signal* since it represents the mean response of the detector to the incident radiation. From (12.10), the mean signal in the output voltage is then $eR\eta a_{phot}$. We can thus define a *signal-to-noise ratio*¹ or *SNR* by

$$\text{SNR}_{out}^2 = \frac{(eR\eta a_{phot})^2}{\text{Var}\{V_{out}(t)\}} = 2RC \frac{(\eta a_{phot})^2}{\eta a_{phot} + a_{dark}}. \quad (12.22)$$

The ideal detector has $\eta = 1$ and $a_{dark} = 0$. We can express how closely the real detector approaches the ideal by defining a *detective quantum efficiency* or *DQE* as

$$\text{DQE} \equiv \left(\frac{\text{SNR}_{out}}{\text{SNR}_{in}} \right)^2, \quad (12.23)$$

where SNR_{in} is the signal-to-noise ratio of the input photon stream as seen by an ideal detector and the same RC filter. Thus $\text{SNR}_{in} = (2RCa_{phot})^{\frac{1}{2}}$, and

$$\text{DQE} = \frac{\eta^2 a_{phot}}{\eta a_{phot} + a_{dark}}. \quad (12.24)$$

One way to think about DQE is that it would require N/DQE photons in some time interval to achieve the same SNR_{out} with a real detector as would be obtained with N photons and an ideal detector. Since $\eta \leq 1$ and $a_{dark} \geq 0$, DQE is necessarily ≤ 1 ; real detectors always require more photons for the same SNR than an ideal detector.

Note that the detective quantum efficiency reduces to the quantum efficiency η if there is no thermionic emission or other noise sources. Moreover, DQE for this problem is a function of the photon arrival rate a_{phot} ; it is possible to make $\text{DQE} \simeq \eta$ just by using a bright light source so that $a_{phot} \gg a_{dark}$.

12.1.2 Basics of semiconductor detectors

Vacuum photodiodes are seldom used in practice today, having been replaced by semiconductor photodiodes. The fundamental mechanisms of photodetection with semiconductor devices are surveyed briefly in this section; the reader with a basic understanding of semiconductor physics can skip to Sec. 12.1.3 without loss of continuity.

¹The usage of the term SNR given here is common in electrical engineering, but a distinctly different meaning is emerging in image science. In objective assessment of image quality (one of the main themes of this book), SNR is a measure of performance of some specific task. The ratio of the mean of a random variable to its standard deviation, on the other hand, does not relate directly to tasks. Perhaps the best interpretation of this SNR is that its reciprocal is the average fluctuation in units of the mean.

For detection of visible light, the most common semiconductor material is crystalline silicon (Si). Pure silicon is a poor conductor (actually an insulator at 0 K) because all of its outer electrons are used up in covalent bonds. Each Si atom is bound covalently to four neighbors in the crystalline lattice, and each bond requires two electrons, one from each of the neighboring atoms. Except for a few electrons released from the bonds by thermal excitation, there are no free electrons to participate in conduction.

The same phenomenon can also be explained another way. In a crystalline solid, electrons are confined to specific *energy bands*, consisting of the quantum states allowed by quantum mechanics. According to the Pauli exclusion principle, each state can be occupied by only zero or one electron. In Si there are two energy bands of interest, the *valence band* and the *conduction band*, and there is a forbidden region or *band gap* between them. At low temperature, the valence band is fully occupied (exactly one electron per state) and the conduction band is empty. In this condition there is no electrical conduction in the valence band since there are no available states for electrons to be accelerated into, and there is no conduction in the conduction band because there are no electrons there.

Doping In order to provide charge carriers for conduction, trace amounts of impurity elements are added to the Si in a process called *doping*. There are two kinds of dopants, called *donors* and *acceptors*. For doping of Si, donors are elements such as arsenic (As) or antimony (Sb) from Group V of the periodic table, and acceptors are elements such as gallium (Ga) or indium (In) from Group III. Since Si is in Group IV, it requires four valence electrons to complete its chemical bonds. When an element from Group V is substituted for Si, there is one electron not needed for bonding and hence only loosely bound to the impurity atom. At room temperature there is a high probability that this extra electron will be thermally excited and free to move around in the Si lattice; the impurity has donated an electron to the conduction band. The doped Si is said to be *N-type* (*N* for negative) because of the excess free electrons.

When an element from Group III is substituted for Si, the three available valence electrons are not sufficient to complete all of the bonds. At room temperature, there is a high probability that one of the electrons in the valence band will be incorporated into a bond to the impurity, thereby creating a vacancy, called a *hole*, in the valence band. Under an applied electric field, a valence-band electron can be accelerated into the state vacated when the hole was formed, filling that state but creating a vacancy in another state. If the field is in the $+z$ direction, the actual valence band electron moves in the $-z$ direction but the hole appears to move in $+z$, thus behaving like a mobile positive charge carrier. The acceptor impurity, by accepting an electron, has in effect donated a hole to the valence band. The doped Si in this case is said to be *P-type* because of the excess free holes.

Optical absorption in semiconductors In addition to thermal excitation, holes and electrons can also be created in semiconductors by optical excitation. The physics of this process was discussed in Sec. 10.1.4 where we saw that a transition from an initial state of energy \mathcal{E}_i to a final state of energy \mathcal{E}_f can be induced by light of frequency ν if $h\nu = \mathcal{E}_f - \mathcal{E}_i$. If $h\nu$ is less than the bandgap energy \mathcal{E}_g , this condition cannot be satisfied for an initial state in the valence band and a final state in the conduction band, and no transitions between these two bands are induced.

Moreover, transitions between two states within the valence band generally do not occur since both states are filled, and transitions within the conduction band do not occur since both states are empty. For $h\nu < \mathcal{E}_g$, therefore, there is very little absorption of light.

For $h\nu$ substantially greater than \mathcal{E}_g , however, there are many possible combinations of filled valence-band initial states and empty conduction-band final states, and the light is strongly absorbed by producing these transitions. As a practical matter, the attenuation coefficient for light of energy $h\nu > \mathcal{E}_g$ is about 10^4 cm^{-1} or $1 \mu\text{m}^{-1}$. Thus a photon travels a path length of only about $1 \mu\text{m}$ before absorption. When an absorption event occurs, it creates one electron in the conduction band and one hole in the valence band; both contribute to the electrical conductivity.

Conductivity in semiconductors Consider a homogeneous semiconductor with an electron concentration² of n electrons/cm³ and a hole concentration of p holes/cm³. A uniform electric field E_0 in the $+z$ direction will exert a force in the same direction on the holes and in the opposite direction on the electrons. In addition, however, the carriers experience forces from lattice imperfections, from lattice vibrations or *phonons* and from interactions with other free carriers. All of these interactions retard the acceleration of the carriers by the field, and the carriers quickly reach a *terminal velocity*, much as a sky diver falling from an airplane reaches a terminal velocity at which the force of gravity is balanced by the forces from collisions with air molecules. To a good approximation, the terminal velocity is proportional to the field, and the constant of proportionality, called the *mobility*, is denoted by μ . Adding subscripts e for electrons and h for holes, we can write the terminal velocities as

$$\mathbf{v}_e = -\mu_e \mathbf{E}_0, \quad \mathbf{v}_h = \mu_h \mathbf{E}_0. \quad (12.25)$$

More discussion of mobility and its physical origins will be found in Sec. 12.2.1.

The mean current density (Amperes/cm²) is the carrier concentration (cm⁻³) times the charge per carrier (Coul) times the mean velocity (cm/sec); it is given, for electrons and holes, respectively, by

$$\mathbf{J}_e = -ne\mathbf{v}_e, \quad \mathbf{J}_h = pe\mathbf{v}_h. \quad (12.26)$$

Note that these two currents are in the same direction since both velocity and charge have opposite signs for electrons and holes.

The total mean current density \mathbf{J} , is thus given by

$$\mathbf{J} = \mathbf{J}_e + \mathbf{J}_h \equiv \sigma \mathbf{E}_0, \quad (12.27)$$

where σ , called the *conductivity*, is given by

$$\sigma = e(n\mu_e + p\mu_h). \quad (12.28)$$

Practical units of mobility are cm²/V-sec and those of conductivity are (Ohm-cm)⁻¹, where 1 Ohm = 1 Volt/Ampere.

²Consistent use of SI units would require concentrations to be measured in m⁻³, but the semiconductor literature normally uses hybrid units with lengths in cm.

Photoconductivity A simple way to make a photodetector is to shine light on a homogeneous semiconductor and observe the change in conductivity. Two experimental setups are shown in Fig. 12.3. In both geometries, the light is travelling in the $+z$ direction, and for simplicity we assume that the detector material is thin in this direction so that photoelectric interactions occur uniformly within the material. Suppose the incident photon irradiance³ is I_p photons/(cm² sec) and a fraction η of the photons are absorbed. (For an optically thin detector, $\eta = \alpha L_z$, where α is the absorption coefficient for the light.) If we assume that each absorption event results in the production of one electron-hole pair, then the light causes the mean carrier densities to increase at the rates

$$\left[\frac{\partial n}{\partial t} \right]_{light} = \left[\frac{\partial p}{\partial t} \right]_{light} = \frac{1}{L_z} \eta I_p. \quad (12.29)$$

The carrier concentrations can also change because of recombination and trapping. In a recombination event, a conduction-band electron fills a valence-band hole, with the energy being converted to photons or phonons. Trapping occurs when an electron or hole is attracted to an impurity or lattice defect and the binding energy is such that thermal fluctuations are unlikely to free it over the time scale of interest in some measurement. The traps correspond to localized energy states somewhere near the middle of the forbidden gap. (They are not themselves forbidden since an impurity breaks the translational symmetry, which is what gives rise to the band structure in the first place.)

Fig. 12.3 Two configurations for observing photoconductivity. In (a) the light impinges directly on a face of the photoconductive material, and the conductivity is measured by observing a current that flows perpendicular to the direction of the light flux. In (b), the light passes through a transparent electrode before striking the photoconductive material, and the current flow is parallel to the light flux.

Trapping and recombination are actually quite complicated, but a simple phenomenological model will serve our purposes here. We assume that the carrier

³Note that we use capital I for irradiance, and to avoid confusion we therefore use lower-case i for current. One might, of course, wonder why either I or i is used for current. It apparently goes back to Georg Simon Ohm, who often referred to the 'intensity of the current' through a load. Thus there was once the same degree of confusion about the word *intensity* in electrical engineering as there is today in optics!

concentrations n and p relax towards their thermal equilibrium values, n_0 and p_0 respectively, according to

$$\left[\frac{\partial n}{\partial t} \right]_{tr} = -\frac{n - n_0}{\tau_e}, \quad \left[\frac{\partial p}{\partial t} \right]_{tr} = -\frac{p - p_0}{\tau_h}, \quad (12.30)$$

where τ_e and τ_h are characteristic time constants for electrons and holes, respectively. These time constants are called *lifetimes* since an excess carrier lasts an average time τ before it recombines or is trapped. It is usually a good approximation to assume that τ_e and τ_h are independent of any applied electric field.

In the steady state, the electron concentration is given by

$$\left[\frac{\partial n}{\partial t} \right]_{light} + \left[\frac{\partial n}{\partial t} \right]_{tr} = 0, \quad (12.31)$$

or

$$n = n_0 + \frac{\tau_e}{L_z} \eta I_p, \quad (12.32)$$

and similarly for holes. The mean steady-state conductivity is then found from (12.28) to be

$$\sigma = \sigma_0 + \frac{\tau_e \mu_e + \tau_h \mu_h}{L_z} \eta e I_p, \quad (12.33)$$

where σ_0 is the dark conductivity. This formula shows that the change in conductivity is linearly related to the mean photon irradiance. Real photoconductors may exhibit nonlinearities since the lifetimes and mobilities may depend on the carrier concentrations (Bube, 1992).

P-N junctions A P-N junction is formed when P-type and N-type materials are brought together as shown in Fig. 12.4. Both pieces are initially electrically neutral; the N-type material has a density n of free electrons, but since these all came from donor atoms, there is an equal density $N_d = n$ of ionized (hence positively charged) donors. Similarly, the P-type material has an initial density p of free holes and an equal density $N_a = p$ of negatively charged ionized acceptors.

When the two materials are joined as shown in Fig. 12.4b, the free electrons from the N-type material diffuse into the P-type material, leaving behind the immobile positive donor ions. Once in the P-type material, the electrons encounter many holes and quickly recombine. Similarly, the free holes from the P-type material diffuse into the N-type material and recombine, leaving behind the immobile negative acceptor ions. In the steady state, there is a region devoid of free carriers but containing a layer of fixed negative charges on the P side and fixed positive charges on the N side (see Fig. 12.4b). The field due to this double layer retards further diffusion of the free carriers. The region without any free carriers is called the *depletion region*. The potential as a function of position across the depletion region is illustrated in Fig. 12.4c and the associated electric field is shown in Fig. 12.4d.

In the absence of any applied bias voltage, there is no net current flowing across a P-N junction, but there are four individual current components, as illustrated in Fig. 12.5. First, there are a few holes generated by thermal fluctuations in the N-type material, where they are referred to as *minority carriers*. If one of these holes diffuses into the depletion region, it feels an accelerating field that sweeps

it across the junction. (The field direction is such that it retards the diffusion of electrons from N to P, hence it must accelerate holes in that direction.) Similarly, electrons generated thermally on the P side can diffuse into the depletion region and be swept into the N-type material. We refer to these two current components as *hole generation current* and *electron generation current*, respectively. Note that they are in the same direction, so there is a nonzero net generation current.

Fig. 12.4 Diagrams to illustrate the formation of a P-N junction. (a) N-type and P-type semiconductor materials before they are joined. In the N-type material, circles with plus signs denote ionized donor atoms and minus signs denote the free electrons. In the P-type material, circles with minus signs denote ionized acceptor atoms and plus signs denote the free holes. Note that a few free holes are created on the N side and a few free electrons are created on the P side by thermal excitation across the band gap. (b) After the two materials are joined, free holes diffuse into the N side and free electrons diffuse into the P side, where they recombine. A depletion region is created by the ionized dopant atoms left behind, and equilibrium is reached when the electric field from these ions retards further diffusion. (c) Illustration of the potential energy of an electron as it tries to move through the depletion region. Note that the direction of the potential is such that it opposes passage of an electron from N side to P side. (d) Electric field corresponding to the potential of (c) in the absence of any applied voltage. Note that a positive field accelerates a hole to the right and an electron to the left.

The two other current components arise from carriers that happen to be energetic enough to diffuse across the potential barrier and still reach the other side. There are copious electrons on the N side, but if they diffuse into the depletion region, they are repelled by the negative charges associated with acceptor ions, and they are dragged back by the positive charges of the donor ions. The electrons have

a thermal distribution of velocities, however, and a tiny fraction of them will have sufficient velocity in the $+z$ direction to get over the potential barrier. When they do, they enter the undepleted portion of the P-type material and recombine. For this reason, the resulting current component is called the electron *recombination current*.

Fig. 12.5 Energy bands in a P-N junction at zero bias, showing the free electrons and free holes. On the N side, there are many free electrons but only a few energetic enough to surmount the potential barrier; those that do constitute the electron recombination current i_{er} , an electron flow from left to right on the figure. On the P side, there are a few thermally generated free electrons, but they are readily swept across the barrier from right to left, producing the electron generation current i_{eg} . Similar considerations apply to holes, though the diagram must be turned upside down in order to depict a hole potential. Thus the few free holes on the left are readily swept across the barrier to form the hole generation current i_{hg} .

In thermal equilibrium with no applied external bias, the electron recombination current must be exactly equal and opposite to the electron generation current. This cancellation is required by the thermodynamic *principle of detailed balance*, but it is also plausible on physical grounds. Recall that there are many electrons on the N side but very few of them are sufficiently energetic to surmount the potential barrier. On the other hand, there are very few electrons on the P side, but essentially all of those that reach the depletion region are swept across. The product of the number of carriers times the probability of crossing the barrier must be the same for the two current components to maintain thermodynamic equilibrium. Similar considerations show that there is a hole recombination current to exactly balance the hole generation current at zero bias.

Effect of bias Now suppose that a bias voltage V_b is applied to the P-N junction as shown in Fig. 12.6a, with the positive terminal attached to the P side. Now the potential barrier is reduced in height by an amount V_b , and a larger fraction of holes on the P side and electrons on the N side can surmount the barrier; thus both recombination currents are increased. The generation currents are essentially unchanged since they arise from minority carriers (holes on the N side or electrons on the P side) that diffuse into the depletion region and get swept across by the field; even the reduced field is adequate for this purpose. With the recombination currents increased and the generation currents unchanged by the applied voltage, there is now a net current in the conventional direction from positive terminal to negative. The current increases rapidly with bias voltage in this direction, which is called *forward bias*.

If the direction of the bias is reversed and the positive terminal is attached to the N side as shown in Fig. 12.6b, then the height of the potential barrier is increased. Fewer majority carriers (electrons on the N side, holes on the P side) are energetic enough to surmount the barrier in this case, and the recombination currents are reduced. In the limit of a large reverse bias, the only currents remaining are the small generation currents due to minority carriers.

Fig. 12.6 Effect of a bias voltage on the energy bands of Fig. 12.5. (a) Forward bias; (b) reverse bias. Note that the two generation currents are relatively unaffected by the bias, but the two recombination currents are increased by forward bias and reduced by reverse bias.

These considerations are summarized in the *current-voltage characteristic curve* illustrated in Fig. 12.7. The difference in behavior in the forward- and reverse-bias conditions makes the junction into a rectifying device called a *diode*. Mathematically, the current i through an ideal P-N junction when a voltage V_b is applied is given by

$$i = i_s \left[\exp \left(\frac{eV_b}{k_B T} \right) - 1 \right], \tag{12.34}$$

where k_B is Boltzmann’s constant, T is the absolute temperature and i_s is just the sum of the two generation currents. When V_b has a large negative value, $i = -i_s$, so i_s is called the *reverse-bias saturation current*.

Fig. 12.7 Current-voltage characteristic of a P-N junction without illumination.

Effect of light If we want to use a P-N junction as a photodetector, we have to get light into the depletion region. Light absorbed in an undepleted region changes the conductivity of that region but does not greatly affect the total current since most of the voltage drop is across the depletion region. Since light with $h\nu > \mathcal{E}_g$ penetrates only about $1 \mu\text{m}$ or so, we must minimize the amount of material between the external surface of the semiconductor and the depletion region. A suitable geometry is shown in Fig. 12.8. The light traverses a transparent conducting layer and penetrates into the semiconductor. The junction is designed so that there is very little undepleted material ($< 1 \mu\text{m}$) before the light enters the depletion region. The thickness of the depletion region is substantially greater than $1 \mu\text{m}$, so essentially all of the light is absorbed in the depletion region.

Fig. 12.8 Geometry of a photodiode.

When a photon is absorbed in the depletion region, producing a hole-electron pair, both carriers are accelerated by the field, holes towards the P side and electrons towards the N side. One might think that each absorbed photon would contribute a total charge of $2e$ to the external circuit, so the mean current would be $-2e\eta I_p A$ (where A is the entrance area of the detector, I_p is the photon irradiance and η is the fraction of light absorbed in the depletion region), but the factor of 2 in this expression is incorrect. We shall see why in Sec. 12.1.3 when we analyze the P-N junction photodetector in more detail. For now, suffice it to say that the mean current due to the light is $-e\eta I_p A$.

Because we now have another current source—photogeneration of electron-hole pairs in the depletion region—the current-voltage characteristic (12.34) is modified to

$$i = -e\eta I_p A + i_s \left[\exp \left(\frac{eV_b}{k_B T} \right) - 1 \right]. \quad (12.35)$$

This characteristic is illustrated in Fig. 12.9. Note that the sign of the photocurrent is such that it effectively increases the reverse-bias saturation current. As discussed earlier in this subsection, this current arises from thermally generated minority carriers that are swept across the depletion region, and the light provides additional carriers to be swept across.

One very useful limit of (12.35) is when a large reverse bias is applied, so that V_b is large and negative. Then

$$i = -e\eta I_p A - i_s. \quad (12.36)$$

The current flowing in the circuit in this case is a direct linear (affine) measure of the photon irradiance, independent of the bias voltage.

Fig. 12.9 Current-voltage characteristic of a photodiode with illumination.

12.1.3 Shot noise in semiconductor photodiodes

The discussion in Sec. 12.1.1 of shot noise in vacuum photodiodes is generally applicable to semiconductor photodiodes, but there are some important differences between the two kinds of devices. In the vacuum diode, only one kind of carrier is produced, and it is always produced at the same location, the photocathode. In the semiconductor, holes and electrons are produced, and the position of the photoelectric interaction is a random variable. Finally, electrons are accelerated across the gap in the vacuum diode, but both carriers quickly reach a terminal velocity in a semiconductor.

We can analyze these effects with a simple model. Suppose that light is propagating in the $+z$ direction and that the depletion region extends from $z = 0$ on the P side to $z = L_z$ on the N side. Assume also that the lateral dimensions (L_x and L_y) of the P-N junction are large compared to L_z . If an electron-hole pair is produced at the interaction point $z = z_{int}$ in the depletion region, the hole must travel a distance z_{int} and the electron must travel $L_z - z_{int}$ to reach undepleted material. Since the undepleted material is a good conductor, it may be considered part of the external circuit, and we need to consider the effect of carrier motion only within the depletion region.

For simplicity, we assume that the field in the depletion region has a constant value (which may be a good approximation at large reverse bias). In that case, the hole moves at constant speed $v_h = \mu_h E_0$ for a time $T_h = z_{int}/(\mu_h E_0)$, and the electron moves at speed $v_e = \mu_e E_0$ for a time $T_e = (L_z - z_{int})/(\mu_e E_0)$. A conservation-of-energy argument similar to the one in Sec. 12.1.1 then shows that the hole and electron currents in the external circuit (for a single photoelectric interaction) are, respectively,

$$i_{0h}(t) = -\frac{eE_0\mu_h}{L_z}, \quad 0 \leq t < \frac{z_{int}}{\mu_h E_0}; \quad (12.37)$$

$$i_{0e}(t) = -\frac{eE_0\mu_e}{L_z}, \quad 0 \leq t < \frac{L_z - z_{int}}{\mu_e E_0}. \quad (12.38)$$

Comparison of these expressions with (12.2) shows that the semiconductor diode gives two rect-function pulses rather than the single triangular one obtained with the vacuum diode. Both pulses are negative since the electrons move towards the load resistor in the external circuit and the holes move away.

At zero bias, the field E_0 is approximately given by the bandgap potential difference (*i.e.*, \mathcal{E}_g expressed in eV) divided by L_z . Since \mathcal{E}_g is around 1 eV and L_z is typically a few microns, E_0 is of order 10^3 – 10^4 V/cm. Typical mobilities are a few thousand $\text{cm}^2/\text{V}\cdot\text{sec}$, so the carrier speeds in the depletion region are of order 10^7 cm/sec. Therefore the resulting pulse widths in (12.37) and (12.38) are of order 10^{-11} sec for zero bias, and even less for reverse bias. If these widths are short compared to the reciprocal bandwidth of the circuit, then we can approximate the rects by delta functions. Taking care to preserve normalization, we write

$$i_{0h}(t) \simeq -\frac{z_{int}}{L_z} e \delta(t), \quad i_{0e}(t) \simeq -\frac{L_z - z_{int}}{L_z} e \delta(t). \quad (12.39)$$

One interpretation of this result is that each carrier induces a total charge proportional to the distance it travels and independent of the field and mobilities.

Of course, we do not observe these pulses separately. The total current flowing in the circuit for one electron-hole pair is

$$i_0(t) = i_{0h}(t) + i_{0e}(t) = -e \delta(t). \quad (12.40)$$

Thus the total induced charge per electron-hole pair is e , not $2e$.

Since (12.40) is identical to (12.4), the remainder of the discussion in Sec. 12.1.1 is still applicable to semiconductor diodes. Note especially that $i_0(t)$ is independent of the interaction position z_{int} , so this random variable does not affect the statistics of the photocurrent under the present model. The key assumptions that caused z_{int} to cancel out were that both carriers eventually reach the undepleted region (no trapping or recombination in the depletion region) and that the lateral dimensions of the diode are large ($L_x, L_y \gg L_z$). We shall come back to the effects of trapping in the depletion region below.

Mean photocurrent As in Sec. 12.1.1, we now assume that the radiation is temporally stationary and that the Poisson postulates are satisfied. The rate of photoelectric generation of electron-hole pairs is ηa_{phot} , where η is the fraction of photons absorbed in the depletion region and a_{phot} is the rate of arrival of photons,

$$a_{phot} = AI_p. \quad (12.41)$$

Here, $A = L_x L_y$ is the cross-sectional area of the diode and I_p is the (nonrandom) photon irradiance.

The total photocurrent $i_p(t)$ is now a Poisson random process of the form (12.8), and from (11.95) its mean is

$$\langle i_p(t) \rangle = -\eta a_{phot} = -\eta AI_p. \quad (12.42)$$

Total current There is a dark current in semiconductor photodiodes analogous to the thermionic emission from the photocathode in a vacuum diode, but the physics is rather different. As we saw in Sec. 12.1.2, there are actually four components to the dark current in a P-N junction: electron and hole generation currents and

electron and hole recombination currents. The sum of the means of these currents is zero at zero bias in the dark, but each current component carries its own noise, and the noises do not cancel even if the means do.

To the extent that each electron or hole flowing in the diode produces a current pulse short compared to the reciprocal of the system bandwidth, we can express the total current as a sum of point processes,

$$i_{tot}(t) = -ez_p(t) - ez_{eg}(t) - ez_{hg}(t) + ez_{er}(t) + ez_{hr}(t), \quad (12.43)$$

where the subscripts have the following meanings: $p \Rightarrow$ *photoelectric*, $eg \Rightarrow$ *electron generation*, $hg \Rightarrow$ *hole generation*, $er \Rightarrow$ *electron recombination*, $hr \Rightarrow$ *hole recombination*. Each random process is a sum of delta functions as in (12.8), and each has its own rate a with an appropriate subscript. All of the rates are positive by definition, so the signs in (12.43) indicate the directions of the corresponding currents. The rates for the generation and recombination components depend on temperature and on the bias voltage across the diode, but in thermal equilibrium at zero bias, $a_{eg} = a_{er}$ and $a_{hg} = a_{hr}$.

A great simplification arises if we can assume that each of the five random processes in (12.43) is statistically independent of the other four, but to make this assumption we must neglect several effects. The first is Coulomb interaction of one charge carrier with another. The basic argument that validates this assumption is that the field in the depletion region is rather strong, of order 10^4 V/cm, so the motion of each carrier is determined by this field and not by the weaker fields of the other carriers. We must also assume that the rate for one current is independent of the magnitudes of the other currents. Effects that could invalidate this assumption include heating of the material at high current and changes in bias arising from the voltage drop across the external circuit. The latter effect is minimized by use of an operational amplifier as in Fig. 12.2b. Finally, fluctuations in ambient temperature or bias voltage can produce correlations among the current components. Good engineering practice will usually control these factors adequately, however, and there is seldom a serious objection to assuming statistical independence of the component currents.

An additional useful assumption is that each of the five random processes is stationary. From the discussion in Sec. 11.3.1, we know the conditions under which $z_p(t)$ is a stationary Poisson process; basically, the photon irradiance must be nonrandom and independent of time, and all photoelectric events must produce identical output pulses. Similarly, the four thermal processes are stationary if the temperature is constant since the rates are determined by the temperature. Moreover, all carriers entering the depletion region produce identical current pulses if there is no trapping or recombination in the depletion region. Under these conditions, $z_{eg}(t)$, $z_{hg}(t)$, $z_{er}(t)$ and $z_{hr}(t)$ are all stationary Poisson random processes.

With these assumptions, the overall current is a stationary random point process, though not exactly a Poisson point process because of the factors of $\pm e$. Instead, from the discussion in Sec. 11.3.3, we can see that the mean current is

$$\langle i_{tot}(t) \rangle = -ea_p - ea_{eg} - ea_{hg} + ea_{er} + ea_{hr}, \quad (12.44)$$

and the stationary autocovariance function is [cf. (11.97)]

$$K_{i_{tot}}(\Delta t) = [e^2 a_p + e^2 a_{eg} + e^2 a_{hg} + e^2 a_{er} + e^2 a_{hr}] \delta(\Delta t) = e^2 a_{tot} \delta(\Delta t), \quad (12.45)$$

where a_{tot} is the total rate of electrons crossing the junction due to all processes, with no regard to the direction of the currents. Because the factors $\pm e$ are squared, the covariances add even when the mean currents tend to cancel.

The power spectral density of the total current is the Fourier transform of (12.45), or

$$S_{i_{tot}}(\nu) = e^2 a_{tot}, \quad (12.46)$$

so the current noise is white (within our approximation of short transit time).

RC filtering As with vacuum photodiodes, we now investigate the effect of passing $i_{tot}(t)$ through an RC filter. Repeating the calculations in Sec. 12.1.1 with due attention to the signs of various terms, we find [cf. (12.10) and (12.11)]

$$\langle V_{out}(t) \rangle = R[-ea_p - ea_{eg} - ea_{hg} + ea_{er} + ea_{hr}], \quad (12.47)$$

$$\text{Var}\{V_{out}(t)\} = \frac{R}{2C} [e^2 a_p + e^2 a_{eg} + e^2 a_{hg} + e^2 a_{er} + e^2 a_{hr}]. \quad (12.48)$$

To simplify these expressions, we consider a large reverse bias so that the recombination currents are zero (no majority carriers can surmount the potential barrier) and the reverse-bias saturation current i_s is given by $ea_{eg} + ea_{hg}$. Since $a_p = \eta AI_p$, we can now write the mean and variance of the filter output as

$$\langle V_{out}(t) \rangle = -R\eta AI_p - Ri_s, \quad (12.49)$$

$$\text{Var}\{V_{out}(t)\} = \frac{R}{2C} [e^2 \eta AI_p + ei_s]. \quad (12.50)$$

The mean photocurrent is $-e\eta AI_p$, and $-i_s$ is the mean dark current, so (12.49) is Ohm's law and (12.50) is the shot noise associated with the total mean current [cf. (12.11)].

Trapping So far we have assumed that any carrier that enters the depletion region is swept across. One consequence of this assumption is that all photoelectric events in the depletion region produce identical output current pulses, so the noise is determined solely by Poisson statistics. In real photodiodes, however, there is always some probability that an electron or hole will be trapped at a defect in the depletion region. When this occurs, the induced current pulse in the external circuit is smaller than for a carrier that makes it all the way across. Since trapping is a random phenomenon, the noise is increased in the presence of trapping.

With trapping, there are three new random variables to consider for each photoelectric event: the random depth of interaction z_{int} , the random distance travelled by the electron and the random distance travelled by the hole. Suppose a hole and an electron are generated at time $t = 0$ and at depth $z = z_{int}$, that the electron moves in the $+z$ direction by a distance d_e (where $0 < d_e \leq L_z - z_{int}$), and that the hole moves in the $-z$ direction a distance d_h (where $0 < d_h \leq z_{int}$). (Hence d_e and d_h are both positive numbers.) If we can assume, as we did above, that the transit times are small compared to the reciprocal bandwidth of the circuit, the current induced in the external circuit can be written as

$$i_0(t) = i_{0h}(t) + i_{0e}(t) = -e \left[\frac{d_h}{L_z} + \frac{d_e}{L_z} \right] \delta(t) \equiv -e\beta \delta(t), \quad (12.51)$$

where $0 < \beta \leq 1$. Note that $\beta = 1$ if there is no trapping since then $d_e = L_z - z_{int}$ and $d_h = z_{int}$.

Equation (12.51) may seem to imply that the induced charge need not be an integral multiple of e , in violation of charge quantization, but two points should be kept in mind. First, charge is quantized but current is not; an electron can move an arbitrary distance and hence induce an arbitrary current. Second, even when the total current is integrated on a capacitor to get a voltage, it is the total charge, arising from many current pulses of the form (12.51) that is quantized, not the charge from each pulse independently. Quantization of charge on a capacitor plate, called *Coulomb blockade*, has indeed been observed experimentally, but it is of little practical concern in electronic devices.

A first-principles treatment from this point would deduce the probability density function for β from knowledge of the physics of photon absorption and carrier trapping, but for present purposes it will suffice to assume that the mean $\bar{\beta}$ and variance σ_β^2 of the random amplitude β are known. It is not necessary to know how the statistics of β depend on those of z_{int} , d_e and d_h .

Suppose the photoelectric events comprise a stationary Poisson point process of rate a_p , with the n^{th} event occurring at time t_n ($0 < t_n \leq T$) but inducing a delta-function current pulse with strength $-e\beta_n$. Then the current is not a Poisson process because the pulses are not identical. We assume, as usual, that all events are statistically indistinguishable and independent, so the mean and variance of β_n are the same for all events, and β_n is statistically independent of β_m for $n \neq m$. The total photocurrent is then

$$i_p(t) = -e \sum_{n=1}^N \beta_n \delta(t - t_n). \quad (12.52)$$

There are now $2N + 1$ random variables: the set $\{t_n\}$, the set $\{\beta_n\}$ and N itself. It will serve as an excellent test of the reader's comprehension of random point processes to retrace the derivation in Sec. 11.3.3 and show that the mean and autocorrelation function of the photocurrent are given by

$$\langle i_p(t) \rangle = -ea_p \bar{\beta}, \quad (12.53)$$

$$\langle i_p(t) i_p(t') \rangle = e^2 a_p (\sigma_\beta^2 + \bar{\beta}^2) \delta(t - t') + e^2 a_p^2 \bar{\beta}^2. \quad (12.54)$$

If there is no trapping, $\bar{\beta} = 1$ and $\sigma_\beta^2 = 0$, and we are back to the usual results for stationary Poisson random processes.

With trapping, however, the mean and variance on the output of the *RC* filter are both modified. Neglecting generation and recombination currents for simplicity, we find [cf. (12.47) and (12.48)]

$$\langle V_{out}(t) \rangle = -ea_p R \bar{\beta}, \quad (12.55)$$

$$\text{Var}\{V_{out}(t)\} = \frac{e^2 a_p R}{2C} (\sigma_\beta^2 + \bar{\beta}^2). \quad (12.56)$$

The detective quantum efficiency in this case is given by

$$\text{DQE} = \frac{\bar{\beta}^2 \eta}{\sigma_\beta^2 + \bar{\beta}^2}, \quad (12.57)$$

where η is the usual quantum efficiency (the probability of a photon producing a photoelectric event). Note that $\text{DQE} \rightarrow \eta$ as $\sigma_{\beta}^2 \rightarrow 0$, regardless of $\bar{\beta}$; the absolute size of the current pulse does not affect DQE (if there are no other noise sources), but its randomness does.

12.2 OTHER NOISE MECHANISMS

So far we have focused on different manifestations of shot noise or photon noise, but in real detectors there are other noise mechanisms as well. In this section we shall discuss the most important ones, including thermal or Johnson noise, generation-recombination noise arising from random fluctuations in the number of free carriers in a semiconductor, a somewhat mysterious process known as $1/f$ noise, and a kind of noise called kTC noise, which is peculiar to gated integrators.

12.2.1 Thermal noise

The thermal motion of charge carriers in any conductor leads inevitably to fluctuations in the current. This phenomenon was reported independently in 1928 by J. B. Johnson and H. Nyquist in two papers with nearly identical titles in the same issue of *Physical Review* (Johnson, 1928; Nyquist, 1928). The terms *Johnson noise* and *Nyquist noise* are both used in the literature, with perhaps a 75% chance that Johnson will be given sole credit. We shall use the broad term *thermal noise* to describe Johnson/Nyquist noise and any other fluctuations that would disappear at absolute zero temperature.

There are many ways of looking at thermal noise, including the equipartition principle, the fluctuation-dissipation theorem and stochastic differential equations. We shall touch briefly on these various approaches, emphasizing concepts useful in analyzing imaging systems.

Thermodynamic probabilities and equipartition A basic result of statistical mechanics is that the probability of occurrence of any state j in thermal equilibrium is given by

$$\text{Pr}(j) = \frac{1}{Z} \exp\left(-\frac{\mathcal{E}_j}{k_B T}\right), \quad (12.58)$$

where \mathcal{E}_j is the energy of the state. The normalizing constant Z , called the *partition function*, is usually written as

$$Z = \sum_j \exp\left(-\frac{\mathcal{E}_j}{k_B T}\right), \quad (12.59)$$

where the sum is over all possible states of the system. In many cases, there is a continuum of states, so the probability becomes a probability density function and the discrete sum over the index j must be replaced by an appropriate integral.

For a system consisting of N free particles of mass m , the state j is specified by stating the velocity \mathbf{v}_n for each particle. The energy is the sum of the kinetic energies of the particles:

$$\mathcal{E} = \sum_{k=1}^N \frac{1}{2} m v_k^2 = \sum_{k=1}^N \frac{1}{2} m (v_{kx}^2 + v_{ky}^2 + v_{kz}^2), \quad (12.60)$$

where v_{kx} is the x -component of \mathbf{v}_k , etc.

An immediate consequence of (12.58) and (12.60) is that all components of all velocities are normally distributed with zero mean. For example, the marginal probability density function on v_{kz} is

$$\text{pr}(v_{kz}) = \sqrt{\frac{m}{2\pi k_B T}} \exp\left(-\frac{\frac{1}{2}mv_{kz}^2}{k_B T}\right). \quad (12.61)$$

Since current in a circuit is linearly related to the velocity of charge carriers, it follows that thermal noise currents must be normally distributed as well.

The average energy associated with any velocity component (say v_{kz}) is

$$\left\langle \frac{1}{2}mv_{kz}^2 \right\rangle = \frac{1}{2}k_B T. \quad (12.62)$$

This is quite a general result, known as the *equipartition principle*: Each quadratic contribution to the energy has an average value of $\frac{1}{2}k_B T$, and the associated dynamical variable (here v_{kz}) is normally distributed.

Basic equations for thermal noise A simple way to get from the equipartition principle to a practical formula for thermal noise is to consider a resistor R in parallel with a capacitor C . The energy stored in the capacitor is $\frac{1}{2}CV^2$, where V is the voltage across the parallel combination. This voltage is the only dynamical variable necessary to specify the energy of the system. By equipartition, we must have

$$\frac{1}{2}C \langle V^2 \rangle = \frac{1}{2}k_B T, \quad (12.63)$$

or

$$\langle V^2 \rangle = \frac{k_B T}{C}. \quad (12.64)$$

But we know from (12.19) that the effective noise bandwidth B is given by $(4RC)^{-1}$, so we can also write

$$\langle V^2 \rangle = 4Rk_B T B. \quad (12.65)$$

This fundamental equation shows that the noise variance is proportional to the resistance, to the absolute temperature and to the circuit bandwidth. An alternative—and more general—derivation of (12.65) will be given below after we state the fluctuation-dissipation theorem.

One way to interpret (12.65) is in terms of equivalent circuits, as shown in Fig. 12.10. The actual noisy resistor can be modeled as a noise free resistor in series with a zero-mean random voltage source that produces an RMS noise of $\sqrt{4Rk_B T B}$. By Thevenin's theorem an alternative equivalent circuit is a noise-free resistor in parallel with a zero-mean random current source that produces an RMS current of $\sqrt{4k_B T B/R}$. The latter circuit is convenient for comparing the thermal noise current to the photocurrent from a photodiode.

Another interpretation of (12.65) is in terms of *available noise power*. Maximum power is transferred from a source to a load if the resistance of the load equals the internal resistance of the source. Thus a noisy resistor R in parallel with another resistor of resistance R' will transfer the maximum possible power to the second resistor if $R = R'$ (and of course the second resistor will transfer the same amount of power back to the first if they are in thermal equilibrium). The noise voltage from the first resistor is then divided evenly between itself and the second

resistor, and the voltage that appears across the load is $V/2$, where the variance of V is still given by (12.65). The average power transferred to a matched load is

$$P_{\max} = \frac{\langle V^2 \rangle}{4R} = k_B T B. \quad (12.66)$$

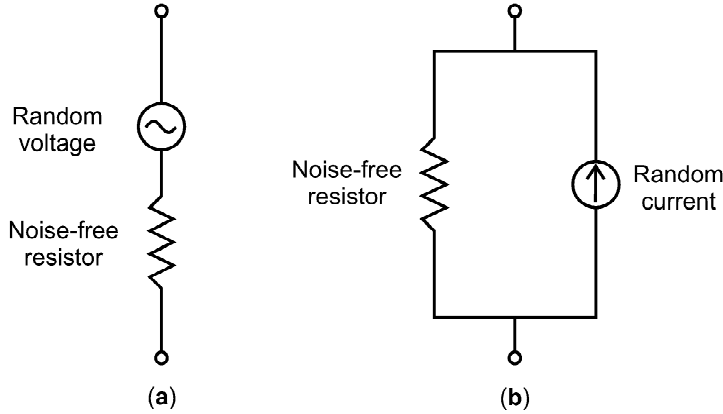

Fig. 12.10 Equivalent circuits for a resistor with thermal noise. *Left:* Series equivalent circuit with a random voltage source. *Right:* Parallel equivalent circuit with a random current source.

Thus the available power is $k_B T B$, and the available power per unit bandwidth is $k_B T$. Since $k_B T$ is an energy (with SI units of Joules) and B has units of Hz or sec^{-1} , $k_B T B$ has units of Joules/sec or Watts. Numerically, at room temperature (300 K) and a bandwidth of 1 MHz, $k_B T B = 4 \times 10^{-15}$ Watts, a seemingly tiny number but nevertheless often the dominant noise in practical electronic circuits and photodetectors.

Finally, we can also interpret (12.65) in terms of the power spectral density of the noise, $S_V(\nu)$. Since the frequency ν does not appear in (12.65), we must be dealing with a white-noise process. If we assume that

$$S_V(\nu) = 2R k_B T, \quad (12.67)$$

then (12.65) follows since the variance is the autocovariance function at zero shift and, for a zero-mean process, the autocovariance function is the inverse Fourier transform of the power spectral density. Thus (12.67) requires that

$$\langle V^2 \rangle = \int_{-B}^B d\nu S_V(\nu) = 4R k_B T B, \quad (12.68)$$

in agreement with (12.65).

The expression in (12.67) can be regarded as the power spectral density of the voltage source in the equivalent circuit of Fig. 12.10a. The corresponding spectral density for the current source in Fig. 12.10b is, by Thevenin's theorem,

$$S_i(\nu) = \frac{2k_B T}{R}. \quad (12.69)$$

Thermal noise in P-N junctions We have already analyzed the noise properties of generation and recombination currents in P-N junctions. In Sec. 12.1.3 we considered the shot noise from these currents and showed in (12.46) that the power spectral density of the current was white. Since generation and recombination currents arise from thermal fluctuations, however, one might wonder how they relate to thermal noise. We shall now show that in thermal equilibrium (no bias or illumination), they are in fact the same thing.

A P-N junction can be considered to be a nonlinear resistance. For a linear resistor, the resistance R is V/i , and for a nonlinear element an effective differential resistance R_d can be defined as $\partial V/\partial i$. We can find R_d for a P-N junction in the dark at zero bias by differentiating the current-voltage characteristic (12.34):

$$\frac{1}{R_d} \equiv \left[\frac{\partial i}{\partial V_b} \right]_{V_b=0} = \frac{ei_s}{k_B T}. \quad (12.70)$$

Since the thermal fluctuations are always so small that the current-voltage characteristic is locally linear, we can compute the thermal noise associated with R_d just as we would from a linear resistor. In particular, we know from (12.69) that the power spectral density for the thermal-noise current is $2k_B T/R$, and if we replace R with R_d we find

$$S_{\Delta i}(\nu) = \frac{2k_B T}{R_d} = 2ei_s. \quad (12.71)$$

There is no net current across an unilluminated P-N junction at zero bias, but there are four component currents: electron and hole generation and recombination currents. As discussed in Sec. 12.1.2, the two generation currents persist at reverse bias, and i_s is given by $ea_{eg} + ea_{hg}$. Thus the positive quantity $a_{eg} + a_{hg} = i_s/e$. At zero bias there are two other contributions to the total rate, namely a_{er} and a_{hr} , and the total rate a_{tot} is $2i_s/e$. The power spectral density of the shot noise associated with this total rate is then $e^2 a_{tot} = 2ei_s$, which is identical to (12.71).

The shot noise due to thermally generated generation and recombination currents is thus the same thing as thermal noise in an unilluminated P-N junction at zero bias. At large reverse bias, on the other hand, the recombination currents are zero and the rate of carrier transport across the junction is reduced from $2i_s/e$ to i_s/e , so the noise power spectral density (and variance after filtering) are also reduced a factor of 2. The differential resistance R_d is very high at large reverse bias, so the thermal contribution to $S_{\Delta i}(\nu)$ is negligible, but the shot-noise associated with the two generation currents remains. The system is no longer in thermal equilibrium at reverse bias, so there is no reason to expect that the thermal expressions will account for all of the noise.

Fluctuation-dissipation theorem The basic principle that dictates the inevitability of thermal noise is the *fluctuation-dissipation theorem*, which was stated precisely and given a quantum-mechanical basis by Callen and Welton (1951). A succinct derivation is given by Mandel and Wolf (1995), and a more detailed treatment is given by Kogan (1996). Here we merely state the key results without derivation.

Consider a temporally shift-invariant system in which some dynamical variable $y(t)$ responds linearly to a stimulus $x(t)$. For a monochromatic stimulus expressed as the real part of $X(\nu) \exp(-2\pi i\nu t)$, the response has a similar form with amplitude $Y(\nu)$ given by

$$Y(\nu) = H(\nu) X(\nu), \quad (12.72)$$

where $H(\nu)$ is the transfer function. In addition, assume that the variables are defined so that a time average of the product $x(t)y(t)$ is the power delivered from the stimulus to the system. For example, $x(t)$ could be a current across a resistor and $y(t)$ the resulting voltage, or $x(t)$ could be the force exerted by an electric field and $y(t)$ the velocity of a charged particle. Note, however, that we cannot take $x(t)$ as the electric field and $y(t)$ as the resulting displacement of a charged particle; even though these variables are linearly related, the product $x(t)y(t)$ is not a power, dimensionally or physically.

With the proper choice of variables and a monochromatic stimulus, the power transfer is given by (see Sec. 10.1.2)

$$P = \frac{1}{2} \operatorname{Re}\{Y(\nu) X^*(\nu)\} = \frac{1}{2} |X(\nu)|^2 \operatorname{Re} H(\nu). \quad (12.73)$$

Thus the real part of the transfer function controls the power dissipation.

The fluctuation-dissipation theorem says that the dynamical variable $y(t)$ will undergo thermal fluctuations $\Delta y(t)$ with a power spectral density $S_{\Delta y}(\nu)$ proportional to $\operatorname{Re} H(\nu)$. The full quantum-mechanical calculation (Mandel and Wolf, 1995) shows that

$$S_{\Delta y}(\nu) = 2h\nu \left[\frac{1}{2} + \frac{1}{e^{h\nu/k_B T} - 1} \right] \operatorname{Re} H(\nu). \quad (12.74)$$

The reader should verify the dimensional consistency of this equation.

The factor in square brackets in (12.74) is the mean number of quanta associated with a mode of the radiation field in thermal equilibrium, and $h\nu$ times this factor is the mean energy. As $T \rightarrow 0$, the mean energy approaches the zero-point value $\frac{1}{2}h\nu$. For practical problems with ordinary electrical circuits or photodetectors, it is almost always valid⁴ to say that $h\nu \ll k_B T$. With this approximation, the mean number of quanta in the mode is very large, so quantum-mechanical effects become negligible and (12.74) takes a simple form (independent of Planck's constant h):

$$S_{\Delta y}(\nu) = 2k_B T \operatorname{Re} H(\nu). \quad (12.75)$$

Now we see that fluctuations in $y(t)$ have a power spectral density controlled entirely by the dissipative part of the transfer function, with the constant of proportionality just given by $2k_B T$.

As an application of this theorem, let the dissipative system be an ideal resistor where the input $x(t)$ is the current through the resistor and the output $y(t)$ is the voltage $V(t)$ across it. Then $H(\nu)$ is the constant R for all ν , and the power spectral density of the voltage fluctuations is

$$S_{\Delta V}(\nu) = 2R k_B T, \quad (12.76)$$

in agreement with (12.67).

Stochastic differential equation The fluctuation-dissipation theorem tells us how large the thermal fluctuations in a dissipative system must be, but it sheds no light

⁴As a useful rule of thumb, an energy $\mathcal{E} = 1$ eV corresponds to a temperature $\mathcal{E}/k_B = 11,600$ K and to a frequency $\mathcal{E}/h = 2.4 \times 10^{14}$ Hz.

on how they arise in the first place. We shall now show how both the fluctuations and the dissipation can be derived from a common differential equation.

Consider a single free electron in a solid. Forces are exerted on the electron by an applied (possibly time-dependent) electric field $\mathbf{E}_0(t)$ in the $+z$ direction and by thermal motion of atoms and other electrons in the material. The equation of motion for the z component of the electron velocity is (Reif, 1965; Riskin, 1984)

$$m \frac{dv_z(t)}{dt} = -eE_0(t) + F_z(t), \quad (12.77)$$

where $F_z(t)$ is the z -component of the total fluctuating force on the electron. Since $F_z(t)$ is random, (12.77) is a *stochastic differential equation*.

The main thing we need to know about $F_z(t)$ is that it fluctuates very rapidly. That is, $F_z(t)$ is a sample function of a temporal random process with a very short correlation time, of order 10^{-13} sec in semiconductors, so it is short compared to any time interval over which we can observe the system in the laboratory. In particular, the correlation time is short compared to the lifetime τ introduced in Sec. 12.1.2. The lifetime is the mean time before trapping or recombination, and it is typically milliseconds or microseconds for electrons in semiconductors. We shall neglect trapping and recombination altogether in this section but reintroduce them in Sec. 12.2.2.

We can write the velocity component $v_z(t)$ as

$$v_z(t) = \bar{v}_z(t) + \Delta v_z(t), \quad (12.78)$$

where the overbar indicates a time average over an interval long compared to the correlation time of the force but short compared to the time dependence of E_0 . Similarly, we can write the random force as

$$F_z(t) = \bar{F}_z(t) + \Delta F_z(t). \quad (12.79)$$

One might expect $\bar{F}_z(t)$ to be zero because forces acting in the $+z$ direction have the same probability as forces acting in $-z$. That would be true for an electron at rest, but the average motion $\bar{v}_z(t)$ breaks the symmetry. To first order in $\bar{v}_z(t)$ we can write

$$\bar{F}_z(t) = -\alpha \bar{v}_z(t), \quad (12.80)$$

where $\alpha > 0$ since the average force must be in the direction of decelerating the moving electron.

A time average of (12.77) yields

$$m \frac{d\bar{v}_z(t)}{dt} = -eE_0(t) - \alpha \bar{v}_z(t). \quad (12.81)$$

For constant field, the steady-state solution of this equation is $\bar{v}_z = -eE_0/\alpha$. If we identify \bar{v}_z with the average electron velocity in (12.25), we see that e/α is the electron mobility μ_e . Thus, after reinserting the fluctuating terms, we can rewrite (12.77) as

$$\frac{dv_z(t)}{dt} + \frac{e}{m\mu_e}v_z(t) = -\frac{e}{m}E_0(t) + \frac{1}{m}\Delta F_z(t). \quad (12.82)$$

Equation (12.82) is known as the *Langevin equation*.

Solution of the Langevin equation For notational simplicity, we define $e/(m\mu_e)$ as γ and $\Delta F_z(t)/m$ as the force per unit mass, denoted $\Delta f_z(t)$. Then the Langevin equation in the absence of an applied field is

$$\frac{dv_z(t)}{dt} + \gamma v_z(t) = \Delta f_z(t). \quad (12.83)$$

If one considers a specific sample function $\Delta f_z(t)$ of the fluctuating force, then this is an ordinary inhomogeneous differential equation with the solution

$$v_z(t) = v_z(0)e^{-\gamma t} + \int_0^t dt' e^{-\gamma(t-t')} \Delta f_z(t'). \quad (12.84)$$

Of course, $v_z(t)$ is also a sample function of a random process, and we can now study its mean and autocorrelation function. The mean is immediately zero since there is no applied field and the $+z$ and $-z$ directions are indistinguishable. To find the autocorrelation function of $v_z(t)$, we take advantage of the fact that $\Delta f_z(t)$ fluctuates very rapidly (with zero mean), so that its autocorrelation function can be written as

$$\langle \Delta f_z(t') \Delta f_z(t'') \rangle = C \delta(t' - t''), \quad (12.85)$$

where C will be determined below. With this assumption, the autocorrelation function for $v_z(t)$ becomes

$$\begin{aligned} \langle v_z(t_1) v_z(t_2) \rangle &= v_z^2(0) e^{-\gamma(t_1+t_2)} + \int_0^{t_1} dt' \int_0^{t_2} dt'' e^{-\gamma(t_1+t_2-t'-t'')} C \delta(t' - t'') \\ &= v_z^2(0) e^{-\gamma(t_1+t_2)} + C \int_0^{\min[t_1, t_2]} dt' e^{-\gamma(t_1+t_2-2t')} \\ &= v_z^2(0) e^{-\gamma(t_1+t_2)} + \frac{C}{2\gamma} e^{-\gamma(t_1+t_2)} \left[e^{2\gamma \min[t_1, t_2]} - 1 \right] \\ &= v_z^2(0) e^{-\gamma(t_1+t_2)} + \frac{C}{2\gamma} \left[e^{-\gamma|t_1-t_2|} - e^{-\gamma(t_1+t_2)} \right]. \end{aligned} \quad (12.86)$$

In typical semiconductors at room temperature, μ_e is about $1000 \text{ cm}^2/\text{V}\cdot\text{sec}$, and m must be interpreted as the effective mass, typically 0.1 times the actual electron mass; with these numbers, $\gamma (= e/m\mu_e)$ is of order 10^{13} sec^{-1} . Therefore, we can neglect the exponential factors involving $t_1 + t_2$, so that

$$\langle v_z(t_1) v_z(t_2) \rangle \simeq \frac{C}{2\gamma} e^{-\gamma|t_1-t_2|}. \quad (12.87)$$

This equation shows that the correlation time of the random process $v_z(t)$, defined as the value of $|t_1 - t_2|$ for which the autocorrelation drops by a factor of $1/e$, is $1/\gamma$. We can express the correlation time as

$$\tau_{sc} = \frac{1}{\gamma}, \quad (12.88)$$

where the notation τ_{sc} is used since this correlation time can be interpreted as the mean time between scattering events.

We can now determine the constant C by appealing to the equipartition principle. Since $\frac{1}{2}m \langle v_z^2(t) \rangle = \frac{1}{2}k_B T$, we must have

$$\langle v_z(t_1) v_z(t_2) \rangle = \frac{k_B T}{m} e^{-\gamma|t_1-t_2|}. \quad (12.89)$$

If we are not concerned with time scales as small as τ_{sc} , we can use

$$\lim_{\gamma \rightarrow \infty} \frac{\gamma}{2} e^{-\gamma|\Delta t|} = \delta(\Delta t) \quad (12.90)$$

to obtain

$$\langle v_z(t_1) v_z(t_2) \rangle = \frac{2k_B T \mu_e}{e} \delta(t_1 - t_2). \quad (12.91)$$

Relation to current noise Consider a homogeneous semiconductor of dimensions $L_x \times L_y \times L_z$ ($L_x, L_y \gg L_z$) with electrodes on the faces $z = 0$ and $z = L_z$ connected to an external circuit. We know from (12.2) that a moving electron with velocity $\mathbf{v}(t)$ induces a current in the circuit given by

$$i_0(t) = -\frac{e}{L_z} v_z(t). \quad (12.92)$$

It follows from (12.91) and (12.92) that the autocorrelation function of this current is

$$\langle i_0(t) i_0(t + \Delta t) \rangle = \frac{2k_B T e \mu_e}{L_z^2} \delta(\Delta t). \quad (12.93)$$

Now suppose the semiconductor has a density of n electrons per unit volume, or a total of $N = nL_x L_y L_z$ electrons. The total current is still a zero-mean random process. Since the fluctuations in the motions of different electrons are uncorrelated, the autocorrelation function of the total current is

$$\langle i(t) i(t + \Delta t) \rangle = N \langle i_0(t) i_0(t + \Delta t) \rangle = \frac{2nA k_B T e \mu_e}{L_z} \delta(\Delta t), \quad (12.94)$$

where $A = L_x L_y$.

We can rewrite (12.94) in terms of the resistance of the specimen, which, with (12.28), is given by

$$R = \frac{L_z}{\sigma A} = \frac{L_z}{en\mu_e A}. \quad (12.95)$$

Thus the autocorrelation function for the current is

$$\langle i(t) i(t + \Delta t) \rangle = \frac{2k_B T}{R} \delta(\Delta t) \quad (12.96)$$

and the corresponding power spectral density is

$$S_i(\nu) = \frac{2k_B T}{R}, \quad (12.97)$$

in agreement with (12.69).

This expression shows that the noise power is independent of frequency, but recall that we approximated the autocorrelation function by a delta function in (12.91). The reader is invited to show that the more general result is

$$S_i(\nu) = \frac{2k_B T}{R} \frac{1}{1 + (2\pi\nu\tau_{sc})^2}. \quad (12.98)$$

The white-noise expression (12.97) is thus valid if $2\pi\nu\tau_{sc} \ll 1$, which is easily satisfied in all practical electronic circuits, but the total power, integrated over all frequencies is finite.

Another straightforward generalization is to consider an applied field in the derivation above. Then the mean velocity is not zero, but the autocorrelation function of the velocities is essentially unchanged; thermal velocities are so much larger than drift velocities that the drift can be neglected in the autocorrelation. Thus, even though thermal noise can be described microscopically as current noise or shot noise, it does not depend on the mean current.

Diffusion and the Einstein relation We have seen that random thermal forces on an electron account for both the finite mobility and the thermal noise. As we shall now demonstrate, they also account for Brownian motion and diffusion.

Consider an electron (or any other particle) whose z coordinate at time $t = 0$ is denoted $z(0)$. As a result of the random thermal forces, it will be at some other coordinate $z(t)$ at time t . The mean-squared distance moved in the $+z$ direction is given by

$$\langle [z(t) - z(0)]^2 \rangle = \left\langle \left[\int_0^t dt_1 v_z(t_1) \right]^2 \right\rangle. \quad (12.99)$$

If we write the squared integral as a product of two identical integrals and interchange order of integration and expectation,⁵ we obtain

$$\langle [z(t) - z(0)]^2 \rangle = \int_0^t dt_1 \int_0^t dt_2 \langle v_z(t_1) v_z(t_2) \rangle. \quad (12.100)$$

Inserting the delta-function form (12.91) for the autocorrelation of $v_z(t)$ and performing two easy integrals, we find

$$\langle [z(t) - z(0)]^2 \rangle = \frac{2k_B T \mu_e}{e} t. \quad (12.101)$$

We have thus rediscovered a well-known result from the theory of Brownian motion and other diffusion processes: the RMS displacement grows as the square-root of time. The *diffusion constant* D is defined such that (Reif, 1965)

$$\langle [z(t) - z(0)]^2 \rangle = 2Dt. \quad (12.102)$$

We see at once that

$$D = \frac{k_B T}{e} \mu_e, \quad (12.103)$$

which is the celebrated *Einstein relation* linking the diffusion constant to the mobility.

⁵The validity of this step is discussed in Sec. 8.2.2, but the theorem cited there specifically rules out white-noise processes. To justify the interchange we have to say that it is done before letting $\gamma \rightarrow \infty$.

12.2.2 Generation-recombination noise

Generation-recombination noise or *GR noise* is the noise associated with thermal fluctuations in carrier density in a semiconductor. Since the conductivity is proportional to the carrier density, GR noise can be thought of as fluctuations in resistance of a specimen. If an electric field is applied to the specimen, the resistance fluctuations lead to current fluctuations, so this mechanism is an important noise source in photoconductors.

GR noise should not be confused with the shot noise due to generation and recombination currents in P-N junctions. In Sec. 12.1.3 we analyzed the latter noise in terms of shot noise, and then in Sec. 12.2.1 we saw that it could also be interpreted as thermal noise, at least at zero bias. What we are calling GR noise in this section occurs in homogeneous semiconductors (as opposed to junctions), and it is fundamentally the result of resistance fluctuations rather than shot noise.

Simple model for GR noise Consider again a piece of semiconductor with dimensions $L_x \times L_y \times L_z$ ($L_x, L_y \gg L_z$) with electrodes on the faces $z = 0$ and $z = L_z$. If a bias voltage V_b is applied to the electrodes, the charge carriers experience a field $E_0 = V_b/L_z$ in the $-z$ direction. For simplicity we consider only electrons.

Each *free* electron moves with constant velocity $\mu_e E_0$ in the $+z$ direction, corresponding to a current $-e\mu_e E_0/L_z$, but the electrons do not remain free so the current is not constant. If an electron recombines or is trapped, its current immediately ceases. If the electron is thermally excited out of a trap at a later time, or a new free electron is generated by thermal excitation from the valence band, then this electron is very quickly accelerated to its terminal velocity (on a time scale of picoseconds), and the current resumes. The resulting current waveform due to a single electron is illustrated in Fig. 12.11; this random process is often referred to as a *random telegraph wave*, and its statistics directly control the statistics of GR noise.

Fig. 12.11 Typical waveform of a single electron that is randomly trapped.

Statistics of the random telegraph wave Consider a single electron and define a random process $y(t)$ to have the value 1 when the electron is free and zero when it is trapped. The mean of this process is

$$\langle y(t) \rangle = \Pr[y(t) = 1] = \Pr[\text{electron is free}] \equiv p_1. \quad (12.104)$$

The autocorrelation function (for $\Delta t > 0$) is

$$\begin{aligned} \langle y(t) y(t + \Delta t) \rangle &= \Pr[y(t) = 1 \text{ and } y(t + \Delta t) = 1] \\ &= \Pr[y(t + \Delta t) = 1 | y(t) = 1] p_1. \end{aligned} \quad (12.105)$$

If p_1 is independent of time, the process is stationary.

We can further decompose the event that $y(t + \Delta t) = 1$ given that $y(t) = 1$ into two mutually exclusive possibilities: either no transitions between the free and trapped states occur in the interval Δt , or one or more transitions occur. If no transitions occur, then $\Pr[y(t + \Delta t) = 1|y(t) = 1] = 1$. If one or more transitions occur, then it is reasonable to assume that the electron loses all memory of its previous state, and $\Pr[y(t + \Delta t) = 1|y(t) = 1] = \Pr[y(t + \Delta t) = 1] = p_1$. Thus

$$\langle y(t) y(t + \Delta t) \rangle = p_1 \{ \Pr(\text{no trans in } \Delta t) + p_1 [1 - \Pr(\text{no trans in } \Delta t)] \}, \quad (12.106)$$

where $\Pr(\text{no trans in } \Delta t)$ is the probability that the electron makes no transitions and hence remains free for a time Δt . If the transitions are independent events satisfying the Poisson postulates, this probability is given by [cf. 11.6]

$$\Pr(\text{no trans in } \Delta t) = e^{-\Delta t/\tau}, \quad (12.107)$$

where τ is the lifetime of the electron in the free state.

The discussion above was for $\Delta t > 0$, but an autocorrelation function must be symmetrical, so

$$\begin{aligned} \langle y(t) y(t + \Delta t) \rangle &= p_1 \left[e^{-|\Delta t|/\tau} + p_1 \left(1 - e^{-|\Delta t|/\tau} \right) \right] \\ &= (p_1 - p_1^2) e^{-|\Delta t|/\tau} + p_1^2. \end{aligned} \quad (12.108)$$

Defining the zero-mean process $\Delta y(t) = y(t) - \langle y(t) \rangle$, we see that the autocovariance of $y(t)$ is given by

$$K_y(\Delta t) = \langle \Delta y(t) \Delta y(t + \Delta t) \rangle = (p_1 - p_1^2) e^{-|\Delta t|/\tau}. \quad (12.109)$$

From telegraph wave to GR noise Now assume there are N_{tot} electrons in the volume and that the generation and recombination processes act independently on different electrons. Under this assumption, the mean and autocovariance of the current are given by

$$\langle i(t) \rangle = -N_{tot} \frac{e\mu_e E_0}{L_z} p_1; \quad (12.110)$$

$$K_i(\Delta t) = \langle \Delta i(t) \Delta i(t + \Delta t) \rangle = N_{tot} \left[\frac{e\mu_e E_0}{L_z} \right]^2 (p_1 - p_1^2) e^{-|\Delta t|/\tau}. \quad (12.111)$$

But $N_{tot} p_1$ is the mean number of free electrons, denoted \bar{N} and given in terms of the mean density n of free electrons by

$$\bar{N} = N_{tot} p_1 = nAL_z, \quad (12.112)$$

where $A = L_x L_y$. The mean resistance of the specimen, now denoted \bar{R} , is given by (12.95), and it follows from (12.110) and (12.112) that the mean current obeys Ohm's law,

$$\langle i(t) \rangle = V_0 / \bar{R}, \quad (12.113)$$

where $V_0 = E_0 L_z$ is the applied voltage.

The autocovariance can also be expressed in terms of V_0 and \bar{R} . Since the number of free carriers is much less than the total number of carriers in a semiconductor (or else it wouldn't be *semi*), $p_1 \ll 1$ and we can neglect the term proportional to p_1^2 in (12.111). A little algebra then yields

$$K_i(\Delta t) = nA \frac{(e\mu_e E_0)^2}{L_z} e^{-|\Delta t|/\tau} = \frac{\langle i(t) \rangle^2}{\bar{N}} e^{-|\Delta t|/\tau} = \frac{V_0^2}{\bar{N} \bar{R}^2} e^{-|\Delta t|/\tau}. \quad (12.114)$$

Power spectral density The power spectral density of the GR current fluctuations is obtained by Fourier transforming (12.114), with the result,

$$S_{\Delta i}(\nu) = \frac{V_0^2}{\bar{N} \bar{R}^2} \frac{2\tau}{1 + (2\pi\nu\tau)^2}. \quad (12.115)$$

A useful alternative form is

$$S_{\Delta i}(\nu) = \bar{N} \left[\frac{e\mu_e E_0}{L_z} \right]^2 \frac{2\tau}{1 + (2\pi\nu\tau)^2}. \quad (12.116)$$

Though one of these expressions has \bar{N} in the denominator and one has it in the numerator, they are nonetheless equivalent since $\bar{R} \propto 1/\bar{N}$.

This power spectral density is similar in form to the thermal-noise expression in (12.98), but there are two key differences. First, the relevant relaxation time for GR noise is the lifetime, which is microseconds to milliseconds, while the relaxation time for thermal noise is τ_{sc} , which is of order 10^{-13} sec. For frequencies of importance with ordinary laboratory electronics, $2\pi\nu\tau_{sc} \ll 1$ but $2\pi\nu\tau$ may be comparable to or greater than one, so the rolloff in (12.115) should not be neglected. In fact, measurement of the power spectral density of GR noise is a useful technique for determining the lifetime.

Second, we see that the power spectrum of the GR noise current in a homogeneous semiconductor is proportional to the square of the mean current and hence to the square of the applied voltage. The power spectral density of thermal noise, on the other hand, is independent of applied voltage (basically because thermal velocities are large compared to drift velocities).

Variance and its interpretation In discussing shot noise and thermal noise, we assumed that the relevant fluctuations were very rapid so that the power spectral density was essentially constant. To that approximation, the variance of the current was then infinite; to get back to a finite variance, we had to invoke an additional filtering step with finite bandwidth. With GR noise, as we have noted, the fluctuations tend to be much slower, so the power spectral density in (12.115) will not usually be well approximated by a constant. Thus the variance of the GR noise current is finite even without a filter.

Specifically, from (12.114) the variance is given by

$$\text{Var}\{i(t)\} = K_i(0) = \frac{V_0^2}{\bar{N} \bar{R}^2}. \quad (12.117)$$

The ratio of the square of the mean to the variance is thus

$$\text{SNR}_i^2 \equiv \frac{\langle i(t) \rangle^2}{\text{Var}\{i(t)\}} = \bar{N}. \quad (12.118)$$

This expression has a simple interpretation. The mean number of free electrons is \bar{N} , but the electrons are generated independently and thus obey Poisson statistics. The variance in the number is also \bar{N} , as is the ratio of the mean number squared to the variance. Since $i(t) = V_0/R(t)$ and $R(t)$ is proportional to $1/N(t)$, $\Delta i(t)/\langle i(t) \rangle = -\Delta R(t)/\bar{R} = \Delta N(t)/\bar{N}$ and (12.118) follows. Thus GR noise is basically the result of the Poisson fluctuations in the number of free carriers, leading to fluctuations in resistance which are converted to fluctuations in current if a constant voltage is applied.

GR noise in photoconductors As we saw in Sec. 12.1.2, a photoconductor is essentially a resistor whose resistance depends on illumination. The resistance fluctuations of GR noise are therefore an important limitation to the ability to detect weak illumination with photoconductors. In addition, a photoinduced carrier has a random lifetime, and this randomness is a further limitation to detection performance. This is also a form of GR noise, even though it involves photogeneration rather than thermal generation (Kingston, 1995). We shall now analyze a photoconductor where both of these effects are present.

The starting point for the discussion will be a slight modification of (12.116). If we write the total mean number of free electrons \bar{N} as the sum of a thermal component \bar{N}_{th} and a component \bar{N}_p from photoexcitation, we have

$$S_{\Delta i}(\nu) = (\bar{N}_{th} + \bar{N}_p) \left[\frac{e\mu_e E_0}{L_z} \right]^2 \frac{2\tau}{1 + (2\pi\nu\tau)^2}. \quad (12.119)$$

Similarly, the mean current from (12.110) becomes

$$\langle i(t) \rangle = -(\bar{N}_{th} + \bar{N}_p) \frac{e\mu_e E_0}{L_z}. \quad (12.120)$$

Now consider explicitly the geometry of Fig. 12.3b, where both the illumination and the mean current flow are in the $+z$ direction. Also, assume for simplicity that the hole mobility and/or lifetime are small so that the photoconductivity is mediated solely by electrons. From (12.32) we obtain

$$\bar{N}_p = \tau A\eta I_p. \quad (12.121)$$

If we recognize that $L_z/(\mu_e E_0)$ is the transit time T_{tr} across the detector, we can write the mean photocurrent as

$$\langle i_p(t) \rangle = -\frac{\tau}{T_{tr}} eA\eta I_p. \quad (12.122)$$

Since $A\eta I_p$ is the mean number of electrons per second generated by the illumination, we see that each electron contributes a current equivalent to that produced by a charge $-e\tau/T_{tr}$. The ratio of lifetime to transit time,

$$G \equiv \frac{\tau}{T_{tr}}, \quad (12.123)$$

is called the *photoconductive gain*.

In many practical detectors, G is greater than 1, which requires a little explanation. One might think that the life of an electron would end when it reached the anode, as indeed it does in a photodiode. In a linear photoconductor with ohmic (non-rectifying) contacts, however, a new electron is injected at the cathode as soon as one disappears at the anode. Depending on τ and T_{tr} , this process can be repeated many times (Bube, 1992).

From (12.119), the low-frequency power-spectral density of the current can now be written as

$$S_{\Delta i}(0) = 2\tau\bar{N}_{th} \left[\frac{e\mu_e E_0}{L_z} \right]^2 + 2Ge\langle i_p \rangle. \quad (12.124)$$

The first term is what we had before for the GR noise associated with thermally generated carriers. The second term, however, looks more like shot noise. Comparison with (12.13) shows that this term can be interpreted (except for a factor of 2 which we explain below) as the shot noise associated with carriers of charge Ge (Kingston, 1995). Note, however, that both G and $\langle i_p \rangle$ are proportional to the applied voltage, so the second term in (12.124) still varies as voltage squared.

The extra factor of 2 in (12.124) comes from the randomness in the time an electron lives before recombination or trapping, an effect we have already analyzed in discussing trapping in P-N junctions. We saw in (12.56) that the noise variance (or power spectral density) is increased by a factor of $\sigma_\beta^2 + \bar{\beta}^2$ if each carrier contributes a random charge βe to the output current. In the present problem, β is proportional to the free time T , which is exponentially distributed:

$$\text{pr}(T) = \frac{1}{\tau} e^{-T/\tau}, \quad (T \geq 0). \quad (12.125)$$

From the mean and variance of this density, as given in Sec. C.5.3, it follows that $(\sigma_T^2 + \bar{T}^2) = 2\tau^2$, accounting for the extra 2 in (12.124).

12.2.3 $1/f$ noise

In 1925 J. B. Johnson (later to discover thermal noise) was studying noise in vacuum tubes with thermionic cathodes. He observed the shot noise associated with the thermionic emission and saw that it had a flat temporal power spectrum, but he also discovered a component of the noise that had increased power at lower frequencies, with the power spectral density varying approximately as the reciprocal of the temporal frequency (Johnson, 1925; Kogan, 1996). A year later, Schottky (who had earlier discovered shot noise proffered an explanation in terms of slow, random changes in the emission from the thermionic cathode, and he dubbed the effect *flicker noise* (Schottky, 1926). The flickering consists of slow, large-amplitude variations (see Fig. 12.12) that might today be called *drift* or *trending*.

Fig. 12.12 Three typical waveforms of $1/f$ noise.

Since 1925 it has been found that virtually any current-carrying device has such excess low-frequency noise. Moreover, very similar behavior has been found in a wide variety of other fields, including seasonal temperatures, average rainfall, vehicular traffic flow, potentials across nerve membranes, loudness and pitch of music

and even stock-market indices (Keshner, 1982). The most common term for this phenomenon, in all of these fields, is *1/f noise*, even though the power spectrum seldom varies exactly as $1/f$ (and even though it is common to use ν or ω rather than f for temporal frequency).

A comprehensive treatment of electronic $1/f$ noise in solids is given by Kogan (1996), and broad general reviews are given by Mandelbrot (1999), West and Shlesinger (1990), Gardner (1978), Keshner (1982) and Schroeder (1991). Another excellent source with a different bent is Lukyanchikova (1996); this book views noise processes in semiconductors not so much as a limitation on device performance but rather as a tool for investigating the fundamental physics and measuring key parameters of semiconductor materials and devices.

Power spectral density and autocorrelation function The most striking manifestation of $1/f$ noise is that the power spectral density of some temporal random process $x(t)$ varies as

$$S_x(\nu) \propto \frac{1}{|\nu|^\beta}, \quad (12.126)$$

where β is a positive number, usually in the range $1 \leq \beta < 2$. Since the variance of a stationary, zero-mean random variable is given by

$$\text{Var}(x) = \int_{-\infty}^{\infty} d\nu S_x(\nu), \quad (12.127)$$

we must have infinite variance if (12.126) holds for all ν . For this reason, many workers have assumed that there must be some low-frequency cutoff, but all attempts to date to find one have failed. For example, Caloyannides (1974) studied the noise in certain transistors down to 5×10^{-7} Hz, or 1 cycle in 3 weeks,⁶ and found no deviation from (12.126).

The power spectral density in (12.126) implies that the temporal correlations persist over very long times. One might think that the form of the autocorrelation would be given by (3.168), which gives the Fourier transform of $|\nu|^{-\beta}$, but in fact the function $|\nu|^{-\beta}$ in (12.126) is not the same thing as the generalized function $|\nu|^{-\beta}$ defined by Lighthill and discussed in Sec. 2.3.3 [see (2.96)]. As we saw there, the generalized function must have a strong negative singularity at the origin, while power spectral densities are never negative. We can, however, directly transform the power spectral density (at least for $\beta < 1$) and get the autocorrelation function. Since a power spectral density is an even function, we can write

$$R(\Delta t) = 2 \int_0^{\infty} d\nu S_x(\nu) \cos(2\pi\nu\Delta t). \quad (12.128)$$

With (12.126) and the change of variables $u = 2\pi\nu\Delta t$, we find

$$R(\Delta t) \propto |\Delta t|^{\beta-1} \int_0^{\infty} du u^{-\beta} \cos u. \quad (12.129)$$

The integral converges for $0 < \beta < 1$, but the important point for this discussion is that it is just some constant,⁷ independent of Δt , so we see that $R(\Delta t) \propto |\Delta t|^{1-\beta}$,

⁶The number of seconds in a year is approximately $\pi \times 10^7$.

⁷The reader who really must know what this constant is can consult Gradshteyn and Ryzhik (1980), formula 3.761.9.

which approaches $|\Delta t|^0$ or constant as $\beta \rightarrow 1$. A $1/f$ process is therefore one where the distant past strongly influences the present.

Observed variance If (12.126) is valid for all frequencies, the ensemble-average variance is infinite, but it does not follow that an experimenter would ever measure an infinite variance. Suppose a single sample function of duration T of the random process $x(t)$ is available, say for $-\frac{1}{2}T < t \leq \frac{1}{2}T$. The experimenter might define a sample mean m and variance s^2 by

$$m = \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt x(t), \quad (12.130)$$

$$s^2 = \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt [x(t) - m]^2. \quad (12.131)$$

Now suppose that $x(t)$ is zero-mean and stationary, with the power spectral density given by (12.126). What are the expected values of m and s^2 ?

To find the expected value of m , we must interchange the order of statistical averaging and integration over t . This interchange is legal since the integral of the absolute value of the integrand is finite before and after taking the expectation (see Sec. 8.2.2). It is finite before expectation since experimental values of $x(t)$ must be finite and the range of integration is finite, and after taking the expectation inside the integral, the result is in fact zero:

$$\langle m \rangle = \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt \langle x(t) \rangle = 0. \quad (12.132)$$

The expectation of s^2 is more delicate. The integral in (12.131) is still finite before taking the average, but the ensemble average of $x^2(t)$ is infinite if (12.126) holds for all ν . Surprisingly, however, $\langle s^2 \rangle$ is finite. To see why, express the sample function $x(t)$ in terms of its Fourier transform as

$$x(t) = \int_{-\infty}^{\infty} d\nu X(\nu) \exp(2\pi i\nu t). \quad (12.133)$$

Then the sample mean is given by

$$m = \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt \int_{-\infty}^{\infty} d\nu X(\nu) \exp(2\pi i\nu t) = \int_{-\infty}^{\infty} d\nu X(\nu) \operatorname{sinc}(\nu T), \quad (12.134)$$

and the sample variance is

$$\begin{aligned} s^2 &= \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt \left| \int_{-\infty}^{\infty} d\nu X(\nu) [\exp(2\pi i\nu t) - \operatorname{sinc}(\nu T)] \right|^2 \\ &= \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt \int_{-\infty}^{\infty} d\nu \int_{-\infty}^{\infty} d\nu' X(\nu) X^*(\nu') \\ &\quad \times [\exp(2\pi i\nu t) - \operatorname{sinc}(\nu T)][\exp(-2\pi i\nu' t) - \operatorname{sinc}(\nu' T)]. \end{aligned} \quad (12.135)$$

Now we want to take the expectation inside not one but three integrals, and two of them are on the infinite line. To legalize this step, suppose that $S_x(\nu) \propto |\nu|^{-\beta}$ only for $|\nu| > \nu_1$, where ν_1 will be allowed to approach zero. All integrals then remain finite, and we have

$$\begin{aligned} \langle s^2 \rangle &= \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt \int_{-\infty}^{\infty} d\nu \int_{-\infty}^{\infty} d\nu' \langle X(\nu) X^*(\nu') \rangle \\ &\times [\exp(2\pi i\nu t) - \text{sinc}(\nu T)][\exp(-2\pi i\nu' t) - \text{sinc}(\nu' T)]. \end{aligned} \quad (12.136)$$

We know from the temporal counterpart of (8.181), however, that

$$\langle X(\nu) X^*(\nu') \rangle = S_x(\nu) \delta(\nu - \nu') \quad (12.137)$$

for any stationary random process, so

$$\langle s^2 \rangle = \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt \int_{-\infty}^{\infty} d\nu S_x(\nu) |\exp(2\pi i\nu t) - \text{sinc}(\nu T)|^2. \quad (12.138)$$

A little algebra then yields

$$\langle s^2 \rangle = \int_{-\infty}^{\infty} d\nu S_x(\nu) [1 - \text{sinc}^2(\nu T)]. \quad (12.139)$$

The factor $[1 - \text{sinc}^2(\nu T)]$ suppresses low frequencies, $|\nu| < T^{-1}$, so the integral in (12.139) no longer diverges, even if $\nu_1 \rightarrow 0$. Specifically, if $S_x(\nu) = C/|\nu|^\beta$ for all ν , then

$$\langle s^2 \rangle = CT^{\beta-1} \int_{-\infty}^{\infty} \frac{dy}{|y|^\beta} [1 - \text{sinc}^2(y)], \quad (12.140)$$

where $y \equiv \nu T$. The integral is finite for $1 < \beta < 2$, so the expectation of s^2 increases with increasing measurement time in this range. Arbitrarily large T implies arbitrarily large experimental variances. On the other hand, for any finite T , s^2 is an infinitely biased estimate of the ensemble variance.

Other experimental observations For linear electrical devices, such as resistors and photoconductors, it is usually found that the power spectral density of the fluctuating voltage across the device is proportional to the square of the mean voltage and inversely proportional to the mean number of free carriers \bar{N} (Voss and Clarke, 1976). This observation prompted Hooge (1969) to suggest the following empirical relation:

$$S_{\Delta V}(\nu) = \frac{\alpha_H \bar{V}^2}{\bar{N} |\nu|}, \quad (12.141)$$

where α_H is often called the *Hooge constant*, though it varies quite a bit from one material to another (Kogan, 1996).

Since $\Delta i(t) = \Delta V(t)/\bar{R}$, the Hooge relation can also be expressed as

$$S_{\Delta i}(\nu) = \frac{\alpha_H \bar{V}^2}{\bar{N} \bar{R}^2 |\nu|}. \quad (12.142)$$

The factor $\bar{V}^2/\bar{N} \bar{R}^2$ is found also in the GR power spectrum of (12.115), where it occurs because the basic noise mechanism is random fluctuations in resistance. The

Hooge relation thus suggests strongly that $1/f$ noise is also the result of random resistance variations.

The single-point amplitude statistics of $1/f$ noise have also been studied extensively. Occasionally deviations from Gaussian behavior are observed in electronic $1/f$ noise, but usually the probability density function $\text{pr}[V(t)]$ is remarkably close to a univariate normal (Kogan, 1996).

Control of $1/f$ noise Even if the variance of $1/f$ noise is not actually infinite, it is at least very large, and the only way to control it in practice is to make measuring systems insensitive to low frequencies. For electronic systems, a simple coupling capacitor may be effective in suppressing $1/f$ noise. More sophisticated high-pass filters or active systems such as automatic level controls can also be used. In optical systems, a common remedy is to modulate the light by periodically interrupting it with a shutter. (A periodically opened shutter is often called a *chopper*.) Then the electronics of the detector system does not need to pass low frequencies, and most of the $1/f$ spectrum can be filtered out.

Distribution of relaxation times The first attempts at explaining $1/f$ noise mathematically were in the 1930s (Bernamont, 1937; Surdin, 1939). These early workers took the view that $1/f$ noise was basically GR noise but with a distribution of relaxation times. If we start with (12.115) for the GR spectrum but regard τ as a random variable with probability density function $\text{pr}_\tau(\tau)$, we can write

$$S_{\Delta_i}(\nu) = \frac{\bar{V}^2}{N \bar{R}^2} \int_0^\infty d\tau \text{pr}_\tau(\tau) \frac{2\tau}{1 + (2\pi\nu\tau)^2}. \quad (12.143)$$

A convenient assumption, made with essentially no justification in the 1930s, is that τ takes on values in some broad range (τ_1, τ_2) and that its density in this range is given by

$$\text{pr}_\tau(\tau) \propto \frac{1}{\tau}, \quad \tau_1 \leq \tau < \tau_2. \quad (12.144)$$

With this assumption, we find

$$S_{\Delta_i}(\nu) \propto \int_{\tau_1}^{\tau_2} d\tau \frac{1}{1 + (2\pi\nu\tau)^2} = \frac{1}{2\pi|\nu|} [\tan^{-1}(2\pi|\nu|\tau_2) - \tan^{-1}(2\pi|\nu|\tau_1)]. \quad (12.145)$$

Over a broad range of frequencies, this expression can be approximated as

$$\frac{1}{2\pi|\nu|} [\tan^{-1}(2\pi|\nu|\tau_2) - \tan^{-1}(2\pi|\nu|\tau_1)] \simeq \frac{1}{4|\nu|}, \quad \frac{1}{\tau_2} \ll 2\pi|\nu| \ll \frac{1}{\tau_1}. \quad (12.146)$$

Thus this distribution of relaxation times explains the $1/|\nu|$ behavior over a limited range, but of course it still remains to explain the distribution of relaxation times. To account for the experimental observations, the range from τ_1 to τ_2 must cover many decades.

Thermal activation The next step was taken by van der Ziel (1950). He recognized that trapping is a thermally activated process obeying an Arrhenius relation of the form [*cf.* (12.58)]

$$\tau = \tau_0 \exp\left(\frac{\mathcal{E}}{k_B T}\right), \quad (12.147)$$

where \mathcal{E} is the binding energy of a trapped electron and τ_0 is a characteristic of the material and the trap, assumed to be a constant. In semiconductors, \mathcal{E} is of order 0.1–1.0 eV. Thus a distribution in τ can result from a distribution in \mathcal{E} , but because of the exponential a relatively narrow range in \mathcal{E} can lead to a very large range in τ .

If the probability density function of \mathcal{E} , denoted $\text{pr}_{\mathcal{E}}(\mathcal{E})$, is assumed to be known, the corresponding distribution on τ can be found from (C.45); the result is

$$\text{pr}_{\tau}(\tau) = \frac{\text{pr}_{\mathcal{E}}(\mathcal{E})}{|d\tau/d\mathcal{E}|} = \frac{k_B T}{\tau} \text{pr}_{\mathcal{E}}[k_B T \log(\tau/\tau_0)]. \quad (12.148)$$

Now we see that $\text{pr}_{\tau}(\tau)$ varies as $1/\tau$ so long as $\text{pr}_{\mathcal{E}}(\mathcal{E})$ is approximately constant. Moreover, since τ appears in the argument of $\text{pr}_{\mathcal{E}}(\mathcal{E})$ only logarithmically, $\text{pr}_{\mathcal{E}}(\mathcal{E})$ can vary substantially with \mathcal{E} without causing large deviations from the $1/\tau$ behavior.

Some numbers should prove instructive. Suppose $\tau_0 = 10^{-11}$ sec, which is typical for semiconductors, and suppose \mathcal{E} is distributed more or less uniformly over 0.2–0.8 eV. Since $k_B T = 0.025$ eV at room temperature, (12.147) shows that τ varies from 3×10^{-8} sec to about 800 sec. Thus a modest range of \mathcal{E} values can lead to an enormous range of τ values if the process is thermally activated, and (12.148) shows that $\text{pr}_{\tau}(\tau) \propto 1/\tau$ over this range. With the numbers in this example, the approximation in (12.146) is valid from milliHertz to gigaHertz frequencies, and the spectrum follows $1/\nu$ over this range.

A caveat It is important to note that the derivation of a $1/f$ spectrum from a distribution of relaxation times implicitly assumes that the medium is inhomogeneous. In a homogeneous medium, multiple relaxation mechanisms would combine to give an overall effective relaxation rate

$$\frac{1}{\tau_{eff}} = \int_0^{\infty} d\tau \frac{\text{pr}(\tau)}{\tau}. \quad (12.149)$$

Then (12.107) would still hold with τ replaced by τ_{eff} , and the characteristic Lorentzian GR spectrum of (12.116) would be found in spite of the distribution of τ . It is only when the medium can be divided into independent subregions, each characterized by a certain τ and hence a certain GR spectrum, that we should expect multiple relaxation mechanisms to lead to a $1/f$ spectrum.

Relation to log-normals A rather different view of $1/f$ noise and other power-law phenomena has been championed by Montroll, West and Shlesinger in various combinations (*e.g.*, Montroll and Shlesinger, 1982; West and Shlesinger, 1989, 1990). They note that a wide variety of physical processes are cascaded random selections, where the overall probability of a success is the product of probabilities of success on individual tasks. They cite the probability of publishing a scientific paper, the probability of a water droplet making it all the way to the end of the Nile and the probability of an air molecule reaching a particular alveolus in the lung. In all of these cases, they argue, some final random variable should follow a log-normal probability law.

The basic premise is simple: If one has a product of independent random variables,

$$X = \prod_{n=1}^N x_n, \quad (12.150)$$

then the log of the product must be a sum of independent random variables,

$$Y = \ln X = \sum_{n=1}^N \ln x_n. \quad (12.151)$$

By the central-limit theorem (see Sec. 8.3.4), Y tends to a normal distribution as N increases, so X tends to a log-normal. Specifically, the density on X takes the form (see Sec. C.5.9)

$$\text{pr}(X) \simeq \frac{1}{X} \frac{1}{\sqrt{2\pi\sigma_Y^2}} \exp \left[-\frac{(\ln X - \bar{Y})^2}{2\pi\sigma_Y^2} \right]. \quad (12.152)$$

Shlesinger and his colleagues note that this density mimics a $1/X$ over a range that can be large if σ_Y^2 is large, and they offer this observation as an explanation of the ubiquitous appearance of $1/X$ probability densities. To make the connection to electrical $1/f$ noise, they identify X as the relaxation time τ and then appeal to the same reasoning as in (12.144)–(12.146). They do not, however, identify the component variables x_n , nor do they explain why the variance should be large or how the log-normal can approximate a $1/\tau$ behavior over the many decades required to match observed noise spectra. At best, this work is an intriguing suggestion without obvious applicability to electrical noise.

Nonlinear dynamics Another class of explanations for $1/f$ noise centers on chaos and nonlinear dynamics. A readable, semi-popular survey of these approaches is Schroeder (1991).

In a classic paper, Bak *et al.* (1988) argue that many dissipative dynamical systems evolve naturally toward a critical state with no characteristic time or length scale. In this view, $1/f$ noise is not noise at all but rather reflects the intrinsic dynamics of self-organized critical systems.

The prolific scientific output of Benoit Mandelbrot on these themes is collected in Mandelbrot (1999).

Maybe it isn't stationary Another view on $1/f$ noise is that it doesn't have a $1/f$ power spectral density at all—in fact, it doesn't have any power spectral density because it isn't a stationary random process. Mandelbrot (1967) suggested that the paradox of infinite variance could be avoided by treating $1/f$ noise as a nonstationary random process with a time-dependent variance.

Keshner (1982) developed this theme further and gave several intriguing examples, all of which were based on the assumption that the process had a definite beginning at some point in the distant past. If we call the beginning point $t = 0$ and we observe the process from $t = t_1$ to $t = t_2$, where $t_2 - t_1 \gg t_1$, then we might not be able to discern that the process was nonstationary. If we then assumed that the observed segment was a sample function of a stationary random process, we could estimate a power spectral density even though the actual process did not possess one. Under broad assumptions, Keshner's models yield apparent power spectra of $1/f$ form.

There have been several experimental attempts to detect nonstationarity in electronic $1/f$ noise by making repeated measurements on the same device over long periods of time, but uniformly they fail to find evidence for the kinds of mechanism postulated by Keshner (Kogan, 1996). For example, Stoisek and Wolf (1976)

prepared resistors by ion implantation, and no manifestation of nonstationarity was found for 2.5 years after the birth of the devices. Similarly, Tandon and Bilger (1976) observed a semiconductor device called a stabilitron and concluded that it remained essentially invariant for 4.5 years.

Other mechanisms A wide variety of other mechanisms have been postulated for electronic $1/f$ noise, including temperature fluctuations, surface trapping, random scattering of carriers and hopping of carriers from one site to another (van der Ziel, 1988). Each of these mechanisms is capable of limited success in explaining the behavior of certain devices, but none appears to reach the stature of a universal mechanism for this virtually universal phenomenon. Indeed, many authors assert that no single mechanism can ever account for the myriad experimental manifestations of $1/f$ noise.

12.2.4 Noise in gated integrators

In Secs. 12.1.1 and 12.1.3, we considered the effect of an RC filter on the output current from a photodiode. This circuit can be thought of as a *leaky integrator*: the charge on the capacitor builds up by integrating the current but leaks off through the resistor. As we saw in Sec. 12.1.1, the effective averaging time is $2RC$, though the averaging occurs with an exponential temporal weighting.

An alternative to the leaky RC integrator is the *gated integrator* shown in Fig. 12.13. At time $t = 0$ the electronic switch is closed briefly, shorting out the capacitor and setting its voltage to approximately zero. Then the switch is opened and the capacitor begins to integrate the current, so the mean output voltage at time t is

$$\bar{V}_{out}(t) = \frac{1}{C} \int_0^t dt' \bar{i}(t'). \quad (12.153)$$

In practice, the device is usually allowed to integrate for a fixed time t_0 , after which the output voltage is sampled and stored, and then the voltage is reset and the cycle is repeated.

Gated integrators form the basis for a number of important image detectors. It is possible, for example, to replicate the circuit of Fig. 12.13 many times on a silicon integrated-circuit chip and to bond it to a photoconductor made of some other material. Such devices are known as hybrid focal-plane arrays (*hybrid* because two materials are involved, *focal-plane* because they are often placed in the image plane of an optical system). Since the different cells on the device function independently, the analysis presented below for single-element gated integrators is directly applicable to the arrays.

Fig. 12.13 Schematic of a gated integrator.

Charge-coupled devices (CCDs) and various other video detectors can also be regarded as arrays of gated integrators. In a CCD, charge is accumulated for a fixed period in each unit cell, and then the charge signals of all cells in one row of the array are transferred to a shift-register and stepped to an output line. The charge in each cell is set approximately to zero by the transfer operation, so the basic operation of a CCD is that of a gated integrator.

Similarly, in television camera tubes such as vidicons, charge is accumulated on a photoconductive surface and read out periodically by a scanning electron beam. The beam effectively sets the charge to zero, so a vidicon too is a kind of gated integrator. In this case, however, there are no discrete cells and hence no way to identify discrete elementary circuits like Fig. 12.13.

kTC noise The mean output voltage from a single gated integrator has the form (12.153). The corresponding equation for the actual random output is

$$V_{out}(t) = V_{out}(0^+) + \frac{1}{C} \int_0^t dt' i(t'), \quad (12.154)$$

where $V_{out}(0^+)$ is the voltage immediately after the switch is opened, and $i(t)$ is the total random current (dark current, photocurrent and any noise currents that might be present).

One might think that $V_{out}(0^+)$ should be zero, but a small random voltage is required by the equipartition principle. The mean of this voltage is zero, and the variance is given by (12.64) as

$$\text{Var}\{V_{out}(0^+)\} = \frac{k_B T}{C}. \quad (12.155)$$

Since the charge on the capacitor at $t = 0^+$ is $Q(0^+) = CV_{out}(0^+)$, the charge variance corresponding to (12.155) is

$$\text{Var}\{Q(0^+)\} = C^2 \text{Var}\{V_{out}(0^+)\} = k_B T C. \quad (12.156)$$

Because of this expression, the randomness in $Q(0^+)$ is called *kTC noise*, and the same term (rather than *kT-over-C noise*) is applied to the randomness in $V_{out}(0^+)$.

Though the equipartition principle gives the right answer for the kTC noise variance, there are some puzzling aspects to it. First, the kTC noise is of thermal origin, since it vanishes if $T \rightarrow 0$, but it does not seem to be in accord with the fluctuation-dissipation theorem. Ideal capacitors are purely reactive elements and do not dissipate any power, so why should there be fluctuations associated with them? Moreover, when the capacitor is shorted out by the switch, the voltage across it should be zero, so why shouldn't it remain zero when the switch is opened?

To answer these questions, it is necessary to look in more detail at the characteristics of the switch. A switch is a device that changes its resistance from a very low value to a very high value when it is opened. For typical electronic switches, the closed resistance is 1–10 ohms and the open resistance is perhaps 10^{10} – 10^{11} ohms. This resistance is in parallel with the capacitance C , and we know from (12.19) that the bandwidth B of this combination is $(4RC)^{-1}$. The integrating capacitors used in gated integrators are quite small in order to get a large voltage for a small amount of charge. If we take $C = 0.1$ pF, then B is of order 25–250 Hz when the switch is open and 250–2500 GHz when it is closed.

In the closed state, then, the voltage is not zero because the switch is not a perfect short circuit; the voltage fluctuates at hundreds of GHz, and its variance is given by (12.155). When the switch is open, (12.155) still applies, but now the voltage fluctuates very slowly. Indeed, if the integrator is well designed, there should be negligible discharging of the capacitor during one integration period, so this period sets the time scale for the voltage fluctuations. Opening the switch does not change the noise variance but instead freezes in a value that will remain constant for the integration period. During the next integration period, a different value will be frozen in. Since the fluctuations are so rapid in the closed state, the values during successive integration periods are statistically independent.

Correlated double sampling There is a simple way to suppress kTC noise. Suppose the output voltage is sampled twice per integration cycle, once just after a reset ($t = 0^+$) and once just before the next reset ($t = t_0^-$). Both of these voltages can be stored either digitally or on additional capacitors. Since there is very little decay of the initial voltage during the integration period, the first of these voltages is $V_1 = V_{out}(0^+)$ and the second, V_2 , is given by (12.154). If we take the difference, $V_2 - V_1$, the kTC noise disappears and only the desired integrated current remains. We can effectively remove the kTC noise because it is so highly correlated between the two sample points.

Dark current The gated integrator, like any integrator used with a photoconductor, must integrate dark current as well as photocurrent. If we integrate for a time T , the mean output voltage from dark current is $-(e/C)a_{dark}T$ and the variance, under the usual Poisson model, is $(e/C)^2a_{dark}T$. Since kTC noise and dark current are statistically independent, this variance component is just added to (12.155).

12.2.5 Arrays of noisy photodetectors

So far we have considered single photodetectors, but in imaging applications we usually have imaging detectors, often in the form of regular arrays. In that case the detector performance cannot be summarized by a single number such as DQE; instead the characteristics must be stated as a function of spatial position or spatial frequency.

As a simple example, consider a $J \times J$ array of contiguous gated integrators with center-to-center spacing of ϵ and area ϵ^2 . Thus $J = L/\epsilon$, where L is the width of the array, and the total number of detectors is $M = J^2$. The easiest way to characterize the noise properties of this array is in terms of the mean vector and covariance matrix for its output. We have already discussed this problem in detail in Sec. 11.2 for the case where each element is an ideal photon counter, and now we need to extend the discussion to include the additional noise sources introduced above.

To do so, we write the output of the m^{th} detector as a sum of two random variables,

$$g_m = g_m^{(phot)} + \delta g_m, \quad (12.157)$$

where $g_m^{(phot)}$ results from photon absorption and δg_m is the contribution from dark current, Johnson noise and other noise sources. In many real detector arrays, the elements are electrically and optically isolated, so photons absorbed in one element

have no influence on neighboring elements and any excess noise is statistically independent from element to element. With this assumption the elements of $\delta\mathbf{g}$ are independent, and the covariance matrix of this term is diagonal. If we further assume that the detector elements are identical, then

$$\mathbf{K}_{\delta\mathbf{g}} = \sigma_{exc}^2 \mathbf{I}, \quad (12.158)$$

where \mathbf{I} is the $M \times M$ unit matrix and σ_{exc}^2 is the variance of the excess noise in each element.

Moreover, with the exception of trapping noise discussed in Sec. 12.1.3, all of the excess noise sources presented so far in this chapter are independent of the photon flux, so $\delta\mathbf{g}$ is independent of $\mathbf{g}^{(phot)}$. With this restriction, the overall covariance matrix is given by

$$\mathbf{K}_{\mathbf{g}} = \mathbf{K}_{\mathbf{g}}^{(phot)} + \mathbf{K}_{\delta\mathbf{g}}. \quad (12.159)$$

The first term, $\mathbf{K}_{\mathbf{g}}^{(phot)}$, is just what we computed in Sec. 11.2. We know from that discussion that $\mathbf{K}_{\mathbf{g}}^{(phot)}$ is diagonal for a Poisson source, but it can be non-diagonal if we consider random fluence or other non-Poisson effects.

Frequency-domain descriptions The covariance matrix is a complete description of the second-order statistics of a random vector. When the random vector is produced by a regular detector array, however, many authors apparently feel an impulse to invoke a Fourier description. We know from Chaps. 7 and 8 that Fourier descriptions are useful for signals and systems that exhibit translational invariance, and an array of identical detectors looks almost the same when it is shifted by one element, so one might expect a Fourier transform to do something useful; there are several reasons why this expectation might be forlorn.

First, the apparent translational invariance is discrete rather than continuous, so a discrete Fourier transform must be used instead of a Fourier integral. Second, the array is not really invariant to a shift by an integer number of elements since it has finite extent; the only way to get any kind of invariance is to assume that the array wraps around cyclically when shifted (see Sec. 8.2.8). Third, even if we assume that the array itself has this unphysical cyclic property, it does not follow that the noise covariance does; we saw in Chap. 11 that a nonuniform photon fluence leads to nonstationary noise. Finally, to get something like an SNR or DQE in the frequency domain, we must pick a frequency of interest, and a discrete DFT contains only a discrete set of frequencies even though the actual continuous fluence pattern incident on the detector is not so constrained.

We shall return to the topic of DQE in the spatial-frequency domain in Sec. 13.2.9, and we shall deal specifically with some of the problems associated with discrete spatial frequencies in Sec. 16.1 when we discuss digital radiography.

12.3 X-RAY AND GAMMA-RAY DETECTORS

Though x rays and gamma rays are electromagnetic radiation like visible light, the crucial difference is that the energy per photon is much higher. While a photoelectric interaction of visible light in a semiconductor detector, for example, produces a single electron-hole pair, thousands of such pairs are produced in each x-ray or gamma-ray interaction.

A more subtle issue concerns the rate of arrival of photons. In almost all gamma-ray imaging systems in nuclear medicine or gamma-ray astronomy, the average interval between photons is large compared to the resolving time of the electronics, so it is possible to count individual photons. In medical radiography, on the other hand, a relatively short exposure is made with a high flux of x rays, so the individual photons are usually not temporally resolved. When talking about x rays and gamma rays, therefore, we need to distinguish *photon-counting detectors* from *integrating detectors*, the latter term implying that only the integrated effect of many photons is observed.

In Sec. 12.3.1 we review the basic physics of the interaction of high-energy photons with a detector material; readers conversant with these processes can skip to the next section without loss of continuity.

In Sec. 12.3.2 we analyze single-element, photon-counting semiconductor detectors in detail, building on the discussion of optical semiconductor detectors in Sec. 12.1.2.

The discussion of imaging detectors begins in Sec. 12.3.3 with an analysis of photon-counting semiconductor detector arrays. This discussion continues in Sec. 12.3.4, where we show how techniques from estimation theory can be used to get better information about the position and energy of gamma-ray photons. This section and much of the remainder of the chapter presumes some acquaintance with maximum-likelihood estimation, a topic to be treated in detail in Sec. 13.3.4.

Section 12.3.5 discusses photon-counting scintillation detectors, especially the Anger camera, which has been the mainstay of nuclear medicine since the 1950s, and Sec. 12.3.6 treats estimation of photon energy and interaction position in these devices. Then in Sec. 12.3.7 we discuss the statistical properties of images formed from these position and energy estimates.

In Sec. 12.3.8 we discuss integrating detectors of the kind that might be used in digital radiography. This treatment builds heavily on the theory of amplified random processes from Sec. 11.4.

Finally, in Sec. 12.3.9 we discuss the effects that arise specifically in x-ray and gamma-ray detectors when the energy from one incident photon is deposited at two distinct locations due to K x-ray emission or Compton scattering. This section also builds on basic principles developed in Chap. 11, and it should serve to deepen the reader's understanding of random point processes.

12.3.1 Interaction mechanisms

A full understanding of the detection of x rays and gamma rays must take into account the mechanisms by which they interact with the detector material. For the energy range of interest in medical applications, there are two main processes for the initial interaction: *photoelectric absorption* and *Compton scattering*. There is also an elastic scattering mechanism at relatively low energies called *Rayleigh scattering*, and at high energies (above 1 MeV) gamma rays can produce positron-electron pairs, but we shall ignore both of these effects in this discussion.

Many of the interesting properties of x-ray and gamma-ray detectors arise from secondary interactions that take place after the initial photoelectric or Compton event. For example, a high-energy photoelectron or Compton electron can produce many electron-hole pairs in a semiconductor, or it can excite luminescent centers in a scintillator. We then need to understand how these secondary excitations are

distributed spatially and how they result in a detector output. Moreover, the initial interaction events will usually result in secondary high-energy photons as well as electrons, and these photons can also produce electron-hole pairs or excite luminescent centers.

We shall discuss these processes in this section to the extent needed to understand the characteristics of image detectors. Some background material relevant to this section has already been presented in Chap. 10. In particular, the reader is assumed to be familiar with the physics of photoelectric interactions (Sec. 10.1.4) and Compton scattering (Sec. 10.3.7) and with the concept of a cross section (Sec. 10.2.5).

Photoelectric interactions A photoelectric interaction is one in which a photon is absorbed by an electron, the photon disappearing completely in the process and the electron acquiring some kinetic energy. These interactions cannot occur with free electrons since momentum would not be conserved in that case. A photon of energy \mathcal{E}_0 has momentum \mathcal{E}_0/c , and a free electron at rest has zero momentum. If the photon energy is transferred to the electron, it will have kinetic energy $\mathcal{E}_{kin} = \frac{1}{2}mv^2 = \mathcal{E}_0$, where v is the speed of the electron after the interaction and m is its mass. Since momentum $p = mv$ for an electron, it will then have momentum $\sqrt{2\mathcal{E}_0m}$ rather than \mathcal{E}_0/c , so we cannot simultaneously conserve energy and momentum in photoelectric absorption by a free electron.

If the electron is bound to an atom, however, then any excess momentum can be transferred to motion of the atom. The atom is much heavier than an electron, so when it carries away momentum Δp , it acquires only a very small energy $\Delta p^2/2M_a$, where M_a is the mass of the atom. To a good approximation, therefore, we can neglect the energy transferred to the atom and write the kinetic energy of the photoelectron as

$$\mathcal{E}_{kin} = \mathcal{E}_0 - \mathcal{E}_b, \quad (12.160)$$

where \mathcal{E}_b is the initial binding energy of the electron to the atom.

The photon \mathcal{E}_0 is typically in the range 10–100 keV for x rays used in diagnostic radiology and up to 500 keV or so for the gamma rays used in nuclear medicine. The binding energy \mathcal{E}_b depends on the type of atom and the specific energy level. Photoelectric interactions have higher cross sections for more tightly bound electrons, so the dominant interaction is usually with the innermost electron shell, called the *K shell* in x-ray parlance. As an example, iodine is a constituent of scintillation materials such as NaI or CsI, and the K-shell binding energy of iodine is about 35 keV. Thus if a photon of energy 140 keV (a common energy in nuclear medicine) is absorbed by photoelectric interaction with a K-shell electron in iodine, the electron gains a kinetic energy of about 105 keV.

Compton interactions As discussed in Sec. 10.3.7, Compton scattering is the process by which a photon scatters inelastically from a free (or loosely bound) electron. Suppose the electron is initially at rest and a photon of initial energy \mathcal{E}_0 scatters through an angle θ_s . Energy and momentum are conserved if the photon energy \mathcal{E} after interaction is given by (10.226) and the electron acquires an energy $\mathcal{E}_0 - \mathcal{E}$.

Numerically, we saw in Sec. 10.3.7 that 45° scattering of a 140 keV photon gives a scattered photon of energy 129.6 keV, 90° scattering gives 109.9 keV and 180° scattering gives 90.4 keV. The corresponding energies for the Compton electrons are 11.4 keV, 30.1 keV and 49.6 keV, respectively.

Secondary photons Both photoelectric interactions and Compton interactions produce high-energy electrons, and Compton scattering also leaves a high-energy scattered photon. In fact, secondary photons are also produced in photoelectric interactions. Let us suppose, as in the example above, that a photon of energy \mathcal{E}_0 greater than 35 keV is absorbed by a K-shell electron in iodine. This process leaves a vacancy in the K shell that can be filled by a transition of an electron from some higher shell into the K shell. The most probable occurrence is that the transition is from the next higher shell, called the L shell (see Fig. 12.14). This transition results in the emission of an x-ray photon of energy corresponding to the difference in energies of the two shells. This photon, called a K_α x ray, has an energy of about 28 keV in iodine. If the K-shell vacancy is filled by a transition from the next higher level, the M shell, then the photon is called a K_β x ray and has energy about 30 keV.

Of course, the process does not stop there. The transition from, say, the L shell to the K shell leaves a vacancy in the L shell. That vacancy can be filled by a transition from the M shell, yielding a photon of energy around 2 keV, called an L_α x ray. Often we ignore such low energy photons since they are reabsorbed very near the point of emission, but the K x rays can play a significant role in detector performance.

Fig. 12.14 Processes involved in production of a K x ray following absorption of a 140 keV photon in iodine.

Two things can happen to a K x ray when it is produced after a photoelectric interaction: it can interact within the material or it can escape from the volume of the material without interacting. If it interacts within the material, it can do so by either a Compton or photoelectric interaction. In either case, another energetic electron will be produced and another photon. Similarly, if the initial interaction is Compton scattering, the scattered photon can either escape the material or interact within it, and in the latter case the interaction can be either Compton or photoelectric. Accounting for all events in this complex cascade is difficult; usually the best approach is Monte Carlo simulation.

High-energy electrons As we have just seen, an initial interaction, either Compton or photoelectric, results in one or more energetic electrons in the material. If the material is to be used as a detector, we must sense the effects of these electrons. How this is done depends on the type of detector. In a semiconductor detector,

some of the energy of the high-energy electrons is converted to electron-hole pairs that can eventually be sensed on external electrodes. In a scintillation detector, some of the energy of the high-energy electrons is converted to light which we can detect with ordinary optical detectors. In either case, the characteristics of the detector depend on the fraction of the energy converted to a useful form, its spatial distribution, and its statistics.

The major interaction mechanisms for a high-energy electron in a solid are scattering by other free electrons, emission or absorption of phonons (lattice vibrations), and ionization of the lattice via creation of electron-hole pairs. Since detector materials are typically good insulators, there are very few free electrons, and we can concentrate on the two competing processes of electron-phonon interactions and lattice ionization.

We do not need to study these processes in detail here, but a useful mental image is that the electron travels a tortuous path from the point of interaction, generating phonons and electron-hole pairs in its wake. The energy loss along this path is approximately uniform, so a relatively uniform cloud of low-energy electrons and holes is produced. The size of this cloud is roughly $20\ \mu\text{m}$ for a 100 keV electron. In a scintillator, there is another step in which the low-energy electrons are trapped in luminescent centers and eventually recombine with holes and emit optical photons.

12.3.2 Photon-counting semiconductor detectors

Having sketched the process of production of electron-hole pairs following an initial interaction of an x ray or gamma ray, we can now begin to develop more detailed statistical descriptions of the detector output, taking into account charge transport and induction of measurable signals in an external circuit. The basic principles we need for this purpose were developed in Secs. 12.1.2 and 12.1.3 in the context of optical semiconductor detectors, but there are some new complications when x rays and gamma rays are involved.

First, x-ray and gamma-ray detectors must be thick enough to absorb the radiation; it is common to use thicknesses from 1 mm to 1 cm or more, as opposed to $1-10\ \mu\text{m}$ which will suffice for optical detectors. A result of the increased thickness is that trapping effects may be much more severe in semiconductor x-ray and gamma-ray detectors than in optical ones. Moreover, it is quite common for one type of charge carrier (usually holes) to be trapped much more strongly than the other. As we shall see, the combined effect of the random depth of interaction and the strong trapping plays a key role in the detector statistics.

In a semiconductor photodiode for optical use, the material initially has fairly low resistivity, but a thin, high-resistivity depletion region is formed by a P-N junction, and it is this region that is sensitive to light. In a well-designed gamma-ray detector, on the other hand, the whole volume has high resistivity and hence is sensitive to photons. It is perhaps more accurate to refer to gamma-ray detectors as semi-insulators rather than semiconductors.

Finally, because we can detect individual photons, we may ask for more information from each one. Often we want to know not only the position of a photon but also its energy. For example, in nuclear medicine we usually use a radioisotope that emits only a single photon energy, but photons may undergo Compton scatter in the patient's body and arrive at the detector with a reduced energy; it is important to be able to recognize and reject these scattered photons since they convey relatively

little useful information about the object. In some applications — notably positron emission tomography — we also want to estimate the time of arrival of a photon to high precision.

Problem statement Throughout this section we shall consider a single-element (nonimaging) detector in the same configuration as in Sec. 12.1.3, a slab of dimensions $L_x \times L_y \times L_z$, with $L_x, L_y \gg L_z$. Even though L_z is small compared to the lateral dimensions, we shall assume that it is large compared to the dimensions of the charge cloud produced by a gamma-ray absorption; typical sizes might be a charge cloud of 20 μm , a slab thickness of 1–2 mm and lateral dimensions of 1 cm. The electrodes are on the faces $z = 0$ and $z = L_z$, and the photons are incident in the $+z$ direction. The material has homogeneous resistivity (no P-N junction), so a potential difference V_0 between the electrodes establishes a uniform field $E_0 = V_0/L_z$ in the material. Holes drift toward the cathode and electrons toward the anode, with each carrier having some probability of being trapped *en route*.

As we know from Sec. 12.1.3, a moving charge carrier will induce a current pulse in the external circuit even if it is trapped before reaching the electrode. In common practice, this current pulse is integrated with a leaky integrator having a time constant that is large compared to the duration of the current pulse. If the time interval between pulses is large compared to this time constant, then each absorbed gamma ray produces a distinct output pulse, and the amplitude of the pulse is proportional to the total induced charge for that photon. The distribution of output signals for a large number of incident photons is called the *pulse-height spectrum*. Except for normalization, the pulse-height spectrum is the univariate probability density function for the charge induced by a single absorbed gamma ray.

The random variables contributing to the pulse-height spectrum are the depth of interaction z_{int} , the initial number of electron-hole pairs N_{eh} , and the distances travelled by each electron and hole under the influence of the field. In addition, we need to know the probability that the initial interaction is photoelectric vs. Compton, the probability that a K x ray or Compton-scattered photon will escape the detector volume, and if not, the probability density on where it will be reabsorbed. From knowledge of the statistics of these variables, we would first like to compute the pulse-height spectrum. Then, from knowledge of the spectrum, we would like to set some criterion for acceptance of photons and to compute the statistics on the number accepted.

The initial interaction Consider a beam of gamma rays travelling in the $+z$ direction, entering the detector at $z = 0$. The probability density function that an incident gamma ray interacts at $z = z_{int}$ is

$$\text{pr}(z_{int}) = \alpha_{tot} \exp[-\alpha_{tot} z_{int}], \quad (12.161)$$

where α_{tot} is the total attenuation coefficient⁸ including contributions from the Compton and photoelectric effects:

$$\alpha_{tot} = \alpha_C + \alpha_{pe}. \quad (12.162)$$

⁸In Chap. 10, attenuation coefficients were denoted by μ , but we use α here to avoid confusion with mobility.

Since we are considering only two types of interaction, the probability that the initial interaction is photoelectric is α_{pe}/α_{tot} and the probability that it is Compton is α_C/α_{tot} .

The probability that an interaction occurs at all in a detector of thickness L_z is

$$\Pr(\text{int in } L_z) = \int_0^{L_z} dz_{int} \text{pr}(z_{int}) = 1 - e^{-\alpha_{tot}L_z}. \quad (12.163)$$

If we consider only the gamma rays that undergo an interaction in the detector, the probability density function on their interaction depths is

$$\text{pr}(z_{int}|\text{int in } L_z) = \frac{\text{pr}(z_{int})}{\Pr(\text{int in } L_z)} = \frac{\alpha_{tot} \exp(-\alpha_{tot}z_{int})}{1 - \exp(-\alpha_{tot}L_z)}. \quad (12.164)$$

Probability law for N_{eh} As noted above, generation of electron-hole pairs by a high-energy electron is a competition between phonon emission and lattice ionization. The minimum energy required to generate a pair is the bandgap energy \mathcal{E}_g , so an electron of kinetic energy \mathcal{E}_{kin} could in principle produce $\mathcal{E}_{kin}/\mathcal{E}_g$ pairs, but because of the competing process of phonon generation, a smaller number will be produced on average. We can define the mean energy expended per electron-hole pair, \mathcal{E}_{eh} , such that the mean number of pairs is

$$\overline{N}_{eh} = \frac{\mathcal{E}_{kin}}{\mathcal{E}_{eh}}. \quad (12.165)$$

The distribution of N_{eh} about its mean is interesting. If there were no competition from phonon generation or other mechanisms, conservation of energy would require that $N_{eh} = \mathcal{E}_{kin}/\mathcal{E}_g$, which is not a random number at all. At the opposite extreme, if the phonon interaction were so strong that only a small fraction of the electron energy went into creation of electron-hole pairs, the pairs would be generated approximately independently, and N_{eh} would therefore be a Poisson random variable (see the discussion of Poisson and rarity in Sec. 11.1.2).

Thus the variance of N_{eh} should fall between 0, for a material where the electron-phonon interaction is very weak, and \overline{N}_{eh} , for a material where the interaction is strong. This problem was first studied by Ugo Fano (1947), and we define the *Fano factor* F as

$$F = \frac{\text{Var}(N_{eh})}{\overline{N}_{eh}}. \quad (12.166)$$

A value of $F < 1$ implies sub-Poisson behavior, and that is indeed observed experimentally. In Si and Ge, measurements of F are in the range 0.07 to 0.15.

The full probability law $\Pr(N_{eh})$ is difficult to compute but fortunately not very important. If N_{eh} were a Poisson random variable with mean of order 10^4 , we would not hesitate to approximate it by a Gaussian; with the actual sub-Poisson character, we can do the same, writing

$$\Pr(N_{eh}) \simeq \frac{1}{\sqrt{2\pi F \overline{N}_{eh}}} \exp\left[-\frac{(N_{eh} - \overline{N}_{eh})^2}{2F \overline{N}_{eh}}\right]. \quad (12.167)$$

To make contact with Sec. 11.3.1, we note that $\Pr(N_{eh})$ is what we called $\Pr(K|N=1)$ or $\gamma(K)$ there. The moments m_1 and m_2 are now \overline{N}_{eh} and $F\overline{N}_{eh} + \overline{N}_{eh}^2$, respectively.

Drift and diffusion If a photon of energy \mathcal{E}_0 is absorbed photoelectrically, then N_{eh} electron-hole pairs are generated in a compact cloud around the interaction point, and $\bar{N}_{eh} = (\mathcal{E}_0 - \mathcal{E}_b)/\mathcal{E}_{eh}$. Additional pairs may be generated at another location by reabsorption of a K x ray, but for now we focus on this initial charge cloud. There are three forces acting on the charges in the cloud: Coulomb forces between charges, the applied electric field, and random forces from interactions of the charges with lattice vibrations.

The Coulomb forces are initially small since there is a cloud of electrons interspersed with an equal and oppositely charged cloud of holes, but as the two clouds separate, self-repulsion may come into play. Nevertheless, we shall neglect this effect here since the resultant field is usually small compared to the applied field (Marks, 2000). The total field is then approximately the applied field V_0/L_z .

Interactions of the charge carriers with phonons have two effects. As discussed in Sec. 12.1.2, one effect is to create a viscous drag so that the carriers quickly reach a terminal or drift velocity given by the mobility times the field. The other effect is that the carriers acquire a random, zero-mean thermal velocity superimposed on the drift velocity. The effect of this thermal motion is that the carriers can diffuse radially outward from the (moving) center of the cloud, so the electrons comprise a fuzzy ball of charge moving uniformly towards the anode and increasing in radius as it moves. The holes form a similar fuzzy ball moving at a different speed toward the cathode.

The initial radius of the fuzzy ball is approximately the range of the photoelectron, of order $20 \mu\text{m}$ for a 100 keV electron in a typical detector material. To see the effects of diffusion, we neglect this initial radius and suppose that a pointlike distribution of charge is created at $t = 0$. With this assumption, we know from (12.102) that the radius of the distribution at time t is $\sqrt{6Dt}$, where D is the diffusion coefficient.

To estimate how large the ball can get, we need to know D and the maximum time available for diffusion; an important link between these two parameters is provided by the Einstein relation, (12.103). The largest distance either carrier can drift is L_z , so the maximum drift time is

$$t_{\max} = \frac{L_z}{\mu E_0} = \frac{L_z^2}{\mu V_0}, \quad (12.168)$$

where μ is either μ_e or μ_h . With the Einstein relation and a little algebra, we have

$$\sqrt{6Dt_{\max}} = L_z \sqrt{\frac{6k_B T}{eV_0}}. \quad (12.169)$$

Note that no specific material properties enter into this result. Materials with higher mobility have smaller t_{\max} but larger diffusion coefficients, so the radius of the charge cloud after drifting the full thickness of the detector is independent of the mobility.

As a numerical example, if we consider a 1 mm thick detector with 100 Volts bias at room temperature, then $\sqrt{6Dt_{\max}} = 38 \mu\text{m}$. Since this number is small compared to typical detector dimensions, we shall ignore the diffusion for the remainder of this section.

Trapping As the carriers drift, they may be captured by localized defects known as traps (see Sec. 12.1.2). The trapped carriers will eventually be released (detrapped)

by thermal excitation, but this process usually takes a very long time compared to the duration of the current pulse generated by a single photon, so we shall neglect detrapping here; once a carrier has been trapped, it disappears (at least from our theory).

We know from (12.30) that hole trapping occurs at a constant rate determined by the hole lifetime τ_h , and similarly for electrons, so the mean number of carriers diminishes exponentially with time. Since the carriers are drifting at a constant velocity, the mean number also diminishes exponentially along the drift path, and the probability of an individual carrier surviving for a distance d without being trapped decays exponentially with d .

Specifically, the probability of a hole not being trapped after traveling a distance d_h is

$$\Pr(\text{no trapping in } d_h) = e^{-d_h/\lambda_h}, \quad (12.170)$$

where λ_h is the *hole drift length*, given by

$$\lambda_h = \mu_h E_0 \tau_h. \quad (12.171)$$

Similar relations exist for electrons, of course, but we shall continue to discuss holes for definiteness.

Next we need an expression for the probability density function for a hole being trapped at distance d_h from the interaction point. Note that we are taking d_h as a positive number even though the hole is travelling in the $-z$ direction, so the maximum value for d_h is the interaction depth z_{int} . For $d_h < z_{int}$, the probability density on d_h is given by analogy to (12.161) as $\lambda_h^{-1} \exp(-d_h/\lambda_h)$, but we also have to consider what happens when the hole strikes the cathode.

If the cathode contact is ohmic, then it is possible that a compensating hole will be injected at the anode when the initial hole hits the cathode, and then a photoconductive gain will ensue [see (12.123)]. More commonly, however, the cathode contact will be such that there is a very high probability that the hole will be trapped (and eventually recombine) when it hits the cathode. In that case, the overall PDF for trapping at d_h must include a delta function at $d_h = z_{int}$. The weight of this delta function is just the probability that the hole makes it to the cathode, $\exp(-z_{int}/\lambda_h)$, so the desired PDF is⁹

$$\begin{aligned} \text{pr}(d_h) &= e^{-z_{int}/\lambda_h} \delta(d_h - z_{int}) + \frac{1}{\lambda_h} e^{-d_h/\lambda_h} \\ &= e^{-d_h/\lambda_h} \left[\delta(d_h - z_{int}) + \frac{1}{\lambda_h} \right]. \end{aligned} \quad (12.172)$$

The mean and variance of d_h (conditional on the interaction depth z_{int}) can be computed from this density as

$$E\{d_h|z_{int}\} = \lambda_h \left[1 - e^{-z_{int}/\lambda_h} \right], \quad (12.173)$$

$$\text{Var}\{d_h|z_{int}\} = \lambda_h^2 - 2\lambda_h z_{int} e^{-z_{int}/\lambda_h} - \lambda_h^2 e^{-2z_{int}/\lambda_h}. \quad (12.174)$$

⁹The normalization of this density is correct on the interval $0 \leq d_h \leq z_{int} + \epsilon$, where ϵ is a vanishingly small positive quantity. Alternatively, we could multiply the second term by a rect function that is nonzero on the interval $0 \leq d_h \leq z_{int}$, and then the normalization would work on $0 \leq d_h < \infty$.

The corresponding results for electrons are obtained by changing subscript h to e throughout and changing z_{int} to $L_z - z_{int}$.

Conditional PDF of the induced charge By integrating the expression for $i_0(t)$ in (12.51), we see that the random charge induced in the circuit by a single electron-hole pair (say the j^{th}) is

$$Q_j = -\frac{e}{L_z}(d_{hj} + d_{ej}), \quad (12.175)$$

where the electron has travelled a distance d_{ej} and the hole d_{hj} . An assemblage of N_{eh} pairs generated by a single gamma-ray interaction at depth z_{int} thus induces a pulse with total charge Q given by

$$Q = -\frac{e}{L_z} \sum_{j=1}^{N_{eh}} (d_{hj} + d_{ej}). \quad (12.176)$$

We know the probability laws for N_{eh} , z_{int} , d_{hj} and d_{ej} , so we are ready to study the statistics of Q (that is, to compute the pulse-height spectrum). As a first step, we shall compute the conditional PDF of Q for fixed z_{int} and N_{eh} .

Recall that N_{eh} is a large number, of order $10^4 - 10^5$, so Q is a sum of a large number of random variables. Since the trapping events are independent, the central-limit theorem (see Sec. 8.3.4) tells us that the conditional PDF is

$$\text{pr}(Q|z_{int}, N_{eh}) = \frac{1}{\sqrt{2\pi\sigma_Q^2}} \exp \left[-\frac{[Q - \bar{Q}(z_{int}, N_{eh})]^2}{2\text{Var}\{Q|z_{int}, N_{eh}\}} \right], \quad (12.177)$$

where the conditional mean and variance are

$$\bar{Q}(z_{int}, N_{eh}) = -\frac{e}{L_z} N_{eh} [E\{d_h|z_{int}\} + E\{d_e|z_{int}\}], \quad (12.178)$$

$$\text{Var}\{Q|z_{int}, N_{eh}\} = \left(\frac{e}{L_z}\right)^2 N_{eh} [\text{Var}\{d_h|z_{int}\} + \text{Var}\{d_e|z_{int}\}]. \quad (12.179)$$

With (12.173) and the similar expression for electrons, we can also express the conditional mean of the induced charge via the *Hecht relation*,

$$\bar{Q}(z_{int}, N_{eh}) = -\frac{e}{L_z} N_{eh} \left\{ \lambda_h \left[1 - e^{-z_{int}/\lambda_h} \right] + \lambda_e \left[1 - e^{-(L_z - z_{int})/\lambda_e} \right] \right\}. \quad (12.180)$$

Some limits of this expression are instructive. If λ_e and λ_h are both large compared to L_z , as they usually are in Si or Ge detectors, then an expansion of the exponentials shows that

$$\bar{Q}(z_{int}, N_{eh}) \rightarrow -\frac{e}{L_z} N_{eh} \left\{ \lambda_h \frac{z_{int}}{\lambda_h} + \lambda_e \frac{L_z - z_{int}}{\lambda_e} \right\} = -eN_{eh}. \quad (12.181)$$

In this limit, therefore, trapping is negligible and the full charge of N_{eh} electron-hole pairs appears in the external circuit.

The opposite limit is where both carriers are heavily trapped, so that λ_e and λ_h both approach zero. In this case,

$$\bar{Q}(z_{int}, N_{eh}) \rightarrow -eN_{eh} \frac{\lambda_h + \lambda_e}{L_z}. \quad (12.182)$$

Much less charge is induced in this case, but both (12.181) and (12.182) show that the induced charge is independent of z_{int} . Unfortunately, that conclusion does not hold in the intermediate cases.

Suppose, for example, that holes are heavily trapped and electrons are not, so that $\lambda_h \ll L_z$ and $\lambda_e \gg L_z$ (which is often a realistic assumption in compound semiconductors such as CdTe). In the limit as $\lambda_h \rightarrow 0$,

$$\bar{Q}(z_{int}, N_{eh}) \rightarrow -eN_{eh} \frac{L_z - z_{int}}{L_z}. \quad (12.183)$$

In this case, the average induced charge depends linearly on the random depth of interaction; as we shall see shortly, this randomness smears out the pulse-height spectrum.

Effect of carrier-generation statistics The desired overall PDF for Q is given by

$$\begin{aligned} \text{pr}(Q) &= \int_0^{L_z} dz_{int} \text{pr}(z_{int}) \text{pr}(Q|z_{int}) \\ &= \int_0^{L_z} dz_{int} \text{pr}(z_{int}) \sum_{N_{eh}=0}^{\infty} \text{Pr}(N_{eh}) \text{pr}(Q|z_{int}, N_{eh}). \end{aligned} \quad (12.184)$$

We have approximated $\text{pr}(Q|z_{int}, N_{eh})$ by a normal in (12.177), and in (12.167) we also approximated $\text{Pr}(N_{eh})$ by a normal. Since N_{eh} is very large, we can replace the sum over N_{eh} with an integral, and then we have a convolution¹⁰ of two normals, which is another normal. To specify $\text{pr}(Q|z_{int})$ in this approximation, therefore, we need only compute the mean and variance of Q conditional on z_{int} alone.

The mean of Q conditioned on z_{int} is obtained by averaging (12.178) over N_{eh} , with the result

$$E\{Q|z_{int}\} = -\frac{e}{L_z} \bar{N}_{eh} [E\{d_h|z_{int}\} + E\{d_e|z_{int}\}] \equiv -\frac{e}{L_z} \bar{N}_{eh} \bar{d}_{eh}, \quad (12.185)$$

where \bar{d}_{eh} is the mean total distance travelled by a single hole and electron. (Recall that d_e and d_h are both positive numbers, even though the carriers travel in opposite directions.)

The procedure for computing $\text{Var}(Q|z_{int})$ is first to compute the second moment, then to subtract off the square of the relevant mean. A similar procedure was used several times in Sec. 11.4 for discussing random amplification, but that problem should not be confused with the present one. In Sec. 11.4, the double randomness came about since a random number of primaries each generated a random number of identical secondaries. Here we are concerned with a single primary, and the secondaries are not identical since they induce random amounts of charge in the output.

¹⁰The reader who wishes to fill in the details of this calculation will discover that it is necessary to replace N_{eh} with \bar{N}_{eh} in (12.179), but this step is easily justified since $\text{Pr}(N_{eh})$ is sharply peaked.

From (12.178) and (12.179), the second moment of interest is

$$\begin{aligned}
 E\{Q^2|z_{int}\} &= \frac{e^2}{L_z^2} \left\{ \langle N_{eh} \rangle [\text{Var}\{d_h|z_{int}\} + \text{Var}\{d_e|z_{int}\}] + \langle N_{eh}^2 \rangle \bar{d}_{eh}^2 \right\} \\
 &= \frac{e^2}{L_z^2} \left\{ \bar{N}_{eh} [\text{Var}\{d_h|z_{int}\} + \text{Var}\{d_e|z_{int}\}] + [F\bar{N}_{eh} + \bar{N}_{eh}^2] \bar{d}_{eh}^2 \right\}, \quad (12.186)
 \end{aligned}$$

where we have used (12.166). The desired variance is now

$$\text{Var}\{Q|z_{int}\} = \frac{e^2}{L_z^2} \bar{N}_{eh} \left[\text{Var}\{d_h|z_{int}\} + \text{Var}\{d_e|z_{int}\} + F\bar{d}_{eh}^2 \right]. \quad (12.187)$$

With these expressions for the mean and variance, the overall PDF $\text{pr}(Q)$ is given by

$$\text{pr}(Q) = \int_0^{L_z} dz_{int} \text{pr}(z_{int}) \frac{1}{\sqrt{2\pi \text{Var}\{Q|z_{int}\}}} \exp \left[-\frac{[Q - E\{Q|z_{int}\}]^2}{2 \text{Var}\{Q|z_{int}\}} \right]. \quad (12.188)$$

All of the pieces needed for a numerical computation of $\text{pr}(Q)$ with arbitrary trapping are in place; the key equations are (12.164), (12.173), (12.174), (12.185), (12.187) and (12.188), and only a 1D integral is needed. This procedure can be used to study the pulse-height spectrum as a function of material parameters, bias voltage and photon energy, but more insight can be obtained by developing approximate analytic expressions. We shall do so for various assumptions about the degree of trapping.

Pulse-height spectrum when trapping is negligible As we saw in (12.181), \bar{Q} is independent of z_{int} in the limit that trapping is negligible for both carriers, as in Si and Ge. The variances of the drift lengths, $\text{Var}\{d_h|z_{int}\}$ and $\text{Var}\{d_e|z_{int}\}$, also go to zero in this limit, as one can see physically by noting that the drift length for holes approaches its maximum value of z_{int} and the one for electrons approaches $L_z - z_{int}$, and both of these quantities are nonrandom for fixed z_{int} . The same conclusion follows more formally from (12.174) and the corresponding expression for d_e by expanding the exponentials and letting λ_h and λ_e get large.

Thus, when trapping is negligible, the overall mean and variance, from (12.185) and (12.187) respectively, become

$$\bar{Q} = -e\bar{N}_{eh}, \quad (12.189)$$

$$\text{Var}\{Q|z_{int}\} = e^2 F \bar{N}_{eh}. \quad (12.190)$$

We then have $\text{pr}(Q|z_{int}) = \text{pr}(Q)$, so this quantity can be removed from the integral in (12.188), and the integral is then unity. To an excellent approximation, the PDF $\text{pr}(Q)$ for negligible trapping is thus a normal with the mean and variance specified in (12.189) and (12.190).

We can define a signal-to-noise ratio for Q as

$$\text{SNR}_Q = \frac{|\bar{Q}|}{\sqrt{\text{Var}(Q)}} = \frac{\sqrt{\bar{N}_{eh}}}{\sqrt{F}}, \quad (12.191)$$

and the sub-Poisson character of the electron-hole generation process can be seen in the denominator.

Photopeaks and energy resolution If we recall from (12.165) that $\overline{N}_{eh} = \mathcal{E}_{kin}/\mathcal{E}_{eh}$, then we see from (12.189) that (without trapping) the mean induced charge in the external circuit is proportional to the mean kinetic energy of the high-energy electron. For photoelectric events, we also know from (12.160) how the kinetic energy depends on the photon energy, but that equation does not tell the whole story. A photoelectric interaction with a K-shell electron may be followed by emission of a K x ray, and that photon may or may not be reabsorbed in the detector material; if it is, additional electron-hole pairs are created and add to the induced charge Q . The maximum Q , over all possible sequelae of a photoelectric absorption, occurs when the K x ray and all subsequent photons are reabsorbed within the detector. Then the total kinetic energy released is the photon energy \mathcal{E}_0 . Such events contribute a distinct peak, called the *photopeak*, to the pulse-height spectrum. Similarly, events where the K x ray escapes, contribute a lower peak called the *K-escape peak* (see Fig. 12.15), and peaks corresponding to the escape of other photons can often be identified as well.

Fig. 12.15 Schematic pulse-height spectrum showing K-escape peak. The lower-energy peak is centered at a pulse height corresponding to the initial gamma-ray energy minus the K x-ray energy.

Since $\overline{Q} = -e\overline{N}_{eh} = -e\mathcal{E}_0/\mathcal{E}_{eh}$ for photopeak events in a good detector material, it is natural to use the actual induced charge as an estimate of the photon energy \mathcal{E}_0 . We can define an estimated energy by

$$\hat{\mathcal{E}} \equiv -\mathcal{E}_{eh} \frac{Q}{e}, \quad (12.192)$$

and then the pulse-height spectrum can be reinterpreted as a PDF on the new random variable $\hat{\mathcal{E}}$. For all events, $\hat{\mathcal{E}}$ is an unbiased estimator of \mathcal{E}_{kin} , and for photopeak events it is an unbiased estimator of \mathcal{E}_0 . For this reason, a pulse-height spectrum is often called (quite misleadingly) an *energy spectrum*. At best, it is the distribution of *estimated* energies, and the estimate is useful only when trapping is negligible and escape peaks are ignored. We can also reinterpret SNR_Q , defined above, as an SNR for $\hat{\mathcal{E}}$; since the constant $-e/\mathcal{E}_{eh}$ affects numerator and denominator in the same way, we have

$$\frac{\langle \hat{\mathcal{E}} \rangle}{\sqrt{\text{Var}(\hat{\mathcal{E}})}} = \text{SNR}_Q = \frac{\sqrt{\overline{N}_{eh}}}{\sqrt{F}}. \quad (12.193)$$

For photopeak events where $\langle \hat{\mathcal{E}} \rangle = \mathcal{E}_0$, we can write

$$\frac{\sqrt{\text{Var}\{\hat{\mathcal{E}}\}}}{\mathcal{E}_0} = \sqrt{F} \sqrt{\frac{\mathcal{E}_{eh}}{\mathcal{E}_0}}. \quad (12.194)$$

Thus the precision of the energy estimate is better for higher-energy photons and for detector materials with smaller Fano factor and smaller average energy per electron-hole pair.

It is almost universal in the literature to quote the energy resolution as the full-width at half maximum (FWHM) of the photopeak divided by the center position of the photopeak. This ratio is usually denoted $\Delta\mathcal{E}/\mathcal{E}$ (ignoring the fact that the \mathcal{E} in question is an estimate, not an actual energy). As we have seen, Q and hence \mathcal{E} are normally distributed in the absence of trapping, and the FWHM of a normal is 2.35 times its standard deviation, so $\Delta\mathcal{E}/\mathcal{E}$ is 2.35 times the expression in (12.194).

Strong trapping of both carriers If both carriers are heavily trapped, so that λ_h and λ_e approach zero, we see from (12.182) that \bar{Q} is again independent¹¹ of z_{int} , and we have

$$\bar{Q} = -e \frac{\lambda_h + \lambda_e}{L_z} \bar{N}_{eh}. \quad (12.195)$$

Similarly, we see from (12.174) that $\text{Var}\{d_h|z_{int}\} \rightarrow \lambda_h^2$ and $\text{Var}\{d_e|z_{int}\} \rightarrow \lambda_e^2$ in this limit, so the variance of Q from (12.187) becomes

$$\text{Var}\{Q\} = \frac{e^2}{L_z^2} \bar{N}_{eh} [\lambda_h^2 + \lambda_e^2 + F(\lambda_h + \lambda_e)^2]. \quad (12.196)$$

The SNR on Q is now

$$\text{SNR}_Q = \sqrt{\bar{N}_{eh}} \frac{\lambda_h + \lambda_e}{\sqrt{\lambda_h^2 + \lambda_e^2 + F(\lambda_h + \lambda_e)^2}}. \quad (12.197)$$

Thus the beneficial effects of the Fano factor, evidenced in (12.193), are reduced with strong trapping. If $F = 0$, SNR_Q is infinite for no trapping but finite with strong trapping. If $\lambda_h = \lambda_e$, for example, SNR_Q approaches $\sqrt{2\bar{N}_{eh}}$ as $F \rightarrow 0$.

Carrier-generation statistics negligible In the two limits of no trapping and very strong trapping of both carriers, $\text{pr}(Q|z_{int})$ is independent of the interaction depth z_{int} , but in the intermediate cases the spread of the pulse-height spectrum can be dominated by the randomness in z_{int} . In these cases, we can see the basic shape of the spectrum by neglecting the variance of N_{eh} and approximating $\text{pr}(Q|z_{int})$ with a delta function in (12.188). This approximation becomes increasingly valid at higher photon energies since the SNR for Q conditional on z_{int} varies as $\sqrt{\bar{N}_{eh}}$, so the relative width of $\text{pr}(Q|z_{int})$ decreases as energy (and hence \bar{N}_{eh}) increases. In addition, low-energy photons may be absorbed near the surface of the detector, but higher-energy photons are more penetrating so $\text{pr}(z_{int})$ is broader, and hence the width of $\text{pr}(Q|z_{int})$ plays less of a role as energy increases.

With this approximation, (12.188) becomes

$$\text{pr}(Q) = \int_0^{L_z} dz_{int} \text{pr}_{z_{int}}(z_{int}) \delta[Q - \bar{Q}(z_{int})], \quad (12.198)$$

¹¹The limit here is a little tricky. For λ_h small but finite, we have to exclude events where z_{int} is less than about λ_h (*i.e.*, interactions very near the cathode), and for λ_e small but finite, we have to exclude interactions near the anode.

where $\text{pr}_{z_{int}}(z_{int})$ means the same thing as $\text{pr}(z_{int})$. (The reason for the notational change will become apparent shortly.) To perform the integral, we can use (2.33) to write

$$\delta[Q - \bar{Q}(z_{int})] = \frac{\delta[z_{int} - \tilde{z}(Q)]}{\left| \frac{\partial \bar{Q}(z_{int})}{\partial z_{int}} \right|_{z_{int}=\tilde{z}(Q)}}, \quad (12.199)$$

where $\tilde{z}(Q)$ is found by solving $\bar{Q}(\tilde{z}) = Q$. Then we have

$$\text{pr}(Q) = \frac{\text{pr}_{z_{int}}[\tilde{z}(Q)]}{\left| \frac{\partial \bar{Q}(z_{int})}{\partial z_{int}} \right|_{z_{int}=\tilde{z}(Q)}}. \quad (12.200)$$

Since $\text{pr}_{z_{int}}[\tilde{z}(Q)]$ is simply $\text{pr}_{z_{int}}(z_{int})$ evaluated at the specific point $z_{int} = \tilde{z}(Q)$, the pulse-height spectrum in the current approximation is just a remapped version of the PDF on the depth of interaction. Each random depth corresponds to a specific (nonrandom, we assume) amount of charge in the external circuit, so the number of events producing charge between Q and $Q + \Delta Q$ is the same as the number of gamma-ray photons interacting between $\tilde{z}(Q)$ and $\tilde{z}(Q + \Delta Q)$. Some typical pulse-height spectra are shown in Figs. 12.16–12.18.

Electronic noise The analysis above is not complete since it does not include electronic noise in the circuit that reads out the detector signal. As we know from Sec. 12.2, electronic noise is usually a Gaussian random process, but we need to understand how it affects a measured pulse height.

For definiteness, consider an operational amplifier with a parallel RC circuit in the feedback loop, and assume that the amplifier noise can be modeled as a random voltage source in series with the input as shown in Fig. 12.19. A separate low-pass filter is used to limit the overall bandwidth, and the fluctuating output voltage of this filter is denoted $v_f(t)$. For purposes of noise analysis, we can neglect the DC voltage applied to the detector and the current pulse that results when a gamma ray is absorbed. The problem is thus to compute the variance of $v_f(t)$ in terms of the properties of the noise source.

Fig. 12.16 Pulse-height spectrum for a high-quality Germanium detector at cryogenic temperature ($\simeq 100\text{K}$). The gamma-ray source is $^{99\text{m}}\text{Tc}$, which emits photons at energies 18, 20, 21 and 140 keV. The weak response near 90 keV arises from 140 keV photons that are Compton scattered in the detector material, with the scattered photon escaping from the detector. Trapping is negligible in Ge, and the K-escape peaks are not seen since K x rays in Ge have an energy near 10 keV and are therefore reabsorbed without much probability of escape. Note that pulse heights have been converted to energy units for this plot by use of (12.192).

Fig. 12.17 Pulse-height spectrum for a high-quality Mercuric Iodide (HgI_2) detector at room temperature. As in Fig. 12.16, the gamma-ray source is $^{99\text{m}}\text{Tc}$. Moderate trapping is evidenced by the tails on the low-energy side of each peak. The peaks around 110–115 keV correspond to escape of iodine K x rays, and the peaks around 6–75 keV correspond to escape of Hg K_α and K_β photons.

Fig. 12.18 Pulse-height spectrum for a poor-quality Cadmium Telluride (CdTe) detector at room temperature. Again, the gamma-ray source is $^{99\text{m}}\text{Tc}$. Severe trapping is evidenced by the plateau on the low-energy side of the photopeak. Note also that the energy resolution, as measured by the width of the photopeak, is much worse than in Ge or HgI_2 . The rapid rise at the extreme low-energy end of the spectrum is amplifier noise.

Fig. 12.19 Leaky integrator with a noisy operational amplifier and added low-pass filter.

As in Sec. 12.1.1, we can assume that the operational amplifier has very high gain and hence maintains the voltage across its input terminals very near zero. Thus the noise voltage $v_n(t)$ is also the voltage across the detector capacitance, and the fluctuating current through the detector is $C_{det}dv_n/dt$. Since the amplifier has very high input impedance, no current can flow into its input terminals, and the current through the detector must be equal and opposite to the current in the feedback

loop. This condition can be expressed as [cf. (12.5)]

$$C_{det} \frac{dv_n(t)}{dt} = \frac{v_{out}(t) - v_n(t)}{R} + C \frac{d}{dt}[v_{out}(t) - v_n(t)], \quad (12.201)$$

where $v_{out}(t)$ is the voltage at the output of the amplifier. A Fourier transform and a bit of algebra yield

$$V_{out}(\nu) = V_n(\nu) \frac{1 + 2\pi i \nu R C_{tot}}{1 + 2\pi i \nu R C}, \quad (12.202)$$

where $C_{tot} = C + C_{det}$. If the detector had negligible capacitance, this equation shows that the amplifier would function as a voltage follower with $V_{out}(\nu) = V_n(\nu)$, but with real detectors there is a frequency-dependent gain factor that approaches C_{tot}/C as ν gets large. Even though the amplifier with RC feedback functions as a low-pass filter for the current pulse produced by a gamma ray, it does not have a low-pass effect on the noise. The transfer function relating the noise voltage to the amplifier output voltage is given by the ratio in (12.202).

To proceed, we must specify the power spectral density of the noise. For simplicity, we ignore $1/f$ noise and assume that all other sources of electronic noise can be lumped together into a white-noise spectrum $S_n(\nu) = S_n(0) = \text{constant}$. With this assumption and (8.156), the power spectral density for $v_{out}(t)$ is

$$S_{out}(\nu) = S_n(0) \cdot \left| \frac{1 + 2\pi i \nu R C_{tot}}{1 + 2\pi i \nu R C} \right|^2 = S_n(0) \frac{1 + (2\pi \nu R C_{tot})^2}{1 + (2\pi \nu R C)^2}. \quad (12.203)$$

This function is plotted in Fig. 12.20. Note that $S_{out}(\nu)$ approaches $S_n(0)[C_{tot}/C]^2$ as $\nu \rightarrow \infty$, so the power spectral density is not integrable and the variance of $v_{out}(t)$ is infinite.

Fig. 12.20 Power spectral density of noise on the output of the operational amplifier of Fig. 12.18. [Plot of (12.203)]

To get a finite variance, we must include the low-pass filter as in Fig. 12.19. The power spectral density for the filter output voltage $v_f(t)$ is obtained by multiplying (12.203) by $|H_f(\nu)|^2$, where $H_f(\nu)$ is the filter transfer function. With (8.156) and (12.203), the variance of $v_f(t)$ is given by

$$\text{Var}\{v_f(t)\} = S_n(0) \int_{-\infty}^{\infty} d\nu \frac{1 + (2\pi \nu R C_{tot})^2}{1 + (2\pi \nu R C)^2} |H_f(\nu)|^2. \quad (12.204)$$

The integral simplifies if we assume that the filter has the same low-pass characteristic as the amplifier ($R_f = R$, $C_f = C$) and that $H_f(0) = 1$. Then

$$\text{Var}\{v_f(t)\} = S_n(0) \int_{-\infty}^{\infty} d\nu \frac{1 + (2\pi \nu R C_{tot})^2}{[1 + (2\pi \nu R C)^2]^2} = S_n(0) \frac{1}{4RC} \left(1 + \frac{C_{tot}^2}{C^2}\right), \quad (12.205)$$

where we have used Gradshteyn and Ryzhik (1980), formula 3.241.5.

Dark current The variance of $v_f(t)$ as given in (12.205) arises from the amplifier noise alone. An additional variance component comes from the shot noise of the dark current through the detector. This component was analyzed in Sec. 12.1.1, and we do not need to repeat the discussion here, but one key point should be noted: The dark-current originates outside the feedback loop of the amplifier, so it is subject to the filtering action of both the integrating amplifier and the low-pass filter. Unlike the amplifier noise, the dark current does not produce white noise at the amplifier output.

Photopeak variance and SNR In Sec. 12.1.1, we analyzed an operational amplifier with a parallel RC circuit in the feedback loop. By a slight generalization of (12.7), we know that an input current pulse of total charge Q produces an output voltage pulse of height Q/C if the pulse duration is very short compared to RC . If Q is random, the pulse height is also random, with variance given by $C^{-2} \text{Var}\{Q\}$. When the output pulse from the amplifier is fed through the low-pass filter, however, a further change in the pulse height occurs. As illustrated in Fig. 12.21, the pulse height is reduced by a factor of e^{-1} (where e is the base of the natural logarithms, not the charge on the electron) and the peak is shifted to $t = RC$ (where $t = 0$ is the time of the gamma-ray interaction). The contribution of randomness in Q to the variance of $v_f(t)$ at $t = RC$ is thus $(eC)^{-2} \text{Var}\{Q\}$.

If the amplifier noise (but not the dark current) is included, the total variance of the output voltage of the filter is obtained by adding the variances of the independent components:

$$\text{Var}\{v_f(RC)\} = \frac{1}{e^2 C^2} \text{Var}\{Q\} + S_n(0) \frac{1}{4RC} \left(1 + \frac{C_{tot}^2}{C^2}\right). \quad (12.206)$$

It is tempting to identify the variance of $v_f(RC)$ as the variance in the height of the pulse out of the filter, but that step requires some justification. The difficulty is that there are several ways to measure pulse height. Some pulse-height analyzers become active after the pulse exceeds some threshold, and then they find the next maximum of the voltage and call it the height. With this kind of system, the probability density function for the heights relates to the density of maxima of the random process, a notoriously difficult problem (see Middleton, 1996, Chap. 9, and Rice, 1948). An alternative approach is to trigger a delay generator on the leading edge of the pulse and to take a voltage sample after a fixed delay approximately equal to RC . In this approach, the sample need not occur at a maximum, but we regard the voltage at that time as an estimate of the pulse height anyway. Then (12.206) can be directly interpreted as the variance in the (estimated) pulse height. We shall assume this latter approach in what follows.

The SNR on the pulse heights is defined as

$$[\text{SNR}_{ph}]^2 = \frac{(\bar{Q}/eC)^2}{\text{Var}\{v_f(RC)\}}. \quad (12.207)$$

With (12.206), we have

$$[\text{SNR}_{ph}]^2 = \frac{\bar{Q}^2}{\text{Var}\{Q\} + S_n(0) \frac{e^2}{4RC} (C^2 + C_{tot}^2)}. \quad (12.208)$$

One implication of this expression is that there is an optimum choice for the capacitance C ; regarded as a function of C , (12.208) has a maximum when $C = C_{det}/\sqrt{2}$. Other implications are also apparent. To optimize SNR_{ph} , we should use low-noise amplifiers, detectors with low capacitance and large values of RC . The latter measure, however, reduces the count rate that can be accommodated without pulse overlap.

Overall pulse-height spectrum Implicit in most of the discussion above is the assumption that the initial gamma-ray interaction transfers a definite energy \mathcal{E}_{kin} to the detector material, and for the most part we have considered photopeak events where $\mathcal{E}_{kin} = \mathcal{E}_0 - \mathcal{E}_b$. In practice, however, \mathcal{E}_0 is a random variable, and \mathcal{E}_{kin} is also a random variable even when conditioned on \mathcal{E}_0 . In nuclear medicine, for example, gamma rays may scatter in the patient's body and lose a random amount of energy, so the energy \mathcal{E}_0 of a photon striking the detector is random. Moreover, in any detector there is an additional randomness arising from escape of secondary photons, so \mathcal{E}_{kin} is random as well. Under these circumstances, the pulse-height spectrum is quite complicated (see Figs. 12.16 – 12.18), and it would be very misleading to characterize it with a single number like an SNR. What we need now is an expression for the overall probability density on the pulse heights, accounting for randomness in \mathcal{E}_{kin} and \mathcal{E}_0 as well as all of the random detector effects treated so far.

Fig. 12.21 Pulse outputs from (a) the operational amplifier and (b) the low-pass filter of Fig. 12.19.

A good starting point is (12.188), which we can now view as a conditional density and relabel as $\text{pr}(Q|\mathcal{E}_{kin})$. Then we can write¹²

$$\begin{aligned} \text{pr}(Q) &= \int_0^\infty d\mathcal{E}_{kin} \text{pr}(Q|\mathcal{E}_{kin}) \text{pr}(\mathcal{E}_{kin}) \\ &= \int_0^\infty d\mathcal{E}_{kin} \int_0^\infty d\mathcal{E}_0 \text{pr}(Q|\mathcal{E}_{kin}) \text{pr}(\mathcal{E}_{kin}|\mathcal{E}_0) \text{pr}(\mathcal{E}_0). \end{aligned} \tag{12.209}$$

¹²Equation (12.209) leaves out one potentially significant effect. When an x ray or scattered photon is reabsorbed within the detector, the PDF on the total induced charge Q depends not only on the initial interaction depth z_{int} , which was already accounted for in (12.188), but also on the depth at which the secondary photon is absorbed. (Lateral position of the absorption is unimportant in the slab geometry.)

Usually the only feasible way to evaluate this expression is Monte Carlo simulation, but two separate simulations are required: a simulation of scatter and escape in the detector material to estimate $\text{pr}(\mathcal{E}_{kin}|\mathcal{E}_0)$, and a simulation of scatter and absorption in the patient's body and in any collimating structures to estimate $\text{pr}(\mathcal{E}_0)$.

After Monte Carlo evaluation of $\text{pr}(Q)$, we still need to transfer the charge signal through the integrating amplifier and low-pass filter to get the pulse height. With the assumptions listed above, this is merely an amplitude scaling by a factor of $1/(eC)$, but we also need to add the electronic noise. This latter step is just convolution with a zero-mean Gaussian with variance given by (12.205).

Windowing and counting statistics What do we do with a pulse-height spectrum in gamma-ray imaging systems? Ideally, we would use the entire spectrum from every detector and attempt to extract as much information about the object as possible. In common practice, however, a simple binary decision is made on each pulse: it is either accepted into the image or rejected. The usual approach is to accept an event only if its pulse height lies in some preset range of values around the photopeak. This range is usually called an *energy window*, but that is a distinct misnomer; it is a window on pulse heights rather than energies of incident photons. With complicated spectra such as Figs. 12.16–12.18, the relation between pulse height and energy is tenuous to say the least.

The fraction of photons absorbed by the detector that are accepted by the window depends in a complicated way on the actual distribution of incident energies, all of the noise sources considered above, and the escape processes. If we know the pulse-height spectrum, we can compute the probability of an incident photon being accepted by the window, denoted $P^{(acc)}$, by integrating the spectrum over the window range. Knowing $P^{(acc)}$, we can discuss the statistics of the number of detected photons.

Consider first the case where the detector observes a Poisson source for a fixed time τ , and assume that a fraction α of the emitted photons strike the detector and a fraction η of those are absorbed. By the discussion in Sec. 11.1.3, we know that binomial selection of a Poisson random process yields a Poisson random variable; in the present problem we have three successive binomial selections, so the number of recorded counts is a Poisson random variable with mean $f_0\tau\alpha\eta P^{(acc)}$, where f_0 is the mean number of photons per second emitted by the source. In effect, the quantum efficiency of the detector is reduced by the factor $P^{(acc)}$.

Other results from Chap. 11 are also applicable with this factor of $P^{(acc)}$. If we have a system of M detectors, we have to add subscripts to the quantities defined above to specify a particular detector. If we count until a preset total number of counts N_{tot} is recorded, then the number recorded in the m^{th} detector follows a binomial law with mean $N_{tot}\alpha_m\eta_m P_m^{(acc)}$, and the multivariate distribution on the counts in all detectors is multinomial as in (11.42). If the mean number of counts in each detector is small, the multinomial limits to a multivariate Poisson as in (11.48).

Finally, all of the discussion of doubly stochastic processes in Sec. 11.2.2 is immediately applicable with the additional factor of $P_m^{(acc)}$ in each quantum efficiency.

12.3.3 Semiconductor detector arrays

So far we have discussed single-element, nonimaging detectors for x rays or gamma rays. With the slab geometry, no information is obtained about the interaction position of a photon except that it lies within the slab, and we have assumed that the lateral dimensions L_x and L_y are large, so only rudimentary spatial information is obtained. More complete information could be obtained by using an array of single-element detectors — a lot of separate slabs, each with its own electronics — but this would be expensive because of cost of fabricating many small detectors and the amount of electronics required. Moreover, the resolution would still be limited by the conditions on the slab geometry. In this section we shall discuss photon counting semiconductor detectors in which spatial resolution is obtained by using a slab detector with many separate electrodes rather than one continuous one.

The objective of this section is to develop mathematical and statistical descriptions of the output signals from such multi-electrode semiconductor detectors. In Sec. 12.3.4 we shall learn how to use the signals to form an image.

Electrode geometries and readouts The basic slab detector can be made into a detector array just by adding more electrodes. An approach dating back to the 1960s is to place a set of strip electrodes on one side of the slab and a set of orthogonal strips on the other side as shown in Fig. 12.22. When a high-energy photon is absorbed, a charge is induced primarily on one strip on each side, so the event is localized to approximately the area of overlap of the orthogonal strips. The index of the active strip on one side can specify the x or row index in a pixel matrix and the index of the active strip on the other side can specify the y or column index, so this device is called a *row-by-column detector*. If J strips are used on each side, a $J \times J$ pixel array is defined, but only $2J$ channels of electronics are needed (plus logic circuitry to detect the strongest signal on each side).

Fig. 12.22 Strip detector, with orthogonal strip electrodes on the two sides.

One drawback of row-by-column readout is increased detector capacitance compared to an array of single-element detectors with the same spatial resolution. If each strip has width ϵ and length $J\epsilon$, then the capacitance on the input to each amplifier is proportional to the strip area $J\epsilon^2$ while the resolution area is ϵ^2 . As we saw in (12.208), increased detector capacitance results in poorer pulse-height resolution.

Another useful geometry, shown in Fig. 12.23, consists of a slab detector with a continuous metal electrode on one side and a set of small square electrodes on the other side. The small electrodes define pixels in the image array, so this geometry

is referred to as *pixellated*.¹³ Now each pixel electrode needs its own electronics chain, but fortunately they can all be fabricated on a single silicon chip in an *application-specific integrated circuit* or *ASIC*. The ASIC can then be bonded to the semiconductor detector slab as shown in Fig. 12.23. The resulting assembly is often called a *hybrid array* because two different semiconductor materials are used, one to absorb the gamma rays and provide charge signals and one to read out the signals and pass them on to additional off-chip electronics.

The readout ASIC may use gated integrators, as shown in Fig. 12.13 and discussed in Sec. 12.2.4, with one integrator provided for each pixel electrode. In operation, the voltage across the integrating capacitor is set to zero, and the system then integrates the incoming charge for a fixed time T . This charge includes both leakage current and the induced charge following a gamma-ray absorption. At the end of the integration time, the voltage is sampled and passed to the external electronics. This transfer operation can be done serially on all pixels during the next integration period, so different pixel signals can be temporally multiplexed to a single output line via electronic switches.

Fig. 12.23 Schematic of a hybrid semiconductor detector with a readout integrated circuit (IC). A continuous metal electrode is deposited on the upper side of the semiconductor slab, and small pixel electrodes are produced photolithographically on the underside. The semiconductor material is cold-welded to the readout IC with indium bumps.

If two or more gamma-ray photons are absorbed in the slab during time T , then the integrated charge is the sum of the leakage charge plus the charges due to all gamma rays. In many applications, however, the rate of arrival of the gamma rays is such that it is unlikely that more than one photon will be absorbed in time T . When we can make this assumption, the hybrid array of gated integrators functions as a photon-counting detector except for an occasional double hit, which we can usually reject by windowing.

Charge spreading and induction In both row-by-column and pixellated detectors, more than one output electrode may receive charge signals from a single gamma-ray interaction. As we saw in Sec. 12.3.2, the initial charge cloud produced by

¹³In commenting on the origin of the word *pixel*, William Safire (Arizona Daily Star, Apr. 3, 1995) cites two unrelated but similar words: *pixilated*—bemused, fey, whimsical (from *pixie*); and *pixilate* (which Safire suggests we should spell *pixelate*), referring to a photographic technique to make cinematography look like animation by deleting frames. We intend neither of these usages here.

a gamma-ray interaction has a finite size, and it grows as the charges drift as a result of Coulomb interactions and diffusion. These effects, collectively known as *charge spreading*, were not an issue in slab detectors with lateral dimensions large compared to the thickness, but pixellated or row-by-column detectors may have electrodes as small as $50\ \mu\text{m}$, so the charge cloud might spread out over several electrodes. Moreover, even without spread, the charge cloud can induce a charge on several electrodes. We need either to minimize these effects or to understand them and use the signals from multiple electrodes intelligently.

One way to minimize charge spreading is to cut grooves around the electrodes, but this approach increases fabrication costs and makes the device more difficult to analyze. In what follows we shall assume that there are no grooves and that the detector is a slab of homogeneous semiconductor with a regular array of pixel electrodes on one side.

We shall also assume that each electrode is connected to a gated integrator, for example on a readout ASIC, and that the integrator holds the electrode at ground potential. We shall neglect the small gaps between the pixels, so essentially the entire pixellated surface of the slab ($z = L_z$) is at ground potential. The continuous electrode on the other side of the slab ($z = 0$) will be the cathode and held at potential $-V_b$. Thus the field inside the slab is still uniform, so all of the calculations on slab detectors above still apply to the total induced charge and the total current through all pixel electrodes, but we now want to compute the signal on each electrode. The mathematical tools needed for this purpose were developed in Chap. 9; specifically, we shall make use of the Green's function for the Poisson equation (Sec. 9.3.3) and Green's theorem (Sec. 9.3.5).

Suppose a gamma ray is absorbed at an arbitrary point \mathbf{r}_{int} in the semiconductor. As in Sec. 12.3.2, the result of the interaction is a cloud of holes and a cloud of electrons, and the overall charge density¹⁴ can be written as

$$q(\mathbf{r}, t) = q_e(\mathbf{r}, t) + q_h(\mathbf{r}, t), \quad (12.210)$$

where the first term comes from the electrons and the second from holes. Both terms include a moving cloud of charge as well as any trapped charge.

This time-varying charge density produces a time-varying potential $\phi(\mathbf{r}, t)$, which is difficult to compute in full generality. A useful approximation, justified by Eskin *et al.* (1999), is that the charge density varies sufficiently slowly that the potential can be computed by the equations of electrostatics rather than the full Maxwell's equations. With this *quasistatic* assumption, the potential must satisfy Poisson's equation,

$$\nabla^2 \phi(\mathbf{r}, t) = -\frac{1}{\epsilon_s} q(\mathbf{r}, t), \quad (12.211)$$

where ϵ_s is the permittivity of the semiconductor. The potential must also satisfy the inhomogeneous Dirichlet boundary conditions $\phi(\mathbf{r}, t) = -V_b$ for $z = 0$ and $\phi(\mathbf{r}, t) = 0$ for $z = L_z$. We shall assume that L_x and L_y are very large compared to L_z , so the lateral boundaries of the slab are not important.

To solve (12.211) subject to these boundary conditions, we need a Green's

¹⁴Recall from Sec. 9.1.1 that we use q for charge density instead of the usual ρ , reserving the latter for spatial frequency. Do not confuse charge density $q(\mathbf{r}, t)$ with total charge $Q(t)$.

function $p(\mathbf{r}, \mathbf{r}_0)$ that satisfies [cf. (9.72)]

$$\nabla_0^2 p(\mathbf{r}, \mathbf{r}_0) = \delta(\mathbf{r} - \mathbf{r}_0), \quad \mathbf{r} \text{ and } \mathbf{r}_0 \text{ in } \mathcal{V}, \quad (12.212)$$

where \mathcal{V} is the volume of the slab. We also require the Green's function to satisfy homogeneous Dirichlet boundary conditions, $p(\mathbf{r}, \mathbf{r}_0) = 0$ if \mathbf{r}_0 is in \mathcal{V} and \mathbf{r} lies on the surface $z = 0$ or $z = L_z$ (or vice versa, \mathbf{r} in \mathcal{V} and \mathbf{r}_0 on the surface). Physically, $p(\mathbf{r}, \mathbf{r}_0)$ is the potential at point \mathbf{r} due to a unit point source at \mathbf{r}_0 in \mathcal{V} plus whatever configuration of sources outside \mathcal{V} is needed to enforce the boundary conditions. Explicit forms for the Green's function will be derived below.

Once we know the Green's function, we can express $\phi(\mathbf{r}, t)$ via (9.73) as

$$\phi(\mathbf{r}, t) = -\frac{1}{\epsilon_s} \int_{\mathcal{V}} d^3\mathbf{r}_0 p(\mathbf{r}, \mathbf{r}_0) q(\mathbf{r}_0, t) - V_b \int_{\mathcal{S}} dx_0 dy_0 \frac{\partial p(\mathbf{r}, \mathbf{r}_0)}{\partial z_0}, \quad (12.213)$$

where \mathcal{S} is now just the surface $z_0 = 0$. (The potential vanishes on $z_0 = L_z$, and we are neglecting the lateral boundaries.)

Next, we need to compute the induced charge on each pixel electrode. For this purpose, we construct a Gaussian pillbox, shown in Fig. 12.24, straddling the inner surface of the m^{th} pixel electrode. The field inside the electrode is zero if the electrode is an ideal conductor, and the normal component (in the $-z$ direction) of the field on the surface of the pillbox inside the semiconductor is $\partial\phi(\mathbf{r}, t)/\partial z$. By Gauss's theorem, the enclosed charge is

$$Q_m(t) = \epsilon_s \int_m da \frac{\partial\phi(\mathbf{r}, t)}{\partial z} = - \int_m da \int_{\mathcal{V}} d^3\mathbf{r}_0 \frac{\partial p(\mathbf{r}, \mathbf{r}_0)}{\partial z} q(\mathbf{r}_0, t) + \text{const}, \quad (12.214)$$

where the area integral is over the inner surface of the m^{th} pixel (in the plane $z = L_z$), and $da = dx dy$.

Fig. 12.24 Gaussian pillbox used to compute induced charge.

The physical interpretation of (12.214) is that a surface charge is induced with just the right distribution to maintain the electrode at ground potential, and the total charge induced on the electrode is the area integral of the surface charge density. The constant term in (12.214) [arising from the second integral in (12.213)] is the charge needed to maintain the DC field in the absence of gamma rays. Our interest is in the charge induced by $q(\mathbf{r}_0, t)$, so we shall drop the constant term. The time-dependent term that remains is the charge pulse due to a gamma-ray interaction.

The time derivative of the charge pulse is the current, which is integrated by the gated integrator. The output voltage of the m^{th} gated integrator at $t = T$ is given from (12.153) as

$$V_m(T) = \frac{1}{C} \int_0^T dt' i(t') = \frac{1}{C} Q_m(T), \tag{12.215}$$

where we have neglected leakage current (for now) and assumed that $Q_m(0) = 0$. With (12.214), we can write (12.215) in the continuous-to-discrete form,

$$V_m(T) = -\frac{1}{C} \int_{\mathcal{V}} d^3\mathbf{r}_0 \Phi_m(\mathbf{r}_0) q(\mathbf{r}_0, T), \tag{12.216}$$

where the dimensionless function $\Phi_m(\mathbf{r}_0)$ is given by

$$\Phi_m(\mathbf{r}_0) = \int_m da \frac{\partial p(\mathbf{r}, \mathbf{r}_0)}{\partial z} \Big|_{z=L_z}. \tag{12.217}$$

In some of the literature on gamma-ray detectors, $\Phi_m(\mathbf{r})$ is called a *weighting potential*, but it isn't really a potential, so we call it simply the *weighting function*.¹⁵

We see from (12.216) that the voltage at the end of the integration period depends on only the final charge distribution $q(\mathbf{r}_0, T)$. Since T is usually long compared to the transit time of charge across the detector, this distribution consists of static charge that was trapped either *en route* to the electrode or at the electrode. (Recall that we are not considering photoconductive gain, so any charge that makes it to the electrode can be considered to be trapped there.)

Fig. 12.25 Infinite sequence of pairs of image charges needed to satisfy boundary conditions.

¹⁵The term *Ramo's theorem* is sometimes used for an equation similar to (12.216). This theorem was proved by S. Ramo (1939) after being introduced by Shockley (1938). Neither Ramo nor Shockley envisioned the kinds of integrating devices under consideration here, and their theorem is essentially the time derivative of (12.216).

Image charges and the Green's function The method of images was introduced in Sec. 9.4.3 as a way of constructing a Green's function satisfying Dirichlet boundary conditions. By (12.212), the Green's function is the potential at point \mathbf{r} in \mathcal{V} due to a point charge at point \mathbf{r}_0 in \mathcal{V} , but this charge produces a nonzero potential on the boundaries, so additional charges outside \mathcal{V} are needed. As in Sec. 9.4.3, we could cancel the potential on $z = 0$ by placing a compensating negative charge at the mirror-image point \mathbf{r}_{0m} outside \mathcal{V} , where $\mathbf{r}_{0m} = (x_0, y_0, -z_0)$ if $\mathbf{r}_0 = (x_0, y_0, z_0)$, but then we would have a nonzero potential on $z = L_z$ from these two charges. Two additional charges would correct this problem and force the potential on $z = L_z$ to zero, but that would then make the potential on $z = 0$ nonzero. To force the Green's function to be zero on both surfaces simultaneously, we need an infinite sequence of pairs of image charges as shown in Fig. 12.25. The Green's function can then be written as (Barrett *et al.*, 1995; Eskin *et al.*, 1999)

$$p(\mathbf{r}, \mathbf{r}_0) = \sum_{k=-\infty}^{\infty} \left[\frac{1}{[(z - 2kL_z - z_0)^2 + |\mathbf{r} - \mathbf{r}_0|^2]^{\frac{1}{2}}} - \frac{1}{[(z - 2kL_z + z_0)^2 + |\mathbf{r} - \mathbf{r}_0|^2]^{\frac{1}{2}}} \right], \tag{12.218}$$

where $\mathbf{r} = (x, y)$ and $\mathbf{r}_0 = (x_0, y_0)$.

Alternative form of the Green's function There is another way of deriving the Green's function that will not only give a useful alternative form, but will also serve to illustrate some important mathematical concepts introduced earlier in the book.

The basic idea is to expand the Green's function in eigenfunctions of the Laplacian operator with the relevant Dirichlet boundary conditions. Since we are ignoring the lateral boundaries, this operator is shift invariant in x and y , and the eigenfunctions are complex exponentials of the form $\exp[2\pi i(\xi x + \eta y)]$ (see Sec. 7.2.4). With any real values of ξ and η , these functions are eigenfunctions of ∇^2 , so the operator has a continuous spectrum (see Sec. 1.4.5) as far as its x - y dependence is concerned.

In the $+z$ direction, we could use sines and cosines as eigenfunctions [see (4.24)], but the boundary conditions now restrict our choices for the spatial frequency, and the spectrum is discrete. The function $\sin(\pi n z / L_z)$ is an eigenfunction of ∇^2 and vanishes at $z = 0$ and $z = L_z$ if n is an integer, but the corresponding cosine does not satisfy the boundary conditions, and no other spatial frequencies can be used in the sine.

Thus the eigenfunctions we need are

$$u_{n\xi\eta}(\mathbf{r}) = \sqrt{\frac{2}{L_z}} \exp[2\pi i(\xi x + \eta y)] \sin(\pi n z / L_z). \tag{12.219}$$

These functions are orthonormal on the slab, satisfying

$$(\mathbf{u}_{n\xi\eta}, \mathbf{u}_{n'\xi'\eta'}) = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy \int_0^{L_z} dz u_{n\xi\eta}^*(\mathbf{r}) u_{n'\xi'\eta'}(\mathbf{r}) = \delta_{nn'} \delta(\xi - \xi') \delta(\eta - \eta'). \tag{12.220}$$

Any function that is square-integrable on the slab and vanishes for $z = 0$ and L_z can be expanded in these functions.

Acting on the eigenfunctions with ∇^2 shows that the corresponding eigenvalues are

$$\lambda_{n\xi\eta} = -\left(\frac{n\pi}{L_z}\right)^2 - 4\pi^2\rho^2, \quad (12.221)$$

where $\rho^2 = \xi^2 + \eta^2$. The eigenvalues are real since ∇^2 is Hermitian.

The spectral decomposition of the Laplacian (with the pertinent boundary conditions) is [cf. (1.86)]

$$\nabla^2 = \sum_{n=1}^{\infty} \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\eta \lambda_{n\xi\eta} \mathbf{u}_{n\xi\eta} \mathbf{u}_{n\xi\eta}^\dagger, \quad (12.222)$$

and the inverse operator is given formally by [cf. (1.87)]

$$\nabla^{-2} = \sum_{n=1}^{\infty} \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\eta \frac{1}{\lambda_{n\xi\eta}} \mathbf{u}_{n\xi\eta} \mathbf{u}_{n\xi\eta}^\dagger. \quad (12.223)$$

The inverse Laplacian is an integral operator whose kernel is the Green's function, which can therefore be written as

$$p(\mathbf{r}, \mathbf{r}_0) = \sum_{n=1}^{\infty} \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\eta \frac{1}{\lambda_{n\xi\eta}} u_{n\xi\eta}(\mathbf{r}) u_{n\xi\eta}^*(\mathbf{r}_0). \quad (12.224)$$

Note the limits on the sum; the eigenfunctions vanish identically for $n = 0$, and terms with negative n are redundant with those for positive n . Therefore we are never dividing by zero in (12.224), and there is no worry about the existence of the inverse.

To get an explicit form for the Green's function, we note that the double integral is an inverse Fourier transform of a rotationally symmetric 2D function, which we can reduce to a single integral by (3.248). By use of (12.219), (12.221), (12.224) and formula 6.532.4 in Gradshteyn and Ryzhik (1980), we then find (Eskin *et al.*, 1999)

$$p(\mathbf{r}, \mathbf{r}_0) = -\frac{1}{\pi L_z} \sum_{n=1}^{\infty} K_0\left(\frac{\pi n |\mathbf{r} - \mathbf{r}_0|}{L_z}\right) \sin\left(\frac{\pi n z}{L_z}\right) \sin\left(\frac{\pi n z_0}{L_z}\right), \quad (12.225)$$

where $K_0(\cdot)$ is the zero-order modified Bessel function. The reader may show the equivalence of this form to (12.218) by use of the Poisson summation formula, (3.197). Both forms are numerically tractable (Eskin, 1997).

Computation of the weighting function We now need to differentiate the Green's function with respect to z and integrate over a pixel area to get $\Phi_m(\mathbf{r})$ as defined in (12.217). This step is most easily accomplished with the eigenfunction expansion of (12.224) where the z -dependence is exhibited in a simple form. We need the derivative only on the pixel surface, $z = L_z$, and we find from (12.219) that

$$\frac{\partial}{\partial z} u_{n\xi\eta}(\mathbf{r})|_{z=L_z} = \sqrt{\frac{2}{L_z}} (-1)^n \frac{\pi n}{L_z} \exp[2\pi i(\xi x + \eta y)]. \quad (12.226)$$

If we define a 2D function $w_m(\mathbf{r})$ to be unity on the surface of the m^{th} pixel and zero elsewhere, and let $W_m(\boldsymbol{\rho})$ be its 2D Fourier transform, we can combine

(12.217), (12.221) and (12.224) to obtain

$$\Phi_m(\mathbf{r}_0) = \frac{1}{\pi} \sum_{n=1}^{\infty} (-1)^n n \sin\left(\frac{n\pi z_0}{L_z}\right) \int_{\infty} d^2\rho \frac{W_m(\boldsymbol{\rho})}{n^2 + (2L_z\rho)^2} \exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r}_0). \quad (12.227)$$

We can interchange sum and integral and then perform the sum by means of formula 1.445.4 in Gradshteyn and Ryzhik (1980); the result is

$$\Phi_m(\mathbf{r}_0) = -\frac{1}{2} \int_{\infty} d^2\rho \frac{\sinh(2\pi z_0\rho)}{\sinh(2\pi L_z\rho)} W_m(\boldsymbol{\rho}) \exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r}_0). \quad (12.228)$$

For $z_0 = L_z$, the ratio of sinh functions is unity, and the integral is proportional to the 2D inverse Fourier transform of $W_m(\boldsymbol{\rho})$. Thus $\Phi_m(\mathbf{r}_0) \propto w_m(\mathbf{r}_0)$, and the weighting function is the pixel function itself in the pixel plane. For $z_0 = 0$, $\sinh(2\pi z_0\rho) = 0$, so the weighting function vanishes identically on the cathode plane.

To get the weighting function for other planes, we recognize that the integral in (12.228) is the 2D inverse Fourier transform of a product, which is a 2D convolution given by

$$\Phi_m(\mathbf{r}_0) = [w_m * s_{z_0}](\mathbf{r}_0), \quad (12.229)$$

where, with the help of (3.248),

$$s_{z_0}(\mathbf{r}_0) = -\pi \int_0^{\infty} \rho d\rho \frac{\sinh(2\pi z_0\rho)}{\sinh(2\pi L_z\rho)} J_0(2\pi\rho r_0). \quad (12.230)$$

Note the curious mixture of coordinates here: \mathbf{r}_0 is the 3D position vector comprised of the 2D vector \mathbf{r}_0 and the distance z_0 , and $r_0 = |\mathbf{r}_0|$. The 2D convolution with a rotationally symmetric, z -dependent kernel yields a 3D function.

In general, numerical methods must be used to evaluate the convolution, but some insight can be gained by examining two limits.

The slab limit If the width ϵ is large compared to L_z , then $W_m(\boldsymbol{\rho}) \simeq \delta(\boldsymbol{\rho})$, and (12.228) yields

$$\Phi_m(\mathbf{r}_0) = -\frac{1}{2} \lim_{\rho \rightarrow 0} \frac{\sinh(2\pi z_0\rho)}{\sinh(2\pi L_z\rho)} = -\frac{z_0}{2L_z}. \quad (12.231)$$

Thus the pixel response to charge near the surface $z_0 = 0$ is very small, and the largest magnitude response is at $z_0 = L_z$. Recall, however, that the weighting function applies to the charge distribution at $t = T$, when presumably all of the charge drift has finished. Electrons that make it to the pixel electrode (the anode) have the full effect, and holes that make it to the cathode have zero effect. As explained in Sec. 12.1.3, an electron-hole pair induces an anode charge of $-e$, not $-2e$, in the absence of trapping.

The small-pixel limit To obtain high sensitivity in a gamma-ray detector, we want to make L_z large, and to obtain high spatial resolution, we want to make the pixel size ϵ small, so it often turns out that the aspect ratio L_z/ϵ is large compared to 1. For the energies used in nuclear medicine and gamma-ray astronomy, L_z is typically in the range 1–10 mm, and pixels can be as small as 0.05 mm.

The function $W_m(\boldsymbol{\rho})$ extends to frequencies of order $1/\epsilon$, and when $L_z \gg \epsilon$, we

can use the asymptotic limit $2\pi L_z \rho \gg 1$ over most of this range. To see why this is useful, note that

$$S_{z_0}(\rho) \equiv \frac{\sinh(2\pi z_0 \rho)}{\sinh(2\pi L_z \rho)} = e^{-2\pi(L_z - z_0)\rho} \left[\frac{1 - e^{-4\pi z_0 \rho}}{1 - e^{-4\pi L_z \rho}} \right]. \tag{12.232}$$

When $z_0 \rho$ and $L_z \rho$ are both large, the factor in square brackets is near unity and $S_{z_0}(\rho) \simeq \exp[-2\pi(L_z - z_0)\rho]$. The greatest error in this approximation occurs near $\rho = 0$, where $S_{z_0}(\rho) \simeq (z_0/L_z) \exp[-2\pi(L_z - z_0)\rho]$, but even this error is small for z_0 near the pixel plane $z = L_z$.

Thus a reasonable approximation to (12.230) is

$$s_{z_0}(\mathbf{r}_0) = -\pi \int_0^\infty \rho d\rho \exp[-2\pi(L_z - z_0)\rho] J_0(2\pi \rho r_0) = \frac{-(L_z - z_0)}{4\pi [(L_z - z_0)^2 + (r_0)^2]^{3/2}}, \tag{12.233}$$

where we have used Gradshteyn and Ryzhik (1980), formula 6.623.2. In the limit that $L_z - z_0 \rightarrow 0$, $s_{z_0}(\mathbf{r}_0) \rightarrow \delta(\mathbf{r}_0)$, so the weighting function exactly in the pixel plane is again proportional to the pixel function.

For finite values of $L_z - z_0$, $s_{z_0}(\mathbf{r}_0)$ has a spatial width of about $L_z - z_0$, so we can regard it as approximately a delta function whenever it is integrated against a substantially broader function. In particular,

$$\Phi_m(\mathbf{r}_0) \simeq w_m(\mathbf{r}_0) \quad \text{for} \quad L_z - z_0 \ll \epsilon. \tag{12.234}$$

Thus the weighting function is independent of z_0 for points within about ϵ of the pixel.

For more distant points, such that $L_z - z_0 \gg \epsilon$, $s_{z_0}(\mathbf{r}_0)$ is broad compared to $w_m(\mathbf{r}_0)$, and we can do the convolution by regarding the latter as the delta function this time. If $w_m(\mathbf{r})$ is centered on $\mathbf{r} = \mathbf{r}_m$, we obtain

$$\Phi_m(\mathbf{r}_0) \simeq \epsilon^2 s_{z_0}(\mathbf{r}_0 - \mathbf{r}_m) \quad \text{for} \quad L_z - z_0 \gg \epsilon. \tag{12.235}$$

By inspection of (12.233), we see that the weighting function now falls off as the inverse square of the z distance from the pixel in this limit.

Fig. 12.26 Behavior of the weighting function in the small-pixel limit. (Courtesy of Josh Eskin.)

The behavior of the weighting function for small and large pixels is shown in Fig. 12.26. The key point is that the pixel is sensitive only to charge that comes within about one pixel width of the electrode; charge trapped outside this sensitive

zone is irrelevant (Barrett *et al.*, 1995; Eskin *et al.*, 1999). If the pixel is the anode, as we have assumed, then holes travel away from the sensitive zone, and hole trapping is far less important than it is with large electrodes. As a result of this *small-pixel effect*, the trapping plateau in a pulse-height spectrum is greatly reduced, and the photopeak fraction is increased.

Mean signals Now that we know the weighting function, we can use it in (12.216) to compute the mean signal from each pixel under various assumptions about charge spreading and trapping. We just need to replace the charge density $q(\mathbf{r}_0, T)$ by its average over all possible paths for the carriers, which we denote by $\bar{q}(\mathbf{r}_0, T)$. Though the notation does not show it, the average here is conditional on both \mathbf{r}_{int} and N_{eh} .

For example, if we neglect carrier diffusion and the finite size of the initial charge cloud, but consider arbitrary trapping of both holes and electrons, then the carriers travel along straight lines, undergoing exponential trapping as they go. After time T (assumed to be much longer than the drift times), the mean electron charge density $\bar{q}_e(\mathbf{r}_0, T)$ is a line of trapped charge extending from the interaction point to the pixel plane (which we assume is the anode) plus a delta function to account for the electrons that make it to the pixel. Specifically,

$$\begin{aligned} \bar{q}_e(\mathbf{r}_0, T) &= -eN_{eh} \delta(\mathbf{r}_0 - \mathbf{r}_{int}) \\ &\times \left[\frac{1}{\lambda_e} \exp\left(-\frac{z_0 - z_{int}}{\lambda_e}\right) \text{step}(z_0 - z_{int}) + \exp\left(-\frac{L_z - z_{int}}{\lambda_e}\right) \delta(z_0 - L_z) \right], \end{aligned} \quad (12.236)$$

where $\mathbf{r}_0 = (\mathbf{r}_0, z_0)$. A similar expression gives the charge density for holes:

$$\begin{aligned} \bar{q}_h(\mathbf{r}_0, T) &= eN_{eh} \delta(\mathbf{r}_0 - \mathbf{r}_{int}) \\ &\times \left[\frac{1}{\lambda_h} \exp\left(-\frac{z_{int} - z_0}{\lambda_h}\right) \text{step}(z_{int} - z_0) + \exp\left(-\frac{z_{int}}{\lambda_e}\right) \delta(z_0) \right]. \end{aligned} \quad (12.237)$$

Note that these densities of trapped charge are assumed to be proportional to N_{eh} , which is a valid assumption if each trap has only a small probability of being filled. Most practical detectors satisfy this condition.

Now we want to use these charge densities to average the voltage $V_m(T)$ defined in (12.216). For notational simplicity, we shall drop the argument and shorten $V_m(T)$ to V_m . Then we can insert (12.236) and (12.237) into (12.216) and perform the integrals for which we have delta functions, yielding

$$\begin{aligned} E\{V_m|\mathbf{r}_{int}\} &= -\frac{e}{C} \bar{N}_{eh} \left[\exp\left(-\frac{z_{int}}{\lambda_e}\right) \delta_{mm_{int}} \right. \\ &+ \frac{1}{\lambda_e} \int_{z_{int}}^{L_z} dz_0 \Phi_m(\mathbf{r}_{int}, z_0) \exp\left(-\frac{z_0 - z_{int}}{\lambda_e}\right) \\ &\left. - \frac{1}{\lambda_h} \int_0^{z_{int}} dz_0 \Phi_m(\mathbf{r}_{int}, z_0) \exp\left(-\frac{z_{int} - z_0}{\lambda_h}\right) \right], \end{aligned} \quad (12.238)$$

where m_{int} denotes the pixel nearest to the interaction (*i.e.*, the one for which $w_{m_{int}}(\mathbf{r}_{int}) = 1$). The notation $\Phi_m(\mathbf{r}_0, z_0)$ means the same thing as $\Phi_m(\mathbf{r}_0)$, and we have used the fact that $\Phi_m(\mathbf{r}_{int}, 0) = 0$. Note also that the expectation has now included an average over N_{eh} .

Several limits of this expression are of interest. First, if there is very little trapping ($\lambda_e, \lambda_h \gg L_z$), then $E\{V_m|\mathbf{r}_{int}\} \simeq -(e/C)\bar{N}_{eh} \delta_{mm_{int}}$; all of the electrons arrive at a single pixel ($m = m_{int}$) and induce the full charge there. Second, for strong trapping of both carriers ($\lambda_e, \lambda_h \ll L_z$), $E\{V_m|\mathbf{r}_{int}\} \simeq -(e/C)\bar{N}_{eh} \Phi_m(\mathbf{r}_{int}, z_{int})$; in contrast to slab detectors, pixellated detectors exhibit a strong dependence on depth of interaction in the strong-trapping limit.

Finally, many materials of interest exhibit good electron transport ($\lambda_e \gg L_z$) but poor hole transport ($\lambda_h \ll L_z$); in these materials,

$$E\{V_m|\mathbf{r}_{int}\} \simeq -\frac{e}{C}\bar{N}_{eh}[\delta_{mm_{int}} - \Phi_m(\mathbf{r}_{int}, z_{int})]. \quad (12.239)$$

Except for interactions that occur within about ϵ of the pixel, $\Phi_m(\mathbf{r}_{int}, z_{int})$ is small compared to one, so the second term makes little contribution to the signal on pixel m_{int} . Its contribution to adjacent pixels may, however, be significant. Hole trapping produces a small positive signal on an anode pixel, while electrons produce a negative one; if no electrons reach a pixel for which $m \neq m_{int}$, only the positive signal is observed. Since this signal depends strongly on z_{int} , it can be used to estimate the depth of interaction (Marks, 2000).

It is not difficult to generalize this calculation to include charge spreading and nonlocal charge deposition, but Monte Carlo methods are usually required to get the relevant charge densities. For examples and many details, see Eskin (1997) and Marks (2000).

Covariance of the output signals The conditional covariance matrix on the output voltages for a specified interaction position \mathbf{r}_{int} is defined as

$$[\mathbf{K}_V(\mathbf{r}_{int})]_{mm'} \equiv E\{\Delta V_m \Delta V_{m'}|\mathbf{r}_{int}\}, \quad (12.240)$$

where $\Delta V_m \equiv V_m - \bar{V}_m(\mathbf{r}_{int})$, and $\bar{V}_m(\mathbf{r}_{int}) \equiv E\{V_m|\mathbf{r}_{int}\}$. The major stochastic effects that influence this matrix are generation of electron-hole pairs, trapping, dark current and electronic noise.

Some of these effects contribute only to the diagonal terms of this matrix (the variance), and some are correlated from pixel to pixel and hence contribute to the off-diagonal elements as well. In particular, dark current and electronic noise are certainly statistically independent from pixel to pixel. In fact, since the pixels are at least nominally identical, a good model for these noise sources is an i.i.d. Gaussian distribution. Carrier generation and trapping may lead to significant correlations.

We shall see, however, that the off-diagonal terms in $\mathbf{K}_V(\mathbf{r}_{int})$ will often vanish if N_{eh} is a Poisson random variable (so that the Fano factor is unity). This result should be expected from Chap. 11 where the word Poisson was taken to be almost synonymous with independent (and hence uncorrelated). On the other hand, in the discussion in Sec. 11.4 on integrating detectors with gain, we did not find that the correlations vanished when the gain process was Poisson. In Sec. 11.4, the variable k_n , the number of secondaries produced by the n^{th} primary, corresponds to what we call N_{eh} here, but there are correlations, evident in (11.226) and (11.238), even when the variance of k_n equals its mean. [From (11.219) we see that $\text{Var}(k_n) = \bar{k}_n$ does not correspond to $s(\mathbf{R}) = 0$.]

The resolution of this apparent paradox is that N_{eh} is only *conditionally* Poisson, since it is computed for a single interaction event. When a Poisson number of interaction events occur over the integration time, the total number of secondaries

is no longer Poisson [cf. (11.198)], and the correlations evident in (11.226) and (11.238) must occur. The reader should not confuse $\mathbf{K}_V(\mathbf{r}_{int})$, which applies to a single interaction event at the specified location \mathbf{r}_{int} , with the covariance matrix \mathbf{K}_Y of an integrating detector with gain as given in (11.238).

Carrier-generation statistics with no trapping In the absence of trapping, all electrons make it to the pixel plane (anode), and all holes make it to the cathode. Since the weighting function $\Phi_m(\mathbf{r}_0)$ is zero for the cathode plane, we can ignore the holes and just account for the distribution of electrons among the pixels. This distribution is affected by nonlocal charge deposition and charge spreading, but for present purposes all we need to know is that there is some probability $\beta_m(\mathbf{r}_{int})$ that an electron generated at \mathbf{r}_{int} arrives at the m^{th} pixel. In the absence of trapping, $\sum_m \beta_m(\mathbf{r}_{int}) = 1$. If N_m is the actual number that arrive at the pixel, then $\sum_m N_m = N_{eh}$, and the conditional mean of N_m is $N_{eh}\beta_m(\mathbf{r}_{int})$.

If we neglect Coulomb interactions between electrons, then each electron will choose a pixel independently of the others, and the conditional probability law (for fixed N_{eh} and \mathbf{r}_{int}) will be the multinomial, (C.164). For $m \neq m'$, we can write

$$\begin{aligned} \langle N_m N_{m'} \rangle &\equiv E\{N_m N_{m'} | \mathbf{r}_{int}\} = \sum_{N_{eh}=0}^{\infty} \Pr(N_{eh}) E\{N_m N_{m'} | N_{eh}, \mathbf{r}_{int}\} \\ &= \beta_m(\mathbf{r}_{int}) \beta_{m'}(\mathbf{r}_{int}) \sum_{N_{eh}=0}^{\infty} \Pr(N_{eh}) N_{eh}(N_{eh} - 1) \\ &= \beta_m(\mathbf{r}_{int}) \beta_{m'}(\mathbf{r}_{int}) [\text{Var}\{N_{eh}\} + \overline{N_{eh}}^2 - \overline{N_{eh}}]. \end{aligned} \quad (12.241)$$

Since $\text{Var}\{N_{eh}\} = F\overline{N_{eh}}$, where F is the Fano factor, we quickly find that

$$\langle \Delta N_m \Delta N_{m'} \rangle = \overline{N_{eh}}(F - 1) \beta_m(\mathbf{r}_{int}) \beta_{m'}(\mathbf{r}_{int}), \quad (m \neq m'), \quad (12.242)$$

where $\Delta N_m = N_m - E\{N_m | \mathbf{r}_{int}\}$. By a similar procedure, the variance of N_m is found to be

$$\text{Var}\{N_m\} = \overline{N_{eh}}\beta_m(\mathbf{r}_{int}) + \overline{N_{eh}}(F - 1)\beta_m^2(\mathbf{r}_{int}). \quad (12.243)$$

We can combine these last two equations into the covariance matrix (Barrett and Swindell, 1981, 1996),

$$[\mathbf{K}_N(\mathbf{r}_{int})]_{mm'} \equiv \langle \Delta N_m \Delta N_{m'} \rangle = \overline{N_{eh}}\beta_m(\mathbf{r}_{int}) \delta_{mm'} + \overline{N_{eh}}(F - 1)\beta_m(\mathbf{r}_{int}) \beta_{m'}(\mathbf{r}_{int}). \quad (12.244)$$

We see that N_m and $N_{m'}$ are uncorrelated if N_{eh} is a Poisson random variable where $F = 1$; this result is expected from the discussion in Sec. 11.2.1 on multinomial selection of a Poisson. We know from earlier discussions in this chapter, however, that N_{eh} is not Poisson, and F may be much less than unity. With such sub-Poisson statistics, there is a negative correlation between N_m and $N_{m'}$; in the limit where $F = 0$ and only two pixels receive charge, a fluctuation in N_m must be accompanied by an equal and opposite fluctuation in $N_{m'}$ since their sum is fixed.

If we consider only the statistics of N_m and neglect electronic noise and dark current, the output voltage of the m^{th} integrator is $-eN_m/C$, so the covariance matrix for the output voltages is

$$[\mathbf{K}_V(\mathbf{r}_{int})]_{mm'} = \frac{e^2}{C^2} \beta_m(\mathbf{r}_{int}) \overline{N_{eh}} \delta_{mm'} + \frac{e^2}{C^2} (F - 1) \overline{N_{eh}} \beta_m(\mathbf{r}_{int}) \beta_{m'}(\mathbf{r}_{int}). \quad (12.245)$$

We reiterate that (12.245) refers to the signals after one integration period in which exactly one gamma-ray interaction occurs, that it is conditional on the interaction location, and that it applies only in the absence of trapping.

Random distribution of trapped charge With trapping, we cannot use the multinomial arguments because we are not just counting particles; as we have seen, electrons and holes induce signals even without reaching the electrodes. The new stochastic effect is the random spatial distribution of trapped charge after time T .

Since the trapped charges are single electrons or holes, the charge density is a spatial point process, and we can use the properties of such processes as developed in Sec. 11.3.3. Specifically, the electron charge density can be written as

$$q_e(\mathbf{r}, T) = -e \sum_{j=1}^{N_{eh}} \delta(\mathbf{r} - \mathbf{r}_j) \equiv -eg_e(\mathbf{r}), \quad (12.246)$$

with a similar expression for holes. Since the number of carriers N_{eh} is not a Poisson random variable, however, we are not dealing with a Poisson point process. Instead, we can start with the general expression (11.92) for the autocovariance of an arbitrary point process.

To adapt (11.92) to the present discussion, we must first distinguish the 3D vector \mathbf{r} from the 2D vector \mathbf{r} . Also, we shall need separate expressions for electrons and holes, so we add subscripts. Finally, we recognize the dependence of all quantities on the interaction position \mathbf{r}_{int} . With these notational changes, the probability density $\text{pr}(\mathbf{r}|N)$ that appears in (11.92) can be replaced (for electrons) by $\text{pr}_e(\mathbf{r}|\mathbf{r}_{int}, N_{eh})$, which is the spatial density of trapped electrons after time T . We include in this density the number of electrons that make it to the electrode as well as the number trapped in the bulk, so the total number is just N_{eh} .

If we assume, as we did in (12.236) and (12.237), that each trap has a small probability of being filled, then the trapping events are independent, and the spatial density of trapped electrons is given, by analogy to (11.83), as

$$\text{pr}_e(\mathbf{r}|\mathbf{r}_{int}, N_{eh}) = \frac{\bar{q}_e(\mathbf{r}, T)}{\int_V d^3\mathbf{r}' \bar{q}_e(\mathbf{r}', T)} = -\frac{1}{eN_{eh}} \bar{q}_e(\mathbf{r}, T), \quad (12.247)$$

and similarly for holes. Recall from the discussion above (12.236) that $\bar{q}_e(\mathbf{r}, T)$ is conditional on both \mathbf{r}_{int} and N_{eh} , so these dependences are hidden on the right-hand side of (12.247). With (12.236), however, $\bar{q}_e(\mathbf{r}, T)$ is linearly related to N_{eh} , and the resulting spatial density $\text{pr}_e(\mathbf{r}|\mathbf{r}_{int})$ is independent of N_{eh} . This conclusion is again a consequence of the assumption that each trap has a small probability of being filled.

By this same assumption, the joint density $\text{pr}(\mathbf{r}, \mathbf{r}'|N)$ that appears in (11.92) factors into the product of the two marginals, and (11.92) becomes

$$K_{g_e}(\mathbf{r}, \mathbf{r}') = \bar{N}_{eh} \text{pr}_e(\mathbf{r}|\mathbf{r}_{int}) \delta(\mathbf{r} - \mathbf{r}') + (F - 1) \bar{N}_{eh} \text{pr}_e(\mathbf{r}|\mathbf{r}_{int}) \text{pr}_e(\mathbf{r}'|\mathbf{r}_{int}), \quad (12.248)$$

where we have used the definition of the Fano factor, (12.166). Not unexpectedly, we see that the random process $g_e(\mathbf{r})$ is delta-correlated for the Poisson case where $F = 1$.

Covariance of the output signals with trapping To compute the covariance matrix on the signals out of the gated integrators, we can use (12.248) along with results

from Sec. 8.2.6 on filtering of random processes. The filtering action is described by (12.216), which has the general form of a continuous-to-discrete (CD) mapping from the point process $q(\mathbf{r}_0, T)$ to the random vector of voltages. With (12.216), we can write the covariance matrix of the voltages as [cf. (8.147)]

$$[\mathbf{K}_V(\mathbf{r}_{int})]_{mm'} = \left(\frac{e}{C}\right)^2 \int_{\infty} d^3\mathbf{r} \int_{\infty} d^3\mathbf{r}' \Phi_m(\mathbf{r}) [K_{g_e}(\mathbf{r}, \mathbf{r}') + K_{g_h}(\mathbf{r}, \mathbf{r}')] \Phi_{m'}(\mathbf{r}'). \quad (12.249)$$

There are no cross-covariance terms since the random processes for holes and electrons are uncorrelated with each other.

Inserting (12.248) and its hole counterpart into (12.249), we get the following generalization of (12.245):

$$\begin{aligned} [\mathbf{K}_V(\mathbf{r}_{int})]_{mm'} &= \left(\frac{e}{C}\right)^2 \bar{N}_{eh} \int_{\infty} d^3\mathbf{r} [\text{pr}_e(\mathbf{r}|\mathbf{r}_{int}) + \text{pr}_h(\mathbf{r}|\mathbf{r}_{int})] \Phi_m(\mathbf{r}) \Phi_{m'}(\mathbf{r}) \\ &+ \left(\frac{e}{C}\right)^2 (F-1) \bar{N}_{eh} \int_{\infty} d^3\mathbf{r} \text{pr}_e(\mathbf{r}|\mathbf{r}_{int}) \Phi_m(\mathbf{r}) \int_{\infty} d^3\mathbf{r}' \text{pr}_e(\mathbf{r}'|\mathbf{r}_{int}) \Phi_{m'}(\mathbf{r}') \\ &+ \left(\frac{e}{C}\right)^2 (F-1) \bar{N}_{eh} \int_{\infty} d^3\mathbf{r} \text{pr}_h(\mathbf{r}|\mathbf{r}_{int}) \Phi_m(\mathbf{r}) \int_{\infty} d^3\mathbf{r}' \text{pr}_h(\mathbf{r}'|\mathbf{r}_{int}) \Phi_{m'}(\mathbf{r}'). \end{aligned} \quad (12.250)$$

This expression reduces to (12.245) in the absence of trapping, where $\text{pr}_e(\mathbf{r}|\mathbf{r}_{int}) \propto \delta(z - L_z)$ and $\text{pr}_h(\mathbf{r}|\mathbf{r}_{int}) \propto \delta(z)$.

One interesting observation about (12.250) concerns the Poisson limit, $F \rightarrow 1$. We are accustomed to Poisson processes leading to uncorrelated measurements, but that is not necessarily the case here. The first integral in (12.250) can be nonzero for $m \neq m'$ if $\Phi_m(\mathbf{r})$ and $\Phi_{m'}(\mathbf{r})$ overlap. A particular trapped charge in the bulk can contribute to the signals on different pixels, so there is a positive correlation. In the absence of trapping, however, the delta function $\delta(z - L_z)$ in the electron distribution reduces the volume integral to an integral over the pixel surface where $\Phi_m(\mathbf{r})$ is the pixel function; then $\Phi_m(\mathbf{r})$ and $\Phi_{m'}(\mathbf{r})$ cannot overlap if $m \neq m'$ and hence there is no correlation.

The non-Poisson parts of (12.250) (the second and third terms) give negative correlations for the usual case where $F < 1$. These correlations do not require that $\Phi_m(\mathbf{r})$ and $\Phi_{m'}(\mathbf{r})$ overlap, but they do require that the charge distribution overlap with both functions. Thus the correlations are stronger for interactions farther from the pixel plane, and they arise only from charge trapped in the bulk. Charge spreading by diffusion enhances these off-diagonal terms in $\mathbf{K}_V(\mathbf{r}_{int})$.

Correlations induced by random depth of interaction So far we have concentrated on the conditional covariance matrix $\mathbf{K}_V(\mathbf{r}_{int})$ for fixed interaction location, as defined in (12.240). As we shall see in Sec. 12.3.5, this is the relevant matrix when we wish to estimate all three coordinates of \mathbf{r}_{int} from the observed signals, but often we want to estimate just the two lateral coordinates x_{int} and y_{int} . In that case we shall need the covariance $\mathbf{K}_V(\mathbf{r}_{int})$ conditional on only the 2D vector \mathbf{r}_{int} ; it is defined by

$$[\mathbf{K}_V(\mathbf{r}_{int})]_{mm'} \equiv E \{ [V_m - \bar{V}_m(\mathbf{r}_{int})] [V_{m'} - \bar{V}_{m'}(\mathbf{r}_{int})] \}, \quad (12.251)$$

where $\bar{V}_m(\mathbf{r}_{int}) \equiv E\{V_m|\mathbf{r}_{int}\}$. By adding and subtracting $\bar{V}_m(\mathbf{r}_{int})$ to each factor in the expectation and doing a little algebra, we find

$$\mathbf{K}_V(\mathbf{r}_{int}) = \langle \mathbf{K}_V(\mathbf{r}_{int}) \rangle_{z_{int}} + \mathbf{K}_{\bar{V}}(\mathbf{r}_{int}), \quad (12.252)$$

where

$$[\mathbf{K}_{\bar{V}}(\mathbf{r}_{int})]_{mm'} = \langle [\bar{V}_m(\mathbf{r}_{int}) - \bar{V}_m(\mathbf{r}_{int})] [\bar{V}_{m'}(\mathbf{r}_{int}) - \bar{V}_{m'}(\mathbf{r}_{int})] \rangle_{z_{int}} . \quad (12.253)$$

The second term in (12.252) arises because the random depth of interaction affects the distribution of charge trapped in the bulk, and this distribution is sensed by two pixels m and m' , especially if they are adjacent. The resulting correlation can be either positive or negative. It is positive when the photon energy is low and L_z/ϵ is large, so that most photons are absorbed a long distance from the pixel plane; then the photons that happen to be absorbed nearer to the pixels contribute more to both $\bar{V}_m(\mathbf{r}_{int})$ and $\bar{V}_{m'}(\mathbf{r}_{int})$. For higher photon energies and smaller L_z/ϵ , more photons are absorbed within ϵ of the pixels where $\Phi_m(\mathbf{r})$ and $\Phi_{m'}(\mathbf{r})$ have little overlap, and the positive correlation is reduced or may become negative. For no trapping, of course, depth of interaction is irrelevant, and $[\mathbf{K}_{\bar{V}}(\mathbf{r}_{int})]_{mm'} = 0$ for $m \neq m'$.

12.3.4 Position and energy estimation with semiconductor detectors

The analysis in Sec. 12.3.3 provides us with a statistical description of the electrode signals in a photon-counting semiconductor gamma-ray detector array, but we still need to form an image from these signals. Two distinct approaches are possible: we can either devise some algorithm based on the pixel signals from a single event to assign that event to an image bin; or we can use all signals from all events to estimate the fluence pattern. The first approach, called *event estimation*, is by far the more common, and it will be the focus of this section. The second approach, *fluence estimation*, requires knowledge of image reconstruction algorithms, so it will be postponed to Chap. 15. For application of fluence estimation to semiconductor detector arrays, see Marks (2000).

In event estimation, the x and y coordinates of the interaction position (*i.e.*, the 2D vector \mathbf{r}_{int}) can be estimated and used to assign the event to a 2D array of image bins, or the depth z_{int} can also be estimated, leading to a 3D array of image bins. In either case, the image bins are referred to as pixels, but they need not be the same size as the pixel electrodes on the detector array. As we shall see, it is possible to obtain spatial resolution better than the size of the electrodes.

As discussed in Sec. 12.3.2, we also usually want to estimate the energy of the event. The energy estimate can be used to create another index into the image array, but more commonly it is used in some decision algorithm for accepting an event into the spatial image array.

The mathematical framework underlying this process of image formation is statistical decision theory, as presented in Chap. 13. This theory includes the theory of parameter estimation, obviously relevant for both position and energy estimation, and classification theory, applicable to the decision to accept or reject an event. We presume here that the reader is conversant with that theory, especially as developed in Sec. 13.3. In particular, we shall use concepts of bias and variance of an estimator freely, and we shall soon make use of maximum-likelihood estimation.

The hottest pixel The simplest algorithm for assigning events to image pixels is just to identify the electrode with the largest signal in the electrode array and to assign the event to the corresponding pixel in an image array of the same size. There is then a 1:1 correspondence between electrodes and image pixels.

This procedure is the obvious one to use in the absence of trapping since then only one electrode gets charge from the gamma-ray interaction; all others merely integrate the dark current. If σ^2 is the variance of the signals due to dark current and electronic noise, and if the interaction produces a mean signal that is at least, say, 3σ or 4σ , then there is essentially zero probability that the wrong pixel will be identified this way. With trapping, however, several electrodes may receive charge from a single gamma-ray interaction, and there may be a significant probability of an incorrect assignment.

In addition to identifying the interaction pixel, we also want to estimate the energy of the incident photon and to accept or reject it based on some preset window (see Sec. 12.3.2). In the absence of trapping, the obvious estimate of energy is the observed signal on the interaction pixel minus an estimate of the contribution from dark current, but with trapping it is not so obvious how to proceed. To use just the signal from one electrode to estimate energy is to ignore useful information from other electrodes.

Linear and quasilinear estimates One simple way to use information from pixels other than the one with the largest signal is to form linear combinations of the signals in some neighborhood around that pixel. For example, if we have identified pixel m_0 as the one with the largest signal, we can define a neighborhood $\mathcal{N}(m_0)$ consisting of a square array of pixels centered on m_0 . With this reduced data set, a possible estimate of \mathcal{E}_0 is

$$\hat{\mathcal{E}} = A \sum_{m \text{ in } \mathcal{N}(m_0)} \left[V_m - \bar{V}_m^{(dark)} \right], \quad (12.254)$$

where A is a constant and $\bar{V}_m^{(dark)}$ is the average of V_m over many integration periods without gamma-ray illumination (a quantity we can easily measure). Alternatively, if we assume that exactly one interaction has occurred in a single integration period, then we can use the entire set of electrode signals for that period. In either case, except for the fact that we have subtracted off the mean dark current, \mathcal{E} is a *linear estimator* of \mathcal{E}_{kin} . We can choose the constant A to minimize the bias in this estimate. With charge spreading but no trapping, for example, $\hat{\mathcal{E}}$ is an unbiased estimator of the deposited energy \mathcal{E}_{kin} (or \mathcal{E}_0 if we consider only photopeak events) if $A = -\mathcal{E}_{eh}C/e$ [cf. (12.192)]. With this choice, the mean of $\hat{\mathcal{E}}$ is \mathcal{E}_{kin} since the mean of the total generated electron charge is given by $-e\mathcal{E}_{kin}/\mathcal{E}_{eh}$, and this charge induces a total mean voltage of Q_e/C . A linear estimator of the x component of the 2D interaction position has a form analogous to (12.254),

$$\hat{x} = \sum_m B_{xm} \left[V_m - \bar{V}_m^{(dark)} \right], \quad (12.255)$$

and similarly for the y component. Again, the coefficients B_{xm} and B_{ym} could be chosen to minimize bias.

One immediate difficulty with (12.255), however, is that the position estimate depends on \mathcal{E}_{kin} since the mean of all terms in the sum is proportional to the deposited energy. To avoid this problem, we can define a *quasilinear estimator* as

$$\hat{\mathbf{r}} = \frac{1}{\hat{\mathcal{E}}} \sum_m \mathbf{B}_m \left[V_m - \bar{V}_m^{(dark)} \right], \quad (12.256)$$

where $\mathbf{B}_m = (B_{xm}, B_{ym})$. This estimator is not linear in the signals $\{V_m\}$ since the denominator $\hat{\mathcal{E}}$ is itself a linear function of the signals. Instead, the form is

$$\hat{\mathbf{r}} = \frac{\sum_m \mathbf{w}_m [V_m - \bar{V}_m^{(dark)}]}{\sum_m [V_m - \bar{V}_m^{(dark)}]}, \quad (12.257)$$

where $\mathbf{w}_m = \mathbf{B}_m/A$.

We can determine the weighting coefficients by making use of the lateral shift-invariance of the slab. If the lateral dimensions L_x and L_y are large compared to L_z and ϵ , then the mean of $V_m - \bar{V}_m^{(dark)}$ (averaged over all random effects including depth of interaction) is some function of $\mathbf{r}_m - \mathbf{r}_{int}$, where \mathbf{r}_m is the 2D location of the m^{th} electrode. Calling this function $f(\mathbf{r}_m - \mathbf{r}_{int})$, we can write

$$E\{\hat{\mathbf{r}}|\mathbf{r}_{int}\} \simeq \frac{\sum_m \mathbf{w}_m f(\mathbf{r}_m - \mathbf{r}_{int})}{\sum_m f(\mathbf{r}_m - \mathbf{r}_{int})}. \quad (12.258)$$

If we now simply take \mathbf{w}_m as the pixel position \mathbf{r}_m , and if we assume that the pixels are small compared to the width of $f(\mathbf{r}_m - \mathbf{r}_{int})$, we find

$$E\{\hat{\mathbf{r}}|\mathbf{r}_{int}\} = \frac{\sum_m \mathbf{r}_m f(\mathbf{r}_m - \mathbf{r}_{int})}{\sum_m f(\mathbf{r}_m - \mathbf{r}_{int})} \simeq \frac{\int_{-\infty}^{\infty} d^2r_m \mathbf{r}_m f(\mathbf{r}_m - \mathbf{r}_{int})}{\int_{-\infty}^{\infty} d^2r_m f(\mathbf{r}_m - \mathbf{r}_{int})}. \quad (12.259)$$

Next we make the obvious change of variables $\mathbf{r}' = \mathbf{r}_m - \mathbf{r}_{int}$. Since left and right are indistinguishable in this problem, we must have $f(\mathbf{r}') = f(-\mathbf{r}')$, and we find readily that

$$E\{\hat{\mathbf{r}}|\mathbf{r}_{int}\} = \mathbf{r}_{int}. \quad (12.260)$$

Thus the simple expedient of choosing the weights in a quasilinear estimator as the pixel coordinates leads to an unbiased estimator of \mathbf{r}_{int} if we can assume that the charge spread is large compared to the pixel width and we can neglect effects from the lateral boundaries. This approach was originally proposed by Hal Anger (1956) in the context of scintillation cameras (to be discussed in Sec. 12.3.5), but it is also applicable to semiconductor arrays.

Problems with linear estimators In spite of the easy implementation, linear estimators have some deficiencies. One way to see them is to reconsider the neighborhood $\mathcal{N}(m_0)$ introduced in (12.254). If we assume that exactly one interaction has occurred in the integration period, then the neighborhood can be as large as desired, up to the size of the array, without changing the choice of weighting coefficients. The mean of $V_m - \bar{V}_m^{(dark)}$ is nonzero only for a few pixels surrounding m_0 , so including additional pixels does not affect the mean of $\hat{\mathcal{E}}$ or $\hat{\mathbf{r}}$, and we deduced the weighting coefficients solely by consideration of the mean values. Intuitively, however, we expect bad things to happen when we make the neighborhood unnecessarily large since we are adding in signals that convey no useful information, yet which are corrupted with noise. In the position estimator, moreover, this effect is exacerbated because we are weighting the signals proportionally to the pixel position, so a signal from a pixel far from the interaction site could receive a large weight and hence a large noise amplification. To minimize these noise problems, we need estimators that account for the variances and covariances of the signals,

not just their means. Statistical estimation theory, the topic of Sec. 13.3, tells us how to find such estimators under different assumptions about our knowledge of the noise in the signals and the distribution of the parameters being estimated. In particular, we show in Sec. 13.3.6 that maximum-likelihood (ML) estimators have certain desirable noise characteristics, so we shall now discuss the application of ML estimation to the problem at hand.

Maximum-likelihood estimation of position and energy An ML estimate of any parameter $\boldsymbol{\theta}$ from a data vector \mathbf{g} requires knowledge of the conditional probability $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$, which is called the likelihood when it is regarded as a function of $\boldsymbol{\theta}$ for fixed \mathbf{g} . In the present problem, $\boldsymbol{\theta}$ includes the interaction position \mathbf{r}_{int} or \mathbf{r}_{int} and the energy \mathcal{E}_0 of the gamma-ray photon. The data vector \mathbf{g} is now the set of pixel signals $\{V_m\}$ for m either in some neighborhood of the hottest pixel or in the entire array. We can denote the signal set as an $M \times 1$ vector \mathbf{V} , where M is either the size of the neighborhood or the size of the array, so the ML estimation problem requires that we maximize $\text{pr}(\mathbf{g}|\mathbf{r}_{int}, \mathcal{E}_0)$ or $\text{pr}(\mathbf{g}|\mathbf{r}_{int}, \mathcal{E}_0)$, depending on whether we want to know the interaction position in 2D or 3D. The 2D and 3D problems are rather different, so we shall discuss them separately.

ML estimation of position in 3D and energy The PDF on \mathbf{V} is fully determined by \mathcal{E}_0 and \mathbf{r}_{int} so long as the entire photon energy is deposited locally at the interaction point, which means we are ignoring K escape and Compton scatter. The only remaining random effects are the random generation and propagation of charge carriers. Since the electrode signals result from many statistically independent electrons and holes, we can appeal to the central-limit theorem (Sec. 8.3.4) to assert that the likelihood is multivariate normal. In Sec. 12.3.3, we developed expressions for the mean of \mathbf{V} and its covariance matrix for fixed \mathbf{r}_{int} and \mathcal{E}_0 , so we can write the likelihood for 3D position estimation as

$$\begin{aligned} \text{pr}(\mathbf{V}|\mathbf{r}_{int}, \mathcal{E}_0) &= (2\pi)^{-\frac{1}{2}M} [\det \mathbf{K}_V(\mathbf{r}_{int}, \mathcal{E}_0)]^{-\frac{1}{2}} \\ &\times \exp \left\{ -\frac{1}{2} [\mathbf{V} - \bar{\mathbf{V}}(\mathbf{r}_{int}, \mathcal{E}_0)]^t \mathbf{K}_V^{-1}(\mathbf{r}_{int}, \mathcal{E}_0) [\mathbf{V} - \bar{\mathbf{V}}(\mathbf{r}_{int}, \mathcal{E}_0)] \right\}. \end{aligned} \quad (12.261)$$

ML estimation requires maximization of $\text{pr}(\mathbf{V}|\mathbf{r}_{int}, \mathcal{E}_0)$ with respect to the unknown parameters \mathbf{r}_{int} and \mathcal{E}_0 . Equivalently, we can maximize the log-likelihood, requiring that

$$\log[\text{pr}(\mathbf{V}|\mathbf{r}_{int}, \mathcal{E}_0)] = \max \text{ at } \mathbf{r}_{int} = \hat{\mathbf{r}}_{ML} \text{ and } \mathcal{E}_0 = \hat{\mathcal{E}}_{ML}. \quad (12.262)$$

Explicitly,

$$\begin{aligned} &\log[\text{pr}(\mathbf{V}|\mathbf{r}_{int}, \mathcal{E}_0)] \\ &= -\frac{1}{2} \log\{\det[\mathbf{K}_V(\mathbf{r}_{int}, \mathcal{E}_0)]\} - \frac{1}{2} [\mathbf{V} - \bar{\mathbf{V}}(\mathbf{r}_{int}, \mathcal{E}_0)]^t \mathbf{K}_V^{-1}(\mathbf{r}_{int}, \mathcal{E}_0) [\mathbf{V} - \bar{\mathbf{V}}(\mathbf{r}_{int}, \mathcal{E}_0)]. \end{aligned} \quad (12.263)$$

Often we can assume that $\log\{\det[\mathbf{K}_V(\mathbf{r}_{int}, \mathcal{E}_0)]\}$ is a slowly varying function of its arguments and treat it as approximately a constant. In that case, maximizing the log-likelihood is equivalent (because of the minus sign) to minimizing the quadratic form in (12.263):

$$[\mathbf{V} - \bar{\mathbf{V}}(\mathbf{r}_{int}, \mathcal{E}_0)]^t \mathbf{K}_V^{-1}(\mathbf{r}_{int}, \mathcal{E}_0) [\mathbf{V} - \bar{\mathbf{V}}(\mathbf{r}_{int}, \mathcal{E}_0)] = \min \text{ at } \mathbf{r}_{int} = \hat{\mathbf{r}}_{ML} \text{ and } \mathcal{E}_0 = \hat{\mathcal{E}}_{ML}. \quad (12.264)$$

Since $\bar{\mathbf{V}}(\mathbf{r}_{int}, \mathcal{E}_0)$ and $\mathbf{K}_V^{-1}(\mathbf{r}_{int}, \mathcal{E}_0)$ are nonlinear functions of their arguments, (12.264) states a nonlinear least-squares problem. Many methods of solution exist, but all amount to searching systematically through the 4D space defined by \mathcal{E}_0 and the three components of \mathbf{r}_{int} . The linear estimators discussed above are useful starting points for the search.

ML estimation in 2D If we want to know only the 2D interaction position \mathbf{r}_{int} , then the depth of interaction z_{int} is a *nuisance parameter*, a topic to be discussed in Sec. 13.3.8. As we shall see in that section, there are three general ways of dealing with a nuisance parameter: we can estimate it along with the parameters of interest; we can assign it some value *a priori*, or we can marginalize the likelihood over the nuisance parameter and then do ML estimation solely on the parameters of interest. Under very general assumptions, the marginalization approach is optimal, but the other two approaches are often computationally easier.

We have already seen how to estimate the nuisance parameter z_{int} when \mathbf{r}_{int} and \mathcal{E}_0 are the parameters of interest. We simply solve the nonlinear least-squares problem (12.264) and discard the estimate of z_{int} . The main drawback to this approach is that the search is over a 4D space when we are interested in only a 3D one.

If we want to assign a typical value to z_{int} , one obvious choice is the mean \bar{z}_{int} as computed from (12.164); it varies from α_{tot}^{-1} to $\frac{1}{2}L_z$ depending on the value of $\alpha_{tot}L_z$. With the substitution $\mathbf{r}_{int} \rightarrow (\mathbf{r}_{int}, \bar{z}_{int})$, the nonlinear least-squares problem in (12.264) is again solved by a 3D search.

The final approach is true 2D ML position estimation, where the likelihood is

$$\text{pr}(\mathbf{V}|\mathbf{r}_{int}, \mathcal{E}_0) = \int_0^{L_z} dz_{int} \text{pr}(\mathbf{V}|\mathbf{r}_{int}, \mathcal{E}_0) \text{pr}(z_{int}), \quad (12.265)$$

where $\text{pr}(z_{int})$ is given in (12.164). We can no longer argue that $\text{pr}(\mathbf{V}|\mathbf{r}_{int}, \mathcal{E}_0)$ is normal; instead, it is essentially a multivariate pulse-height spectrum. The marginal $\text{pr}(V_m|\mathbf{r}_{int}, \mathcal{E}_0)$ is precisely the pulse-height spectrum that would be observed on the m^{th} electrode if the detector were illuminated at normal incidence with photons of energy \mathcal{E}_0 at the point \mathbf{r}_{int} , and we know from inspection of Figs. 12.16–12.18 that pulse-height spectra are far from normal.

ML estimation is not the same as nonlinear least-squares in this case, but we can still maximize (12.265) by means of a 3D search. Evaluation of the likelihood at each step in the search requires numerical integration over z_{int} , but in practice this integral might be approximated by a sum with relatively few terms.

12.3.5 Scintillation cameras

All detectors for x rays and gamma rays operate by converting an absorbed photon into charge. In semiconductor detectors, this charge is sensed directly, but in scintillation detectors the charge is converted to light, and the light is then sensed by optical detectors such as photomultipliers or photodiodes. If multiple optical detectors are used to provide spatial information, and if their temporal response is sufficient to resolve individual pulses from each absorbed gamma ray, then the detector is called a *scintillation camera*.

The basic geometry of a scintillation camera is often quite similar to that of a semiconductor array: a slab crystal absorbs a high-energy photon and produces

light, the light spreads out as it propagates, and many optical detectors receive light from an absorption event. The analogy should be clear — light in a scintillation camera plays the role of charge, and optical detectors substitute for electrodes.

In one respect, however, scintillation detectors are simpler than semiconductor detectors: an optical photon causes no response on an optical detector until it actually reaches the detector surface, while a moving charge induces an output signal without reaching the electrode. Optical photons can be absorbed, which is analogous to charge trapping, but the absorbed photons have no effect on the output signals.

Anger camera The most common detector in nuclear medicine is the *Anger camera* (Anger, 1956), illustrated in Fig. 12.27. It usually consists of a large single crystal of sodium iodide (NaI) doped with thallium (Tl), an optical window and an array of photomultiplier tubes (PMTs). In Anger's original design, seven PMTs were used in a hexagonal configuration, but modern cameras use up to 100 PMTs and cover a field of view of up to a half meter. Many different configurations of PMTs have been tried.

Fig. 12.27 Schematic of an Anger scintillation camera.

In NaI(Tl), an optical photon of energy around 3 eV is produced for every 30 eV of gamma-ray energy on average, so a 150 keV gamma-ray photon produces about 5000 optical photons. The optical window allows the optical photons to spread out over several PMTs, and typically the PMT nearest the interaction point might receive only 500–1000 photons. The photons that reach the photocathode of a particular PMT produce photoelectrons with some quantum efficiency η , usually below 0.3. The PMT amplifies this weak pulse of photoelectrons by about a factor of 10^6 , and an easily measurable output current pulse is produced. All PMTs that receive light produce pulses simultaneously, and the heights of the pulses are measured and used to estimate the interaction position and energy of the gamma-ray photon. The accuracy of these estimates is determined by the statistics of the PMT signals.

The two major noise sources that affect a PMT signal are the random number of photoelectrons produced at each photocathode and the randomness in the gain process. Because the output of the PMT is large, noise in the subsequent electronics can usually be neglected.

Dark current is also negligible, for two reasons. First, the scintillation light from NaI(Tl) is in the blue and near-ultraviolet portion of the spectrum, so there is no need for the PMT to respond to longer wavelengths. Therefore, a photocathode

with a large work function can be used, and few thermal electrons can overcome the potential barrier at the photocathode surface. Second, even if there were a dark current, only the electrons during a gamma-ray pulse would have any effect; thermal electrons between pulses would not trigger the pulse circuitry.

Photoelectron statistics If N_m photoelectrons are produced at the m^{th} photocathode by a single gamma-ray interaction, we want to compute the mean \overline{N}_m and the covariance matrix \mathbf{K}_N . Both of these quantities depend on \mathbf{r}_{int} , the 3D position of the interaction point in the scintillation crystal. In addition, both depend on the energy deposited in the crystal and its spatial distribution; for simplicity, we shall consider only photopeak events and neglect nonlocal charge deposition, so the photon energy \mathcal{E}_0 is assumed to be deposited at \mathbf{r}_{int} .

We denote the mean number of optical photons as $\overline{N}_{opt}(\mathcal{E}_0)$ (independent of \mathbf{r}_{int} for a homogeneous material) and the average fraction of those that reach the m^{th} photocathode as $\beta_m(\mathbf{r}_{int})$. To a first approximation, $\beta_m(\mathbf{r}_{int})$ is $\Omega_m/4\pi$, where Ω_m is the solid angle subtended by the photocathode from point \mathbf{r}_{int} , but a practical Anger camera includes various reflecting surfaces to increase the light collection, so actual computation of $\beta_m(\mathbf{r}_{int})$ is complicated. We shall simply treat $\beta_m(\mathbf{r}_{int})$ as a known function here. The mean number of photoelectrons produced in the m^{th} photocathode, $\overline{N}_m(\mathbf{r}_{int}, \mathcal{E}_0)$, is then the mean number of optical photons that reach the cathode times the quantum efficiency η , or $\overline{N}_{opt}(\mathcal{E}_0)\eta\beta_m(\mathbf{r}_{int})$.

We have already done most of the work necessary to determine the covariance matrix $\mathbf{K}_N(\mathbf{r}_{int})$. In Sec. 12.3.3 we considered the analogous problem for semiconductor detectors without trapping, and we computed the covariance matrix (12.244) for the number of electrons that reach each pixel. To do so, we had to neglect Coulomb interactions between electrons, so that each electron would choose a pixel independently of the others. Photons do not have Coulomb interactions in the first place, so this assumption is rigorously satisfied in scintillation detectors.

All of the steps leading up to (12.244) are then valid for the scintillation camera as long as we replace $\beta_m(\mathbf{r}_{int})$ with $\eta\beta_m(\mathbf{r}_{int})$, and the resulting covariance matrix is¹⁶

$$[\mathbf{K}_N(\mathbf{r}_{int}, \mathcal{E}_0)]_{mm'} = \overline{N}_{opt}(\mathcal{E}_0)\eta\beta_m(\mathbf{r}_{int})\delta_{mm'} + (F-1)\overline{N}_{opt}(\mathcal{E}_0)\eta^2\beta_m(\mathbf{r}_{int})\beta_{m'}(\mathbf{r}_{int}), \quad (12.266)$$

where we have assumed that η is the same for all PMTs.

For several reasons, the off-diagonal elements of $\mathbf{K}_N(\mathbf{r}_{int}, \mathcal{E}_0)$ are less important here than in semiconductor detectors. First, because of the extra conversion step (charge to light), scintillators are less efficient than semiconductors, and we argued in Sec. 12.3.2 that lower efficiency implies a probability law on N_{opt} that is more nearly Poisson and hence a Fano factor nearer to unity. For $F = 1$, the off-diagonal part of $\mathbf{K}_N(\mathbf{r}_{int}, \mathcal{E}_0)$ vanishes, basically because the distribution of optical photons among the PMTs is a multinomial selection of a Poisson (see Sec. 11.2.1).

¹⁶The reader may worry about the requirement in the derivation of (12.244) that the β_m factors sum to unity, which is what led to the use of the multinomial law. This requirement is not met in scintillation cameras because light may be absorbed and because $\eta \neq 1$. We can, however, remove the restriction by supposing that there is an unobserved light sink in which a fraction β_0 of the optical photons are collected, where $\beta_0 = 1 - \sum_{m=1}^M \eta\beta_m$. The conditional multinomial law then holds if all $M + 1$ locations (the M actual detectors and the light sink) are considered, but only the actual detectors are included in the $M \times M$ covariance matrix.

The off-diagonal elements are also relatively unimportant, even if $F \neq 1$, because the quantum efficiency η and the collection efficiency β_m are both small. From (12.266) we see that the off-diagonal terms scale as η^2 while the diagonal ones scale as η , so there is a factor of η reducing the off-diagonal elements relative to the diagonal ones. Similarly, the off-diagonal terms involve the product $\beta_m(\mathbf{r}_{int})\beta_{m'}(\mathbf{r}_{int})$ while the diagonal terms are linear in $\beta_m(\mathbf{r}_{int})$. As we noted above, η is about 0.3 and $\beta_m(\mathbf{r}_{int})$ is about 0.1–0.2 for the PMT nearest the interaction point, and much less for more distant ones. Thus the event that a photoelectron is produced on a particular photocathode is rare compared to the emission of optical photons at the interaction point, and we know from Chap. 11 that rarity implies Poisson implies independent.

An excellent approximation to (12.266) is therefore

$$[\mathbf{K}_N(\mathbf{r}_{int}, \mathcal{E}_0)]_{mm'} = \bar{N}_m(\mathbf{r}_{int}, \mathcal{E}_0) \delta_{mm'}, \quad (12.267)$$

where $\bar{N}_m(\mathbf{r}_{int}, \mathcal{E}_0) = \bar{N}_{opt}(\mathcal{E}_0)\eta\beta_m(\mathbf{r}_{int})$.

Another approximation that is usually justified in Anger cameras is that $\mathbf{K}_N(\mathbf{r}_{int}, \mathcal{E}_0)$ and $\bar{N}_m(\mathbf{r}_{int}, \mathcal{E}_0)$ are independent of the depth of interaction z_{int} . A practical camera will have a reflector on the entrance surface $z = 0$, and the amount of light reaching a particular photocathode is relatively independent of how far from the reflector the light is produced. Without the reflector, the subtended solid angle would depend on z_{int} , but the reflected light compensates for this effect. Thus we can often use (12.267) with $\bar{N}_m(\mathbf{r}_{int}, \mathcal{E}_0)$ replaced by $\bar{N}_m(\mathbf{r}_{int}, \mathcal{E}_0)$.

Statistics of the PMT outputs Knowing the statistics of N_m , we next want to study the statistics of K_m , the number of electrons produced on the output of the m^{th} PMT in a single event. The theory needed for this purpose was developed in Sec. 11.4.1.

Computation of the mean of K_m is little more than a matter of definition. The gain G of the PMT is defined as the average number of output electrons per electron emitted from the photocathode. It is reasonable to assume that all electrons are amplified independently, so the PMT is a linear detector, and the mean total number of photoelectrons in the m^{th} PMT for a single event is given by¹⁷

$$\bar{K}_m(\mathbf{r}_{int}, \mathcal{E}_0) = G\bar{N}_m(\mathbf{r}_{int}, \mathcal{E}_0). \quad (12.268)$$

In the notation of Sec. 11.4.1, G is the same as m_1 , the first moment of the gain distribution (normalized such that $m_0 = 1$). If we know m_1 and the corresponding second moment m_2 , we can express the variance of K_m by the Burgess variance theorem, (11.182). Moreover, if N_m is approximately Poisson, as we have argued above, then we can use (11.183) and write

$$\text{Var}\{K_m\} = \bar{N}_m m_2 = G\bar{K}_m \frac{m_2}{G^2} = G\bar{K}_m \frac{m_2}{m_1^2}. \quad (12.269)$$

As noted in Sec. 11.4.1, the ratio m_2^2/m_1 is called the Swank factor, and we shall denote it here as s . For typical PMTs, s is about 0.8–0.9.

¹⁷Do not confuse K_m or \bar{K}_m with a covariance matrix, which we denote \mathbf{K} with some subscript. We use K here as the number of electrons on the PMT output for consistency with Sec. 11.4.1.

The PMTs act independently, so there is no correlation in their outputs if there is none in their inputs. Thus, if the input covariance is given by (12.267), the output covariance is

$$[\mathbf{K}_k(\mathbf{r}_{int})]_{mm'} = \frac{G}{s} \overline{K}_m(\mathbf{r}_{int}, \mathcal{E}_0) \delta_{mm'}. \quad (12.270)$$

Finally, if the output pulse is integrated with a simple RC integrator with time constant long compared to the pulse duration, then the mean pulse height (for photopeak events) is

$$\overline{V}_m(\mathbf{r}_{int}, \mathcal{E}_0) = \frac{e}{C} \overline{K}_m(\mathbf{r}_{int}, \mathcal{E}_0) = \frac{e}{C} G \overline{N}_{opt}(\mathcal{E}_0) \eta \beta_m(\mathbf{r}_{int}), \quad (12.271)$$

and the covariance matrix on the pulse heights is [*cf.* (12.245)]

$$[\mathbf{K}_V(\mathbf{r}_{int}, \mathcal{E}_0)]_{mm'} = \frac{e^2}{C^2} \frac{G}{s} \overline{K}_m(\mathbf{r}_{int}, \mathcal{E}_0) \delta_{mm'} = \frac{e}{C} \frac{G}{s} \overline{V}_m(\mathbf{r}_{int}, \mathcal{E}_0) \delta_{mm'}. \quad (12.272)$$

In the next section we shall show how (12.271) and (12.272) are used in estimating the interaction position and the energy.

12.3.6 Position and energy estimation with scintillation cameras

In Sec. 12.3.4 we discussed position and energy estimation in the context of semiconductor detectors, but in fact most of the methods introduced there were originally developed for scintillation detectors. A quasilinear estimator was pioneered by Anger in the mid-1950s, and it has been widely emulated and embellished since. ML position estimation was first suggested for scintillation cameras by Gray and Macovski (1976), and it was implemented in practical cameras by W. L. Rogers *et al.* and Milster *et al.* (1984, 1985, 1990). As in the semiconductor case, we prefer the ML approach because of its optimal bias and variance properties.

Statistical model To do ML estimation, we need a probability law, and it is much easier to find one for scintillation cameras than for semiconductors since there are fewer random processes. In semiconductors, as we saw, we have to account for random trapping, which does not arise in scintillators, and dark current, which is usually negligible for the PMTs commonly used in scintillation cameras. In both cases, depth of interaction is random, but the effect is exacerbated in semiconductors because of the trapping and ameliorated in scintillators by the reflecting surfaces.

The dominant stochastic effect in a scintillation camera is fluctuations in the number of photoelectrons. Because the output voltage is the sum of independent contributions from each photoelectron, the central-limit theorem applies, and we can assume that the likelihood $\text{pr}(\mathbf{V}|\mathbf{r}_{int}, \mathcal{E}_0)$ is a multivariate normal with mean and covariance given by (12.271) and (12.272), respectively. Several simplifications of these expressions will serve us well.

First, since the signals are only weakly dependent on the depth of interaction z_{int} , we can replace \mathbf{r}_{int} with \mathbf{r}_{int} . Second, as with semiconductors, the mean signals from scintillators are linear in \mathcal{E}_0 to a good approximation, so (12.271) has the form

$$\overline{V}_m(\mathbf{r}_{int}, \mathcal{E}_0) = \mathcal{E}_0 f_m(\mathbf{r}_{int}). \quad (12.273)$$

The function $f_m(\mathbf{r}_{int})$ is just some constant times $\beta_m(\mathbf{r}_{int})$; it can be determined by calibration measurements or by modeling of the light propagation in the camera.

The third simplification is the diagonal form of the covariance in (12.272), which we can rewrite as

$$[\mathbf{K}_V(\mathbf{r}_{int}, \mathcal{E}_0)]_{mm'} = A\mathcal{E}_0 f_m(\mathbf{r}_{int}) \delta_{mm'}, \quad (12.274)$$

where A is a constant that will turn out not to be very important.

Log-likelihood We argued above that $\text{pr}(\mathbf{V}|\mathbf{r}_{int}, \mathcal{E}_0)$ is a multivariate normal, and we now have the simplified expressions (12.273) and (12.274) for the mean and covariance, respectively. Since the covariance is diagonal and none of the elements is identically zero, it is easy to compute the inverse covariance needed in the multivariate normal PDF. Also, the determinant of a diagonal matrix, which is needed in the normalizing factor of a multivariate normal, is just the product of the diagonal elements. Thus the log-likelihood for estimation of 2D position and energy takes the form [cf. (12.263)]

$$\begin{aligned} & \log[\text{pr}(\mathbf{V}|\mathbf{r}_{int}, \mathcal{E}_0)] \\ = & -\frac{1}{2} \log\{2\pi \det[\mathbf{K}_V(\mathbf{r}_{int}, \mathcal{E}_0)]\} - \frac{1}{2} [\mathbf{V} - \bar{\mathbf{V}}(\mathbf{r}_{int}, \mathcal{E}_0)]^t \mathbf{K}_V^{-1}(\mathbf{r}_{int}, \mathcal{E}_0) [\mathbf{V} - \bar{\mathbf{V}}(\mathbf{r}_{int}, \mathcal{E}_0)] \\ = & -\frac{1}{2} \sum_{m=1}^M \log[2\pi A\mathcal{E}_0 f_m(\mathbf{r}_{int})] - \frac{1}{2} \sum_{m=1}^M \frac{[V_m - \mathcal{E}_0 f_m(\mathbf{r}_{int})]^2}{A\mathcal{E}_0 f_m(\mathbf{r}_{int})}. \end{aligned} \quad (12.275)$$

ML estimation of 2D position and energy The ML estimates of position and energy are found by searching for the maximum of the log-likelihood over the three parameters x_{int} , y_{int} and \mathcal{E}_0 . If we neglect the slow dependence of the log-determinant on these parameters, as we did in Sec. 12.3.4, then the maximum of the log likelihood occurs when the quadratic form in the exponent is minimized. Thus we have the nonlinear least-squares problem [cf. (12.264)]:

$$\sum_{m=1}^M \frac{[V_m - \mathcal{E}_0 f_m(\mathbf{r}_{int})]^2}{\mathcal{E}_0 f_m(\mathbf{r}_{int})} = \min \text{ at } \mathbf{r}_{int} = \hat{\mathbf{r}}_{ML} \text{ and } \mathcal{E}_0 = \hat{\mathcal{E}}_{ML}. \quad (12.276)$$

Note that the constant A has disappeared; the same minimum will be found for all A .

The similarity in form between (12.276) and (12.264) should not conceal the fact that the latter was for 3D position estimation in semiconductor detectors while the former is for 2D estimation in scintillation cameras. We got to (12.276) by assuming that the random depth of interaction in a scintillation camera had no appreciable effect on the mean PMT signals. In a semiconductor material with trapping, on the other hand, depth-of-interaction effects dominate the pulse-height spectrum (see Sec. 12.3.2), so the only way we could get to a simple least-squares problem was to estimate the depth along with the lateral coordinates.

12.3.7 Imaging characteristics of photon-counting detectors

From the position and energy estimates, derived in Sec. 12.3.4 for semiconductor detectors and 12.3.6 for scintillation cameras, we need to form an image. The most common way to do so is to apply some window test, as discussed in Sec. 12.3.2,

and then to bin the position estimates for the events that pass the test into a pixel array. Intuitively, there is some loss of information in this operation, both because photons that do not pass the window test are simply rejected, even though they might convey useful information about the object being imaged, and because the finite bin width adds further uncertainty to the position estimates.

In principle, this information loss could be avoided by storing the raw position and energy estimates or, equivalently, forming from them a random point process. In this section we shall first discuss the properties of this point process, building on the theory developed in Chap. 11, and then we shall discuss the effects of energy windowing and spatial binning.

This treatment is largely motivated by gamma-ray detectors as used in nuclear medicine, but there are position-sensitive optical detectors that fit into a similar framework (except that no energy estimation is involved).

Point processes Suppose we have observed a set of J events and estimated that the j^{th} event occurred at the 2D interaction position $\hat{\mathbf{r}}_j$ and that it deposited energy $\hat{\mathcal{E}}_j$ there. We can then construct the spatio-spectral point process (see Sec. 11.3.8)

$$g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) \equiv \sum_{j=1}^J \delta(\hat{\mathbf{r}} - \hat{\mathbf{r}}_j) \delta(\hat{\mathcal{E}} - \hat{\mathcal{E}}_j), \quad (12.277)$$

where the subscript *det* indicates that we are dealing with the detected events. We shall refer to $g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$ as the *detected image*, with the understanding that the detection process includes estimation of position and energy.

The statistics of the detected image follow from the theory of Poisson random processes developed in Sec. 11.3. In that section we discussed the conditions needed for a point process to be a Poisson process. In essence, these conditions amount to saying that the events are independent. We saw that randomness in the source configuration or source strength could spoil the independence, but let us assume here that the source is nonrandom, so the incident photons are independent and satisfy the conditions for a Poisson point process. In that case $g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$ is also a Poisson point process since the actions of detecting the interaction events and estimating their position and energy do not introduce any dependence or otherwise invalidate the Poisson model. As we know from Sec. 11.1.3, detection is a binomial selection process, which preserves the Poisson character, and the estimation step is a random displacement of each point, which also preserves the Poisson character [see Sec. 11.4.3, especially (11.229)].

Mean detected image The mean of $g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$ is the *spatio-spectral fluence* (or *spectral photon fluence*) $b_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$, defined as the mean number of photons per unit area per unit energy in the detected image. Thus

$$\langle g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) \rangle \equiv b_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}). \quad (12.278)$$

By an extension of the discussion of spatial Poisson processes in Sec. 11.3.2, however, we know that $b_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$ also has another interpretation: after proper normalization, it is the probability density on the position of any individual count. Specifically, the PDF for recording a count at $\hat{\mathbf{r}}$ and $\hat{\mathcal{E}}$ is [*cf.* (11.76)]

$$\text{pr}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) = \frac{b_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})}{\int_{\infty} d^2r \int_0^{\infty} d\mathcal{E} b_{det}(\mathbf{r}, \mathcal{E})} = \frac{1}{J} b_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}), \quad (12.279)$$

where \bar{J} is the mean total number of detected counts.

We can now rewrite (12.278) as

$$\langle g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) \rangle = \bar{J} \text{pr}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) = \bar{J} \int_{\infty} d^2r \int_0^{\infty} d\mathcal{E} \text{pr}(\hat{\mathbf{r}}, \hat{\mathcal{E}}|\mathbf{r}, \mathcal{E}) \text{pr}(\mathbf{r}, \mathcal{E}), \quad (12.280)$$

where $\text{pr}(\hat{\mathbf{r}}, \hat{\mathcal{E}}|\mathbf{r}, \mathcal{E})$ is the PDF for obtaining estimates $(\hat{\mathbf{r}}, \hat{\mathcal{E}})$ when the event actually occurred at $(\mathbf{r}, \mathcal{E})$; in other words, it is the spatio-spectral point response function.

To put this result into a more familiar form, suppose that the incident photons are described by a spectral fluence $b(\mathbf{r}, \mathcal{E})$ and that the detector has a quantum efficiency of η for all \mathbf{r} and \mathcal{E} . Suppose also that the photons strike the detector at normal incidence so that we do not need to distinguish the lateral coordinates of the interaction point, \mathbf{r}_{int} , from the 2D vector that appears in the fluence. Then, by analogy to (12.279), we see that

$$\text{pr}(\mathbf{r}, \mathcal{E}) = \frac{\eta}{\bar{J}} b(\mathbf{r}, \mathcal{E}), \quad (12.281)$$

where \bar{J}/η is the mean number of incident photons. Combining (12.280) and (12.281), we find

$$\langle g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) \rangle = \eta \int_{\infty} d^2r \int_0^{\infty} d\mathcal{E} \text{pr}(\hat{\mathbf{r}}, \hat{\mathcal{E}}|\mathbf{r}, \mathcal{E}) b(\mathbf{r}, \mathcal{E}). \quad (12.282)$$

Unsurprisingly, the mean detected image is the incident spectral fluence blurred by a spatio-spectral point response function and multiplied by the quantum efficiency.

We had, in fact, obtained essentially this same result earlier in Sec. 11.4.3, where we considered gain processes where the secondaries are randomly displaced from the primary photons. A special case considered in that section was mislocation without gain, where each primary produces exactly one secondary; this is just what happens in position and energy estimation, where one absorbed photon results in one point in the detected image.

Bias and variance; distortion and spatial resolution Perhaps the only new insight in (12.282) is that the point response function is also the probability density function associated with the estimation procedure. In fact, we can relate this function to the bias and variance of the estimate as defined in Sec. 13.3.1. To see this relation more clearly, let us ignore the energy estimation and write the PRF as $\text{pr}(\hat{\mathbf{r}}|\mathbf{r})$. From this density we can compute the bias and variance of the position estimate via (13.276) and (13.279).

The bias of the position estimate is a vector defined by

$$\mathbf{B}(\mathbf{r}) \equiv E\{\hat{\mathbf{r}}|\mathbf{r}\} - \mathbf{r}, \quad (12.283)$$

where the conditional expectation is computed with the density $\text{pr}(\hat{\mathbf{r}}|\mathbf{r})$. Note that this bias can, in general, depend on the true position \mathbf{r} .

Since $\hat{\mathbf{r}}$ is a 2D random vector, its second-order statistics are specified by a 2×2 covariance matrix, but we focus here on the two diagonal elements, the variances of \hat{x} and \hat{y} . The variance of the x estimate is defined by

$$\text{Var}\{\hat{x}|\mathbf{r}\} \equiv E\{\hat{x}^2|\mathbf{r}\} - [E\{\hat{x}|\mathbf{r}\}]^2, \quad (12.284)$$

and similarly for the y estimate. Note especially that the variance of \hat{x} measures the spread around the mean estimate, not around the actual x .

The bias and variance of the 2D position estimates can be measured by using a thin beam of gamma rays, all of which strike the detector at normal incidence very near point \mathbf{r} . After a large number of gamma rays from this source have been detected, the resulting image (see Fig. 12.28) is a good representation of the PDF on $\hat{\mathbf{r}}$ conditional on \mathbf{r} . As the number of collected photons approaches infinity, the sample mean of $\hat{x} - x$ approaches the bias component $B_x(\mathbf{r})$, and similarly for the y component. The sample variances also approach the ensemble variances defined in (12.284). The off-diagonal terms manifest themselves as a tilt of the distribution.

Fig. 12.28 Image of many gamma rays, all incident at the same position. As the number of gamma rays approaches infinity, this image approaches the conditional PDF $\text{pr}(\mathbf{r}|\hat{\mathbf{r}})$.

We can relate the biases and variances back to the general descriptions of shift-variant imaging systems introduced in Sec. 7.2. The bias measures the distortion of the image detector, and the variances measure the spatial resolution (see Sec. 7.2.1). If we repeated the measurement described above with a uniformly spaced grid of true interaction positions \mathbf{r} , the position estimates would cluster around a distorted grid, and both the displacement of the estimates from the true grid (distortion) and the spread of the estimates (variance) could vary over the surface of the detector, in general.

Contributions to bias and variance Bias and variance in any estimate can arise from several sources, including modeling error, inaccurate or incomplete system calibration, statistical noise in the data or suboptimal estimators.

In the present problem, an example of modeling error is neglecting the depth of interaction. When we assume that the mean and covariance of the PMT signals are independent of z_{int} , we make an error that can affect both the bias and the variance. The magnitude of this error can be determined only by doing more careful modeling.

System calibration comes into our problem since we need to know the functions $f_m(\mathbf{r}_{int})$ defined in (12.273). To calibrate the camera, we can measure these functions for a finite grid of interaction points and interpolate between grid points, but errors of measurement and interpolation again affect bias and variance.

Finally, even with full knowledge of the system, there may be bias and variance associated with the estimator. As discussed more fully in Sec. 13.3.5, there is a minimum variance, called the Cramér-Rao bound, that can be attained by any

estimator operating on a specific data set. An estimator that achieves this lower bound is said to be *efficient*. An efficient estimator may not exist for many problems, but if one does exist, it is the ML estimator.

Moreover, the ML estimator is always asymptotically unbiased and asymptotically efficient. This statement is usually applied to situations where N independent measurements are made for the same value of the unknown parameter, and the term asymptotic implies the limit as $N \rightarrow \infty$. In a scintillation camera, we get only a single light flash for each \mathbf{r}_{int} and \mathcal{E} we want to estimate, but nevertheless an asymptotic argument can be applied. Specifically, if the number of optical photons gets very large, the ML estimate is again asymptotically unbiased and efficient, which means that it will give better spatial resolution and less distortion than any other estimator in this limit.

Autocovariance of the detected image Now let us assume that we have accounted for the modeling and calibration errors and the estimator performance, so that we know the PDF $\text{pr}(\hat{\mathbf{r}}, \hat{\mathcal{E}}|\mathbf{r}, \mathcal{E})$. Then, for a nonrandom incident spectral fluence, we can compute the mean detected image, or equivalently the detected spectral fluence $b_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$, via (12.282). We argued above that the detected image is a Poisson random process, so we can use a generalization of (11.94) to express its autocovariance function as

$$K_{g_{det}}(\hat{\mathbf{r}}, \hat{\mathbf{r}}', \hat{\mathcal{E}}, \hat{\mathcal{E}}') = b_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) \delta(\hat{\mathbf{r}} - \hat{\mathbf{r}}') \delta(\hat{\mathcal{E}} - \hat{\mathcal{E}}'). \quad (12.285)$$

Binning For storage or display of the image, we must bin the events into some digital matrix. We can, for example, apply an energy window and accept only those events for which $\hat{\mathcal{E}}$ falls in the window and then bin the remaining events into spatial pixels. Thus if $\hat{\mathbf{r}}$ falls in the region of the m^{th} pixel, it contributes one count to that pixel in the final image. Alternatively, we can use multiple energy bins and make one spatial image for each energy.

In both of these cases, we can compute the statistics of the discrete image from what we know about the random process $g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$. Suppose the m^{th} pixel includes only those events for which $\mathcal{E}_m - \frac{1}{2}\Delta\mathcal{E} < \hat{\mathcal{E}} \leq \mathcal{E}_m + \frac{1}{2}\Delta\mathcal{E}$, $x_m - \frac{1}{2}\epsilon < \hat{x} \leq x_m + \frac{1}{2}\epsilon$ and $y_m - \frac{1}{2}\epsilon < \hat{y} \leq y_m + \frac{1}{2}\epsilon$. Then the number of counts g_m in this pixel is obtained by integrating $g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$, as defined in (12.277), over this region:

$$g_m = \int_{\mathcal{E}_m - \frac{1}{2}\Delta\mathcal{E}}^{\mathcal{E}_m + \frac{1}{2}\Delta\mathcal{E}} d\hat{\mathcal{E}} \int_{x_m - \frac{1}{2}\epsilon}^{x_m + \frac{1}{2}\epsilon} d\hat{x} \int_{y_m - \frac{1}{2}\epsilon}^{y_m + \frac{1}{2}\epsilon} d\hat{y} g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}). \quad (12.286)$$

From (12.282), the mean of g_m is

$$\begin{aligned} \bar{g}_m &= \int_{\mathcal{E}_m - \frac{1}{2}\Delta\mathcal{E}}^{\mathcal{E}_m + \frac{1}{2}\Delta\mathcal{E}} d\hat{\mathcal{E}} \int_{x_m - \frac{1}{2}\epsilon}^{x_m + \frac{1}{2}\epsilon} d\hat{x} \int_{y_m - \frac{1}{2}\epsilon}^{y_m + \frac{1}{2}\epsilon} d\hat{y} \bar{g}_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) \\ &= \eta \int_{\mathcal{E}_m - \frac{1}{2}\Delta\mathcal{E}}^{\mathcal{E}_m + \frac{1}{2}\Delta\mathcal{E}} d\mathcal{E} \int_{x_m - \frac{1}{2}\epsilon}^{x_m + \frac{1}{2}\epsilon} d\hat{x} \int_{y_m - \frac{1}{2}\epsilon}^{y_m + \frac{1}{2}\epsilon} d\hat{y} \int_{\infty}^{\infty} d^2r \int_0^{\infty} d\mathcal{E} \text{pr}(\hat{\mathbf{r}}, \hat{\mathcal{E}}|\mathbf{r}, \mathcal{E}) b(\mathbf{r}, \mathcal{E}) \\ &\equiv \int_{\infty}^{\infty} d^2r \int_0^{\infty} d\mathcal{E} h_m(\mathbf{r}, \mathcal{E}) b(\mathbf{r}, \mathcal{E}), \end{aligned} \quad (12.287)$$

where $h_m(\mathbf{r}, \mathcal{E})$ is the overall kernel for the CD mapping from $b(\mathbf{r}, \mathcal{E})$ to the discrete vector \mathbf{g} . This kernel includes all of the complicated effects that go on in the detector

material, position and energy estimation and binning into pixels and energy bins of finite size. At the end, we have our standard linear CD mapping formula.

Autocovariance of the discrete image Since we have argued that $g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$ is a Poisson random process (for nonrandom fluence), counts in different spatial or energy bins must be independent Poisson random variables. Thus we have at once that

$$[\mathbf{K}_g]_{mm'} = \bar{g}_m \delta_{mm'}. \quad (12.288)$$

The indices m and m' can refer to two different spatial pixels in the same energy image or to different energy images; so long as any event can go into only one bin and the fluence is nonrandom, the counts in different bins are independent.

We shall make considerable use of (12.288) in Chap. 14 when we discuss image quality and in Chap. 15 when we discuss inverse problems.

12.3.8 Integrating detectors

So far in this section we have discussed mainly photon-counting detectors, but both semiconductor and scintillator arrays can be operated in an integrating mode where no attempt is made to identify individual gamma rays or x rays. None of the discussion above on position and energy estimation is applicable in this case, and we must go back to the theory developed in Sec. 11.4 to determine the statistical properties of the images.

Scintillator-photodiode arrays For definiteness, we shall consider a scintillation detector with an array of photodiodes for the readout, but semiconductor detectors can be treated similarly. The geometry will be a slab of scintillation material with a regular array of photodiodes of width ϵ on the face $z = L_z$. The specific application of most interest for these detectors is transmission radiography using x rays with a broad spectrum of energies; for a more detailed discussion of this application, see Sec. 16.1.

Though the detector being considered here is qualitatively similar to a scintillation camera, two important differences must be noted. First, x-ray detectors often use fluorescent screens consisting of scintillating grains held together with a partially transparent binder. Scattering from binder-grain interfaces causes the light to diffuse significantly as it propagates from the interaction point to the photodetectors, and light can be absorbed in both the binder and the grains. As a result, depth of interaction is much more important here than it is with the single-crystal scintillators used in scintillation cameras.

Secondly, scintillation cameras are used mainly in nuclear medicine where the gamma-ray source is usually monoenergetic. In medical transmission radiography, on the other hand, the x rays are generated by allowing energetic electrons to strike a metal target, and most of the x rays are *Bremsstrahlung* (German: braking radiation) generated when the electrons are decelerated in the metal. This process produces a broad spectrum of x-ray energies extending from near zero up to the energy of the electron.

The light diffusion and the broad energy spectrum contribute to the variability in the amount of light reaching the photodetectors. Our goal in this section is to show how these effects can be incorporated into the derivation given in Sec. 11.4 of the mean vector and covariance matrix for the output signals after a finite integra-

tion time during which more than one x ray can be absorbed. The procedure will be first to compute the mean and autocovariance function of the output random process as in Sec. 11.4.3 and then to convert to the mean and covariance matrix of the discrete random vector as in Sec. 11.4.5. The reader may wish to review these sections before continuing.

Interaction parameters and the output random process In Sec. 11.4.3, the interaction position of the n^{th} primary event was specified by the 2D vector \mathbf{R}_n , but for x rays interacting in a thick detector we must also specify the depth of interaction z_n and the energy deposited in the interaction, \mathcal{E}_n . We can incorporate these new parameters formally simply by regarding \mathbf{R}_n as a 4D vector with components $(x_n, y_n, z_n, \mathcal{E}_n)$ or $(\mathbf{r}_n, z_n, \mathcal{E}_n)$.

The optical photons created in this interaction can propagate to the plane $z = L_z$, and there they define a 2D random point process $y(\mathbf{r})$ given by [cf. (11.200)]

$$y(\mathbf{r}) = \sum_{n=1}^{N_x} \sum_{k=1}^{k_n} \delta(\mathbf{r} - \mathbf{r}_{nk}), \quad (12.289)$$

where N_x is the number of absorbed x-ray photons, \mathbf{r}_{nk} is the 2D position of the k^{th} optical photon produced by the n^{th} absorbed x ray, and k_n is the number of optical photons reaching $z = L_z$ for the n^{th} absorption. The random variables in (12.289) are the sets $\{\mathbf{r}_{nk}\}$ and $\{k_n\}$ as well as N_x .

It is convenient to define a 2D displacement vector $\Delta\mathbf{r}_{nk}$ such that $\mathbf{r}_{nk} = \mathbf{r}_n + \Delta\mathbf{r}_{nk}$, and then we can write

$$y(\mathbf{r}) = \sum_{n=1}^{N_x} \sum_{k=1}^{k_n} \delta(\mathbf{r} - \mathbf{r}_n - \Delta\mathbf{r}_{nk}). \quad (12.290)$$

In contrast to (11.200), \mathbf{r}_n rather than \mathbf{R}_n appears here. (It would not make sense to subtract a 4D vector from a 2D one.)

Our task now is to compute the mean and autocovariance function of $y(\mathbf{r})$ by methods introduced in Sec. 11.4.3. This will turn out to be relatively easy since we took care in that section not to assume shift invariance. (Even if the fluorescent screen is laterally shift-invariant, it cannot have this property with respect to z_n or \mathcal{E}_n .)

Probability density for the interaction parameters To incorporate the new random variables z_n and \mathcal{E}_n into the derivation of Sec. 11.4.3, we need a probability density function $\text{pr}(\mathbf{R}_n)$, which we can write as

$$\text{pr}(\mathbf{R}_n) = \text{pr}(\mathbf{r}_n, z_n, \mathcal{E}_n) = \text{pr}(z_n|\mathcal{E}_n, \mathbf{r}_n) \text{pr}(\mathcal{E}_n|\mathbf{r}_n) \text{pr}(\mathbf{r}_n). \quad (12.291)$$

To proceed, we need to make some assumptions about the x-ray beam and its interactions. The simplest form of $\text{pr}(\mathbf{R}_n)$ will arise if we assume that all of the x rays are travelling parallel to the z axis, that all of the x-ray interactions are photoelectric and that all of the photon energy is deposited at the interaction site. From the discussion in Sec. 12.3.1, we know that even a photoelectric interaction can result in a secondary photon (a K x ray), but for present purposes we assume that it is reabsorbed a negligible distance from the initial interaction. The effects of nonlocal charge deposition will be discussed in more detail in Sec. 12.3.9.

With these restrictive assumptions, we can relate $\text{pr}(\mathbf{r}_n)$ to the x-ray fluence $b_0(\mathbf{r})$ on the entrance face $z = 0$ by (11.206):

$$\text{pr}(\mathbf{r}_n) = \frac{b_0(\mathbf{r}_n)}{\int_A d^2r b_0(\mathbf{r})}, \quad (12.292)$$

where $A = L_x L_y$ is the area of the detector.

In (12.291), $\text{pr}(\mathcal{E}_n|\mathbf{r}_n)$ is the energy spectrum of the incident gamma rays, which is presumed to be known, and $\text{pr}(z_n|\mathcal{E}_n, \mathbf{r}_n)$ is the PDF on interaction depths. If the properties of the fluorescent screen are independent of x and y , $\text{pr}(z_n|\mathcal{E}_n, \mathbf{r}_n)$ is independent of \mathbf{r}_n and given by (12.161) as

$$\text{pr}(z_n|\mathcal{E}_n) = \alpha(\mathcal{E}_n) \exp[-\alpha(\mathcal{E}_n)z_n], \quad (12.293)$$

where $\alpha(\mathcal{E}_n)$ is the energy-dependent photoelectric absorption coefficient.

With all of the accumulated assumptions, the desired PDF is thus

$$\text{pr}(\mathbf{R}_n) = \alpha(\mathcal{E}_n) \exp[-\alpha(\mathcal{E}_n)z_n] \text{pr}(\mathcal{E}_n|\mathbf{r}_n) \frac{b_0(\mathbf{r}_n)}{\int_A d^2r b_0(\mathbf{r})}. \quad (12.294)$$

To remove the assumption that all of the x rays are travelling in the $+z$ direction, we must specify the angular distribution of the x rays on $z = 0$, for example by stating the photon radiance on that plane; this point will be pursued further in Sec. 16.1.

Spatio-spectral fluence Another way of looking at the distribution of interaction sites and energies is that they define a 4D spatio-spectral point process [cf. (11.135)]

$$g_{ss}(\mathbf{R}) \equiv \sum_{n=1}^{N_x} \delta(\mathbf{r} - \mathbf{r}_n) \delta(z - z_n) \delta(\mathcal{E} - \mathcal{E}_n) = \sum_{n=1}^{N_x} \delta(\mathbf{R} - \mathbf{R}_n). \quad (12.295)$$

Since we are neglecting nonlocal energy deposition (Compton scattering and K x rays), each of the interactions is produced by a different x-ray photon, and these photons are independent unless we consider random fluence, so $g(\mathbf{R})$ is a 4D Poisson point process. We can define the mean of this Poisson process as the *spatio-spectral fluence* $b_{ss}(\mathbf{R})$, and we know from the discussion in Sec. 11.3 that $\text{pr}(\mathbf{R}_n)$ is just a normalized version of that fluence. Specifically, by a slight generalization of (11.83),

$$\text{pr}(\mathbf{R}_n) = \frac{b_{ss}(\mathbf{R}_n)}{\int_D d^4R b_{ss}(\mathbf{R})}, \quad (12.296)$$

where $\int_D d^4R$ implies integration of x and y over the lateral dimensions of the detector, integration over z from 0 to L_z and integration over \mathcal{E} from 0 to the maximum energy in the spectrum.

We can also work backwards and regard (12.296) as a definition of $b_{ss}(\mathbf{R}_n)$ if $\text{pr}(\mathbf{R}_n)$ is known, for example from (12.294). In either case, if we know that $g_{ss}(\mathbf{R})$ is a spatio-spectral Poisson process, its statistics are fully specified by $b_{ss}(\mathbf{R})$.

Averaging over \mathbf{R}_n It is now straightforward to modify the treatment in Sec. 11.4.3 with the new density $\text{pr}(\mathbf{R}_n)$ from (12.294) or (12.296). The modification comes at step (c) of the five-step averaging procedure summarized below (11.207), and

mainly it is a matter of replacing $b(\mathbf{r})$ with $b_{ss}(\mathbf{R})$ at various places.

A slight subtlety arises with the function $p_d(\mathbf{r}, \mathbf{R})$, defined above (11.201) as the shift-variant spread function of the gain mechanism. Had we succumbed in Chap. 11 to the temptation of writing this function as $p_d(\mathbf{r} - \mathbf{R})$, we would not be able to use subsequent results in the present context where \mathbf{r} is 2D and \mathbf{R} is 4D, but with the shift-variant notation there is no problem. In particular, $p_d(\mathbf{r}, \mathbf{R})$ is now defined as mean number of optical photons per unit area at point \mathbf{r} in the plane $z = 0$ when the x-ray interaction is at the 4D point \mathbf{R} .

With this reinterpretation of $p_d(\mathbf{r}, \mathbf{R})$, the definition of the operator \mathcal{H}_1 in (11.213) is modified to

$$[\mathcal{H}_1 \mathbf{b}_{ss}](\mathbf{r}) = \int_D d^4 R p_d(\mathbf{r}, \mathbf{R}) b_{ss}(\mathbf{R}). \quad (12.297)$$

Similarly, the definition of \mathcal{H}_2 in (11.221) becomes

$$[\mathcal{H}_2 \mathbf{b}_{ss}](\mathbf{r}, \mathbf{r}') = \int_D d^4 R_n \text{pr}_{\Delta \mathbf{r}}(\mathbf{r} - \mathbf{r}_n | \mathbf{R}_n) \text{pr}_{\Delta \mathbf{r}}(\mathbf{r}' - \mathbf{r}_n | \mathbf{R}_n) b_{ss}(\mathbf{R}_n) s(\mathbf{R}_n), \quad (12.298)$$

where $s(\mathbf{R}_n)$ is still given by (11.219).

As the reader should verify, no further changes are required in Sec. 11.4.3, and the conditional autocovariance for the optical-photon random process $y(\mathbf{r})$ is given from (11.226) as

$$K_y(\mathbf{r}, \mathbf{r}' | \mathbf{b}_{ss}) = [\mathcal{H}_1 \mathbf{b}_{ss}](\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') + [\mathcal{H}_2 \mathbf{b}_{ss}](\mathbf{r}, \mathbf{r}'). \quad (12.299)$$

This autocovariance is conditional on a specific spatio-spectral fluence $b_{ss}(\mathbf{R})$, which is just the average distribution of interaction points within the detector as a function of 3D position and energy deposition. For x rays at normal incidence, $b_{ss}(\mathbf{R})$ is given by (12.296) and (12.294), but for more complicated x-ray beams a numerical calculation might be required. Nevertheless, (12.299) gives the autocovariance of any nonrandom x-ray source. It would not apply if the source strength fluctuated or if different absorbing objects were placed in the x-ray beam on different repetitions of the experiment.

Discrete photodetectors Now consider an array of photodiodes on the surface $z = L_z$ of the scintillator. If we assume that each photodiode is connected to a gated integrator, the output voltage of the m^{th} photodiode after the integration time T is given by (12.215), where the charge $Q_m(T)$ that appears in that equation results from both dark current and photocurrent. The photocurrent contribution to $V_m(T)$ is related to $y(\mathbf{r})$ by

$$V_m^{ph}(T) = -\frac{e\eta_m}{C_m} \int_m d^2 r y(\mathbf{r}), \quad (12.300)$$

where C_m is the integrating capacitor for photodiode m , η_m is its quantum efficiency, and the integral is over the area of that diode. We carry along the subscript m on η_m and C_m since these parameters may not be well controlled in the semiconductor manufacturing process. We can define an effective gain for the m^{th} photodiode as

$$\Gamma_m = -\frac{e\eta_m}{C_m}. \quad (12.301)$$

This gain is the ratio of the output voltage from the photodiode to the number of optical photons incident on it.

Since (12.300) is a linear continuous-to-discrete mapping, we can obtain the covariance matrix of the output voltages by applying (8.147) to (12.299). All other noise sources, including dark current, kTC noise and electronic noise, can be lumped into a variance term σ_m^2 in V_m . These noise sources are uncorrelated, so they contribute only to the diagonal elements of the covariance matrix. The covariance is thus given by

$$\begin{aligned} & [\mathbf{K}_v(\mathbf{b}_{ss})]_{mm'} \\ &= \left[\Gamma_m^2 \int_m d^2r [\mathcal{H}_1 \mathbf{b}_{ss}](\mathbf{r}) + \sigma_m^2 \right] \delta_{mm'} + \Gamma_m \Gamma_{m'} \int_m d^2r \int_{m'} d^2r' [\mathcal{H}_2 \mathbf{b}_{ss}](\mathbf{r}, \mathbf{r}'). \end{aligned} \quad (12.302)$$

The diagonal elements come from both the excess noise and the fact that $y(\mathbf{r})$ is a point process, and the off-diagonal terms come from the fact that a single x ray can contribute to the output of more than one photodiode.

Gain and offset correction In addition to the gain variations described by Γ_m , there can also be offset voltages arising from dark current or electronic offsets. It is common practice with photodiode arrays to correct the voltages for these variations, defining the final output data by

$$g_m = \frac{V_m - \bar{V}_m^{dark}}{\Gamma_m}, \quad (12.303)$$

where \bar{V}_m^{dark} is the mean of V_m in the absence of x rays.

The covariance matrix for the data vector \mathbf{g} is given by

$$[\mathbf{K}_g(\mathbf{b}_{ss})]_{mm'} = \left[\int_m d^2r [\mathcal{H}_1 \mathbf{b}_{ss}](\mathbf{r}) + \frac{\sigma_m^2}{\Gamma_m^2} \right] \delta_{mm'} + \int_m d^2r \int_{m'} d^2r' [\mathcal{H}_2 \mathbf{b}_{ss}](\mathbf{r}, \mathbf{r}'). \quad (12.304)$$

Note especially that the effect of gain variations has not disappeared. Photodiodes with small gain have relatively more noise after the gain correction if there is any noise source that is independent of the optical flux.

Stationarity? We have by now accumulated a long list of conditions that must be satisfied if we want to consider the noise in \mathbf{g} to be stationary in any sense. First, we know from Sec. 11.4.4 that the optical-photon point process $y(\mathbf{r})$ is stationary only if the 2D x-ray fluence is constant (immediately ruling out any interesting images) and the gain process is independent of lateral position. In the present context, the latter condition requires that the amount of light produced by an x ray and the spread of that light in propagating to the photodiode plane must be independent of x and y . There are many different kinds of material inhomogeneities that could invalidate this assumption. For example, many scintillators use a dopant to provide the light, and stationarity of $y(\mathbf{r})$ requires uniform doping density.

In addition, we know from Sec. 12.2.5 that stationarity is useful in a finite, discrete array only if it is cyclic. If we specify the photodiodes by the 2D multi-index \mathbf{j} , cyclic stationarity requires that $[\mathbf{K}]'_{\mathbf{j}\mathbf{j}}$ depend on $\mathbf{j} - \mathbf{j}'$ modulo \mathbf{J} . This unphysical wrap-around effect never occurs in practice, but it might have a negligible effect on subsequent uses of the covariance matrix if the array is large. Or it might not

(Pineda *et al.*, 2001).

Finally, we have just encountered a new reason for the stationarity assumption to fail — the inevitable gain variations in practical arrays. Even after correction, we see from (12.304) that the excess noise variance will depend on m (or \mathbf{j} if we choose to use a multi-index). To see why this effect negates any possible advantage of a Fourier description of the data, consider the data vector \mathbf{g} in the absence of any x rays, so that

$$[\mathbf{K}_{\mathbf{g}}^{dark}]_{\mathbf{j}\mathbf{j}'} = \frac{\sigma_{\mathbf{j}}^2}{\Gamma_{\mathbf{j}}^2} \delta_{\mathbf{j}\mathbf{j}'}. \quad (12.305)$$

We now take a discrete Fourier transform (DFT) of \mathbf{g} , using the multi-index notation. If both components of \mathbf{j} are assumed to run from 0 to $J - 1$, we can write

$$G_{\mathbf{k}} = \sum_{\mathbf{j}=0}^{J-1} g_{\mathbf{j}} \exp \left[-2\pi i \frac{\mathbf{j} \cdot \mathbf{k}}{J} \right]. \quad (12.306)$$

The covariance matrix is then transformed to

$$\begin{aligned} [\mathbf{K}_{\mathbf{G}}^{dark}]_{\mathbf{k}\mathbf{k}'} &= \sum_{\mathbf{j}=0}^{J-1} \sum_{\mathbf{j}'=0}^{J-1} [\mathbf{K}_{\mathbf{g}}^{dark}]_{\mathbf{j}\mathbf{j}'} \exp \left[-2\pi i \frac{\mathbf{j} \cdot \mathbf{k} - \mathbf{j}' \cdot \mathbf{k}'}{J} \right] \\ &= \sum_{\mathbf{j}=0}^{J-1} \frac{\sigma_{\mathbf{j}}^2}{\Gamma_{\mathbf{j}}^2} \exp \left[-2\pi i \frac{\mathbf{j} \cdot (\mathbf{k} - \mathbf{k}')}{J} \right]. \end{aligned} \quad (12.307)$$

This is as far as we can go in general. If we could assume that $\sigma_{\mathbf{j}}^2/\Gamma_{\mathbf{j}}^2$ was constant, we could perform the sum and find that $\mathbf{K}_{\mathbf{G}}^{dark}$ was diagonal, but in real detectors there will be off-diagonal terms. The natural (Karhunen-Loève) domain for describing the excess noise is the original data domain, where $\mathbf{K}_{\mathbf{g}}^{dark}$ is diagonal; the covariance matrix for this noise component gets more complicated, not less, after the DFT.

We thus have a quandary: The dark noise is diagonal in the original data domain, but if we make all of the other assumptions needed for stationarity, the x-ray part of the covariance is diagonalized in the Fourier domain. To diagonalize the overall covariance, we would have to use a Karhunen-Loève transformation (see Sec. 8.1.6), but it would be just a numerical device; no general theory or new insights would emerge.

The resolution of this quandary will be presented in Sec. 16.1. As we shall see there, we can use the noise characterizations derived in this chapter to compute meaningful, task-based figures of merit for image quality for x-ray detector arrays without needing the Fourier domain.

12.3.9 K x rays and Compton scattering

Throughout most of Sec. 12.3, we have ignored the secondary photons that are created in the initial x-ray or gamma-ray interaction. We know from the qualitative discussion in Sec. 12.3.1 that an initial photoelectric interaction can produce a K x ray that might then be reabsorbed at another point in the detector material. Similarly, if the initial interaction is Compton scattering, the scattered photon can also be reabsorbed in the detector. These reabsorbed photons can deposit energy

at points distant from the initial interaction, creating light or charge there that can be sensed on the exit face of the detector.

In this section we shall discuss the effect of these new energy deposition points with integrating x-ray detectors. The main tool for this purpose will be the 4D spatio-spectral point process defined in (12.295), only now it will be necessary to distinguish the primary (initial) interaction parameters from those for the secondary interactions. We thus rewrite (12.295) as

$$g_{ss}(\mathbf{R}) = g_{ss}^{pri}(\mathbf{R}) + g_{ss}^{sec}(\mathbf{R}) = \sum_{n=1}^{N_x} \delta(\mathbf{R} - \mathbf{R}_n^{pri}) + \sum_{n=1}^{N_{sec}} \delta(\mathbf{R} - \mathbf{R}_n^{sec}), \quad (12.308)$$

where N_x is the number of absorbed x rays and N_{sec} is the number of secondary photon absorptions in the detector (which can be less than N_x since the secondary photons can escape from the detector).

Spatio-spectral fluences We can define spatio-spectral fluences as the means of the component random processes:

$$b_{ss}^{pri}(\mathbf{R}) = \langle g_{ss}^{pri}(\mathbf{R}) \rangle, \quad b_{ss}^{sec}(\mathbf{R}) = \langle g_{ss}^{sec}(\mathbf{R}) \rangle. \quad (12.309)$$

Though it may be complicated in practice, there is no difficulty in principle in computing these fluences from knowledge of the incident x-ray flux and properties of the detector material. Henceforth we shall assume that the fluences are known.

If the primary fluence is nonrandom, $g_{ss}^{pri}(\mathbf{R})$ is a Poisson random process, and its autocovariance function is given by

$$K^{pri}(\mathbf{R}, \mathbf{R}') = b_{ss}^{pri}(\mathbf{R}) \delta(\mathbf{R} - \mathbf{R}'). \quad (12.310)$$

Moreover, by the binomial-selection theorem of Sec. 11.1.3, N_{sec} is a Poisson random variable if N_x is. Once the binomial selection is made, the secondary random process results from a 4D displacement from the primary process, and we know from the discussion around (11.229) that the Poisson character is preserved. Thus we also have

$$K^{sec}(\mathbf{R}, \mathbf{R}') = b_{ss}^{sec}(\mathbf{R}) \delta(\mathbf{R} - \mathbf{R}'). \quad (12.311)$$

It does not follow, however, that the overall interaction pattern $g_{ss}(\mathbf{R})$ is a Poisson random process; it cannot be since \mathbf{R}_n^{sec} and \mathbf{R}_n^{pri} both arise from the n^{th} absorbed x ray and hence are not independent.

Cross-correlation To compute the overall autocovariance, we need to study the cross correlation function,

$$\langle g_{ss}^{pri}(\mathbf{R}) g_{ss}^{sec}(\mathbf{R}') \rangle = \left\langle \sum_{n=1}^{N_x} \delta(\mathbf{R} - \mathbf{R}_n^{pri}) \sum_{n'=1}^{N_{sec}} \delta(\mathbf{R}' - \mathbf{R}_{n'}^{sec}) \right\rangle. \quad (12.312)$$

The average will be performed by methods developed in Sec. 11.3.3. As in that section, we must consider separately terms for which $n = n'$ and those for which $n \neq n'$.

If $n = n'$, then

$$\langle \delta(\mathbf{R} - \mathbf{R}_n^{pri}) \delta(\mathbf{R}' - \mathbf{R}_n^{sec}) \rangle$$

$$\begin{aligned}
 &= \int_D d^4 \mathbf{R}_n^{pri} \int_D d^4 \mathbf{R}_n^{sec} \text{pr}(\mathbf{R}_n^{sec} | \mathbf{R}_n^{pri}) \text{pr}(\mathbf{R}_n^{pri}) \delta(\mathbf{R} - \mathbf{R}_n^{pri}) \delta(\mathbf{R}' - \mathbf{R}_n^{sec}) \\
 &= \text{pr}_{p \rightarrow s}(\mathbf{R}' | \mathbf{R}) \text{pr}_{pri}(\mathbf{R}), \tag{12.313}
 \end{aligned}$$

where $\text{pr}_{p \rightarrow s}(\mathbf{R}_n^{sec} | \mathbf{R}_n^{pri})$ means the same thing as $\text{pr}(\mathbf{R}_n^{sec} | \mathbf{R}_n^{pri})$, but the new notation is required when we substitute \mathbf{R} for \mathbf{R}_n^{pri} and \mathbf{R}' for \mathbf{R}_n^{sec} as dictated by the delta functions.

For $n \neq n'$, we have

$$\begin{aligned}
 &\langle \delta(\mathbf{R} - \mathbf{R}_n^{pri}) \delta(\mathbf{R}' - \mathbf{R}_{n'}^{sec}) \rangle \\
 &= \int_D d^4 \mathbf{R}_n^{pri} \text{pr}(\mathbf{R}_n^{pri}) \delta(\mathbf{R} - \mathbf{R}_n^{pri}) \int_D d^4 \mathbf{R}_{n'}^{sec} \text{pr}(\mathbf{R}_{n'}^{sec}) \delta(\mathbf{R} - \mathbf{R}_{n'}^{sec}) \\
 &= \text{pr}_{pri}(\mathbf{R}) \text{pr}_{sec}(\mathbf{R}'). \tag{12.314}
 \end{aligned}$$

Since $g_{ss}^{pri}(\mathbf{R})$ and $g_{ss}^{sec}(\mathbf{R}')$ are individually Poisson processes (albeit correlated with each other), $\text{pr}_{pri}(\mathbf{R})$ and $\text{pr}_{sec}(\mathbf{R}')$ are just normalized versions of the respective fluences:

$$\text{pr}_{pri}(\mathbf{R}) = \bar{N}_x^{-1} b_{ss}^{pri}(\mathbf{R}), \quad \text{pr}_{sec}(\mathbf{R}') = \bar{N}_{sec}^{-1} b_{ss}^{sec}(\mathbf{R}'). \tag{12.315}$$

Since each of the secondary interactions derives from exactly one primary interaction, there are N_{sec} terms for which $n = n'$ and $N_x N_{sec} - N_{sec}$ terms with $n \neq n'$. Thus

$$\begin{aligned}
 &\langle g_{ss}^{pri}(\mathbf{R}) g_{ss}^{sec}(\mathbf{R}') \rangle \\
 &= \bar{N}_{sec} \left[\text{pr}_{p \rightarrow s}(\mathbf{R}' | \mathbf{R}) \bar{N}_x^{-1} b_{ss}^{pri}(\mathbf{R}) \right] + (\langle N_x N_{sec} \rangle - \bar{N}_{sec}) \left[\bar{N}_x^{-1} b_{ss}^{pri}(\mathbf{R}) \bar{N}_{sec}^{-1} b_{ss}^{sec}(\mathbf{R}') \right]. \tag{12.316}
 \end{aligned}$$

The only remaining expectation to perform is

$$\langle N_x N_{sec} \rangle = \sum_{N_x=0}^{\infty} \text{Pr}(N_x) \sum_{N_{sec}=0}^{\infty} \text{Pr}(N_{sec} | N_x) N_x N_{sec}. \tag{12.317}$$

The conditional probability $\text{Pr}(N_{sec} | N_x)$ is a binomial for which the probability of success can be denoted $p_{p \rightarrow s}$, which is the probability that an absorbed primary x ray will produce an absorbed secondary somewhere in the detector. The average of N_{sec} with respect to $\text{Pr}(N_{sec} | N_x)$ is $p_{p \rightarrow s} N_x$. Since $\text{Pr}(N_x)$ is a Poisson, we have

$$\langle N_x N_{sec} \rangle = \sum_{N_x=0}^{\infty} \text{Pr}(N_x) p_{p \rightarrow s} N_x^2 = p_{p \rightarrow s} (\bar{N}_x + \bar{N}_x^2). \tag{12.318}$$

Inserting this result into (12.317) and doing a little algebra, we find

$$\langle g_{ss}^{pri}(\mathbf{R}) g_{ss}^{sec}(\mathbf{R}') \rangle = p_{p \rightarrow s} \text{pr}_{p \rightarrow s}(\mathbf{R}' | \mathbf{R}) b_{ss}^{pri}(\mathbf{R}) + b_{ss}^{pri}(\mathbf{R}) b_{ss}^{sec}(\mathbf{R}'). \tag{12.319}$$

Overall 4D autocovariance function The autocovariance of $g_{ss}(\mathbf{R})$ (conditional on the specified fluences) is defined by

$$\begin{aligned} & K_{g_{ss}}(\mathbf{R}, \mathbf{R}' | \mathbf{b}_{ss}) \\ &= \langle [g_{ss}^{pri}(\mathbf{R}) + g_{ss}^{sec}(\mathbf{R})][g_{ss}^{pri}(\mathbf{R}') + g_{ss}^{sec}(\mathbf{R}')] \rangle \\ & \quad - [\bar{g}_{ss}^{pri}(\mathbf{R}) + \bar{g}_{ss}^{sec}(\mathbf{R})][\bar{g}_{ss}^{pri}(\mathbf{R}') + \bar{g}_{ss}^{sec}(\mathbf{R}')]. \end{aligned} \quad (12.320)$$

With (12.309)–(12.311) and (12.319), we see that

$$\begin{aligned} & K_{g_{ss}}(\mathbf{R}, \mathbf{R}' | \mathbf{b}_{ss}) \\ &= [b_{ss}^{pri}(\mathbf{R}) + b_{ss}^{sec}(\mathbf{R})] \delta(\mathbf{R} - \mathbf{R}') \\ & \quad + p_{p \rightarrow s} [\text{pr}_{p \rightarrow s}(\mathbf{R}' | \mathbf{R}) b_{ss}^{pri}(\mathbf{R}) + \text{pr}_{p \rightarrow s}(\mathbf{R} | \mathbf{R}') b_{ss}^{pri}(\mathbf{R}')]. \end{aligned} \quad (12.321)$$

We see that the 4D autocovariance contains the expected delta-correlated part proportional to the total fluence plus another part with a correlation structure determined by $\text{pr}_{p \rightarrow s}(\mathbf{R}' | \mathbf{R})$. This function is the probability density for a secondary interaction at \mathbf{R}' given that the primary interaction was at \mathbf{R} (and given that the secondary photon does not escape).

The dependence of $\text{pr}_{p \rightarrow s}(\mathbf{R}' | \mathbf{R})$ on the spatial parts of \mathbf{R} and \mathbf{R}' (the first three components of the 4D vectors) can be computed from knowledge of the attenuation coefficient and the geometry of the detector material. If the detector were infinitely thick, the spatial correlation would extend over a range in $|\mathbf{r}' - \mathbf{r}|$ approximately equal to the reciprocal of the attenuation coefficient, but of course the correlation length cannot exceed L_z in the $+z$ direction. We can envision $\text{pr}_{p \rightarrow s}(\mathbf{R}' | \mathbf{R})$ as a fuzzy ball centered on the primary interaction site and truncated by the detector boundaries.

The fourth component of \mathbf{R}' is the energy deposited in the secondary interaction. If we assume that the secondary photon gives up all of its remaining energy in the secondary interaction, then conservation of energy requires that $\mathcal{E}' + \mathcal{E} = \mathcal{E}_0$ (where \mathcal{E}_0 is the initial energy of the primary photon), so $\text{pr}_{p \rightarrow s}(\mathbf{R}' | \mathbf{R}) \propto \delta(\mathcal{E}' + \mathcal{E} - \mathcal{E}_0)$.

Discrete readouts The 4D autocovariance is not directly observable, but it determines the correlation properties of discrete readout signals in both semiconductor and scintillation detectors. Consider, for example, a scintillation detector with an array of photodiodes as analyzed in Sec. 12.3.8. In that section the energy deposition was described by a Poisson point process, so the only pixel-to-pixel correlation was that induced by the spreading of the optical photons *en route* to the photodiodes. With the secondary interactions, there is another source of correlation since optical photons are generated not only at the primary site, but also at a nearby secondary site. Even if there were no spread of the optical photons, there would be correlations between different pixels.

The implications of these correlations for x-ray imaging will be discussed in Sec. 16.1.

13

Statistical Decision Theory

In the preceding chapters we have considered various descriptions for the deterministic image-formation process (Chaps. 7, 9 and 10) as well as the possible sources of randomness in the resulting images (Chaps. 8, 11 and 12). Armed with this background, we are now able to consider the weighty topic of image quality and imaging system evaluation.

It is our premise that the quality of an imaging system is *defined* by how well inferences about an underlying scene can be made using its image as input. More importantly, image quality must be assessed on the basis of *average* performance of some inference task by some observer or decision-maker. Image quality is thus a statistical concept; statistical decision theory is the key to the mathematical characterization of image quality.

This chapter discusses the kinds of inferences that might be of interest to various imaging communities, how these tasks are approached by predefined decision-makers or observers, and figures of merit for quantifying the performance of these observers. In Chap. 14 we shall discuss many of the practical issues that arise in the application of the mathematical tools provided in this chapter to the problem of the objective assessment of imaging systems. In particular, issues related to estimation of image statistics and figures of merit from a finite set of sample images are presented in Chap. 14. Throughout this chapter we assume full knowledge of the ensemble statistics of the data necessary to calculate the figures of merit under discussion.

13.1 BASIC CONCEPTS

We begin with a discussion of the kinds of inferences or decisions that can be derived from the output of an imaging system. In addition to the image itself, inputs to the decision-making process can include statistical and deterministic models of the imaging system (combined into a likelihood function), prior information about

the objects, and a judgment as to the costs of incorrect decisions and the benefits of correct ones. The discussion of priors and costs will inevitably take us back to the conflict between Bayesian and frequentist approaches to inference. Our general approach to this issue, sketched in the Prologue, will be taken up in more mathematical detail here.

13.1.1 Kinds of decisions

As described in the Prologue, we divide statistical inference into two types: *classification* and *parameter estimation*. Any time there are a finite number of possible outcomes, we refer to the inference as classification. In the imaging literature, the terms *pattern recognition*, *signal detection*, *discrimination*, *discriminant analysis*, *differential diagnosis*, *segmentation*, and *hypothesis testing* fall under this category. Parameter estimation, on the other hand, can be regarded as the limit of hypothesis testing when the number of hypotheses becomes infinite (usually uncountably infinite). Then the premise is that we are interested in extracting one or more numerical parameters from the data, and these parameters can take on any value in some specified range. The medical literature sometimes calls this task *quantitation*.

We treat both kinds of inference within this chapter for, as we shall demonstrate, there are strong connections between the approaches to classification and estimation problems provided by statistical decision theory, as demonstrated in Fig. 13.1. For both inferences the first step is the development of a model for the objects under investigation. For this we make use of the mathematical models for the deterministic aspects of objects described in Chap. 7 and the tools provided in Chap. 8 for characterization of the variability of the objects under consideration. The next step is the generation of a model for the acquired data. Here we must apply whatever knowledge we have of the image-formation process, including the deterministic mapping of an object through the imaging system as well as the noise sources of the system.

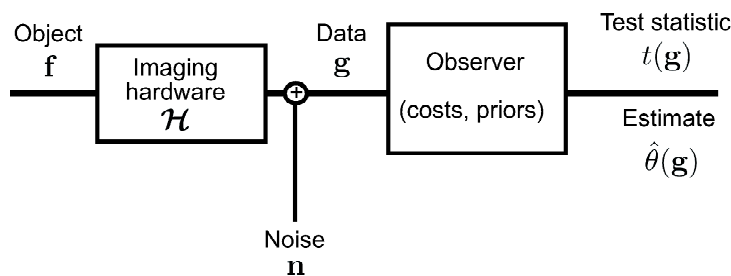

Fig. 13.1 Flow chart showing steps toward the extraction of a test statistic or a parameter estimate.

We call the means by which the task gets done, or the strategy, the observer or decision-maker. For example, the observer in a lesion-detection task on real clinical images might be a radiologist. Alternatively, much research effort is being expended on the development of computer algorithms for such tasks. A special observer known as the *ideal observer* or *Bayesian observer* is defined as the observer that utilizes all statistical information available regarding the task to maximize task

performance as measured by Bayes risk or some other related measure of performance. Thus the performance of the Bayesian observer provides an upper bound against which all other observers can be compared.

Estimation tasks using images as inputs are most often performed by computer algorithms. These algorithms can run the gamut from very *ad hoc* procedures to ones based on optimality criteria involving the bias and/or variance of the resulting estimates.

Returning to Fig. 13.1, we see that one or more operations are applied to the data by the observer to facilitate the inference. If the task is classification, the output of these operations is a *test statistic*. If the task is estimation, the output is the estimate itself. These quantities are random, because they are based on operations on random data. Thus both classification and estimation tasks demand the same kind of information from the practitioner, and both result in the computation of a random quantity at the output to the inference process. As we shall show, the assessment of system performance for both kinds of tasks also has a similar construction.

Classification In classification, the output of an imaging system is observed, and the observer must infer the class membership of the object at the input to the imaging system. The observer usually has some information about the possible objects being imaged, the way in which objects are distorted by the image-acquisition process, and the sources of randomness in the data. In radar, the classification task might be the determination of the presence or absence of a target in the radar signal. In medical applications the task might be tumor detection, or it might be the classification of a detected tumor into a particular class, *e.g.*, malignant or benign. The discrimination of tanks from trucks in aerial photographs is a common military application of statistical decision theory.

The classification problem was studied as early as the middle of the 18th century, when Thomas Bayes published his theory for the testing of hypotheses by statistical inference (Bayes, 1764). The advent of radar and communications technology in the mid-twentieth century rekindled interest in Bayes' theories for statistical decision making (Van Meter and Middleton, 1954; Peterson, 1954). More recently, statistical decision theory has been applied to the evaluation of medical imaging systems (Swets, 1979; Swets and Pickett, 1982; Wagner and Brown, 1985; Barrett, 1990; ICRU Report, 1996) and has contributed to the study of human perception (Tanner and Swets, 1954; Swets, 1964; Lusted, 1968; Burgess *et al.*, 1981; Swensson and Judy, 1981).

A classification problem is categorized according to the number of hypotheses to be distinguished, the nature of the hypotheses, the structure of the data, and the statistics of the signal and noise. Classification tasks can be as simple as the detection of a known (nonrandom) signal in a known background, or as complex as the discrimination of multiple classes comprised of fully random objects described by different probability density functions.

Classification tasks with just two underlying hypotheses or classes from which the data might be drawn are known as *binary* decision problems. Determining whether a reconnaissance image contains a tank is an example of a binary decision problem, because the classification is into one of two possible alternatives — tank or no-tank. As we shall see, the same theory can be extended to the multiple-decision or *L*-class task, where the data are to be assigned to one of *L* possible hypotheses.

The L hypotheses may correspond to L different signals, all in the same location (Burgess and Ghandeharian, 1984b; Eckstein and Abbey, 2001), or one signal in one of L possible locations (Goodenough, 1975; Starr *et al.*, 1975), or a more general set of L hypotheses.

A common example of an L -class task is the pattern-recognition task of character recognition. The character to be classified might be one of a finite number of letters of known font, so that the signals are nonrandom. Alternatively, the characters might have some randomness in one or more parameters; for example, perhaps they might be of known font but with some randomness in scale. At the other extreme, the characters to be classified might be freehand letters, so that the objects have a great deal of randomness associated with them. In Sec. 13.3 we shall show in mathematical detail how increasing levels of randomness in the classes to be discriminated are incorporated in signal-detection theory.

Estimation Classical estimation begins with the assumption that we are given data \mathbf{g} from some known probability law $\text{pr}(\mathbf{g}|\theta)$ and the task is to estimate the scalar parameter θ . As an example, a photon-counting probe might be used to determine the activity in a draining lymph node. Poisson statistics govern the number of detected counts in this case. Since the Poisson law has just one free parameter, the mean count rate, measurements over equal counting intervals will allow the estimation of this rate for the node under test. As a second example, suppose we use a photoconductor to detect light transmitted by an object. If the current at the output of the detector suffers from Johnson noise fluctuations, the randomness of the current can be modeled by a Gaussian random process. While a Gaussian probability density function (PDF) is generally parameterized by a mean and variance, we might make the assumption that the noise variance is independent of the signal, and that this variance has already been characterized for this detector. An estimate of the mean of the Gaussian PDF can then be formed based on measurements at the output of the detector.

The estimation of a single parameter from a measurement, like the example of the photon-counting detector above, is *scalar parameter estimation*. *Vector parameter estimation* involves the determination of more than one parameter, which we arrange in a parameter vector $\boldsymbol{\theta}$. If we had to estimate both the mean and variance of the noise in the Gaussian example above, these two parameters would constitute the vector $\boldsymbol{\theta}$. The task of image reconstruction, a subject we treat in detail in Chap. 15, may also be thought of as a kind of vector parameter estimation.

Determination of the single “best” estimate of one or more parameters is known as *point estimation*. In point estimation no information is provided about the uncertainty in the estimated value. In contrast, *interval* or *region* estimation results in a set of values the parameters might reasonably take on (Casella and Berger, 1990). An interval estimate is not as precise as a point estimate, but is intended to provide confidence that the true value of the parameter is within the estimated interval. The result of an interval estimation procedure for a scalar quantity is straightforward to present in graphical or numerical terms. However, due to the inherent difficulty of representing the output of a region estimation procedure for a large set of numbers, region estimation is not commonly applied to vector estimation problems.

In some circumstances the task is the estimation of the entire probability density function of a random variable from sample values. One approach to this so-

called *density estimation* problem is to parameterize a well-known density function kernel and seek estimates for the underlying parameters, *e.g.*, the mean and variance of a Gaussian PDF. The most common nonparametric method of density estimation is *kernel estimation*, in which a smoothing kernel such as a Gaussian is associated with each observed point in the sample space (Silverman, 1986).

In a sense, image reconstruction is density estimation. We saw in Chap. 11 that an object, when properly normalized, can often be regarded as the PDF for photon emissions, so to estimate the object is to estimate this PDF. In practice, we may adopt some approximate representation such as a voxel expansion for the object, and in that case reconstruction is parameter estimation, albeit with a large number of parameters. As we shall see in Sec. 15.2.2, however, it is also possible to estimate the underlying object function — a density — without discretization. With this exception, we shall say nothing more about density estimation.

Hybrid estimation-classification tasks We are often interested in forming an estimate of one or more parameters that will then be used as input to subsequent decision-making operations. Examples abound of quantities that are extracted from medical images with the end goal being the classification of the tissue or organ as normal or diseased. For instance, a series of nuclear medicine images might be obtained to quantify organ time-activity dynamics, which can be used in the classification of disease in such organs as the liver, heart, or kidney. Alternatively, estimation may follow detection, as is the case when a decision is made in favor of a particular hypothesis, and an estimate is then made of a parameter underlying the objects known to be present under the selected hypothesis. For example, a tumor may first be detected, and then its size is estimated to determine the stage of the disease. When estimation and classification tasks are combined, the overall procedure is termed a *hybrid* estimation-classification task.

Tests of the null hypothesis Classification can also be called hypothesis testing. For some readers this term will conjure up the standard form of significance testing taught in most statistics classes and found in much of the biomedical sciences literature. In this approach, a null hypothesis H_0 is formulated; for example, the parameter θ is a random variable distributed as $\mathcal{N}(0, \sigma^2)$. The complement of the null hypothesis, denoted H_1 , is called the alternative to H_0 . Often the null hypothesis is that one data set is drawn from the same density function as another; the alternative to this hypothesis is that the data sets are different (or, one product is better!). Once the hypotheses are formulated, observed values are tested to see whether the null hypothesis can be accepted or rejected.

Consider the typical scenario in which data are collected from two sets of biological samples, one which underwent a treatment program and one which did not. Now the investigators want to determine whether the mean value of the data from each set is different to see if the treatment program has an effect. A test of the null hypothesis that the data have the same means, assuming Gaussian PDFs with equal variance, is performed. Sample means \bar{x}_1 and \bar{x}_2 are determined from the data and used to test whether $\bar{x}_2 - \bar{x}_1$ is statistically significantly different from 0. Based on standard tables, the probability of obtaining the observed difference in the means is computed. If this probability (the so-called *p*-value) is deemed small enough, at the .01 or .05 level, say, these investigators would claim they have grounds for rejecting the null hypothesis.

There are a number of serious flaws in this approach to assessing the separability of two data sets. First of all, the simple point hypothesis can virtually always be shown to be wrong. Consider two normal distributions $\mathcal{N}(1, 10)$ and $\mathcal{N}(1.01, 10)$. A single sample would have almost no value for distinguishing the two distributions. A physician would say that a diagnostic test based on this variable was worthless, and a physicist would say the two distributions were not significantly different since the difference in means is very small compared to the standard deviation. A determined statistician, on the other hand, could draw not one but many thousand samples and discern that the difference in means is significant at the .01 level. The same statement could be made if the distributions were $\mathcal{N}(1, 1)$ and $\mathcal{N}(2, 1)$ and many fewer samples were used. The point is that so-called statistical significance is a function of the diligence of the experimenter as well as the size of the deviation from the null hypothesis relative to the spread in measurements of a sample. A statistician who reports only a p -value has ignored perhaps the most important aspect of the data: the difference in estimated means divided by the estimated average standard deviation.

A second serious flaw in this approach is that the alternative to the null hypothesis is vague and meaningless. The alternative to the hypothesis that the data have equal means is that the means are different. How different? It does not matter in this framework.

A further objection to this sort of hypothesis testing is that the determination of statistical significance allows the investigator to reject the null hypothesis, when in fact it might be that the model is what is really in need of being rejected. One can easily concoct an illustration where two data sets would result in a rejected null hypothesis for Gaussian PDFs with equal means when in actuality the Gaussian PDF assumption that was made was inappropriate. In the end, it can be quite difficult to know whether it is the model or the hypothesis that should be rejected. For all these reasons we reject the usage of this methodology for the assessment of imaging systems, recommending instead the task-based approach of statistical decision theory with clearly specified alternatives.

13.1.2 Inputs to the process

The data As shown in Fig. 13.1, estimation and classification involve the computation of estimates, in the former, or test statistics, in the latter, based on the data at the output of an imaging system. For a digital imaging system the data consist of the set of M measurements $\{g_m\}$, which might be the set of pixel values or gray levels from a direct imaging system, or the raw measurements from a tomographic imaging system. As usual, these data can be thought of as a point in an M -dimensional observation space, denoted by the $M \times 1$ column vector \mathbf{g} . Each of the elements of \mathbf{g} is a random variable.

The data are the result of an image-formation process whereby a continuous object $f(\mathbf{r})$ is mapped to the data set. The mapping can be represented quite generally by

$$\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}, \quad (13.1)$$

where \mathcal{H} is some appropriate imaging operator, as discussed in Chap. 7. Note that we have written the continuous object as a vector \mathbf{f} in the Hilbert space of square-integrable functions; we emphasize that this notation does not limit our treatment to discrete objects.

The M -dimensional vector \mathbf{n} in (13.1) represents the noise in the data set. The fact that the noise is represented as additive does not restrict us to additive noise conditions. It is understood that the noise is the difference between the expected data set in the absence of noise and the actual data set. That is,

$$\mathbf{n} \equiv \mathbf{g} - \langle \mathbf{g} \rangle_{\mathbf{n}} = \mathbf{g} - \mathcal{H}\mathbf{f}, \quad (13.2)$$

where the angle brackets subscripted by \mathbf{n} denote a statistical average over the noise for an ensemble of data sets acquired with a particular object \mathbf{f} .

Raw images are just one form of input data upon which an observer might base decisions. Decisions might also be based on features extracted from images. These features might be numerified qualitative observations (*e.g.*, spicularity of a lesion on a scale of 1 to 10), or features derived from an image by computer algorithms.

It follows from (13.1) that a model of the deterministic characteristics of the imaging system, specified by \mathcal{H} , is required for drawing inferences based on images. To whatever extent is possible, we want our system model to be accurate so that inference errors are solely the result of the limiting variability in the data, and not due to modeling errors.

Conditional probability model In order to draw an inference from random data, it is vital that a model for the conditional probability density function on the data be constructed and brought to bear on the classification or estimation problem by the decision-maker. Classification strategies hinge on how the data are distributed given a particular underlying object or hypothesis; this information is captured by the conditional density function $\text{pr}(\mathbf{g}|\mathbf{f})$. Alternatively, estimation involves the determination of the value of some feature θ of the object given the data in hand. The strategy for estimating this feature will depend to a large degree on the effect this feature has on the data set. We write the probability density function for the data conditioned on a particular value of this feature by $\text{pr}(\mathbf{g}|\theta)$. The conditional probability densities $\text{pr}(\mathbf{g}|\mathbf{f})$ and $\text{pr}(\mathbf{g}|\theta)$ are referred to as *likelihood* functions since they tell how likely it is that a given data set is obtained when some underlying state of nature is true.

Imperfect or incomplete knowledge of the likelihood function results in additional classification or estimation errors beyond what would occur as a result of the limiting uncertainty in the data due to measurement noise. In particular, it may be hard to determine $\text{pr}(\mathbf{g}|\theta)$ in an estimation problem if the vector θ has low dimensionality. For example, many possible data sets could be obtained from objects with the same tumor volume, so that it would be quite difficult to determine the probabilistic relationship between tumor volume and the data. If, on the other hand, θ has high dimensionality, we can be more hopeful of making sense of $\text{pr}(\mathbf{g}|\theta)$. For example, if θ is a vector of expansion coefficients used to represent the object, we might be able to approximate the mapping of (13.1) by writing $\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n} \approx \mathbf{H}\theta + \mathbf{n}$ (for a linear imaging system). In that case we can presume that $\text{pr}(\mathbf{g}|\theta) \approx \text{pr}(\mathbf{g}|\mathbf{f})$. This density is something we can compute by making use of the techniques presented in Chaps. 8, 11, and 12.

In the Prologue we describe our philosophy regarding the interpretation of $\text{pr}(\mathbf{g}|\mathbf{f})$, which we believe is naturally interpreted in terms of relative frequencies and hence can, in principle, be obtained by repeated experimental observation. In most cases, however, the basic physics of the measurement process tells us the form of $\text{pr}(\mathbf{g}|\mathbf{f})$, in a frequentist sense, and we do not have to actually do the experi-

ments. For example, in a photon-counting situation, we know that the statistics will be Poisson under broad conditions discussed in Chap. 11.

Priors When the object has some randomness, the density function for the data depends on the probability density function on the object as well as the measurement noise. Consider a classification problem for which there exists a distribution of possible objects for each hypothesis H_j . We write the conditional density function on the data under H_j as¹

$$\text{pr}(\mathbf{g}|H_j) = \int_{\mathbb{U}} d\mathbf{f} \text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}|H_j), \quad (13.3)$$

where the conditional probability $\text{pr}(\mathbf{f}|H_j)$ is the object prior. From Chap. 8 we know that it is difficult to be precise about the meaning of $\text{pr}(\mathbf{f}|H_j)$ for realistic problems since \mathbf{f} is in principle infinite-dimensional. As discussed in Sec. 8.4, we can avoid this problem by using a finite-dimensional object representation such as (7.27) with an $N \times 1$ vector of coefficients $\boldsymbol{\alpha}$. In that case (13.3) becomes

$$\text{pr}(\mathbf{g}|H_j) = \int_{\infty} d^N \alpha \text{pr}(\mathbf{g}|\boldsymbol{\alpha}) \text{pr}(\boldsymbol{\alpha}|H_j). \quad (13.4)$$

Now we need only an N -dimensional prior on $\boldsymbol{\alpha}$ instead of the infinite-dimensional prior on \mathbf{f} . As discussed in Sec. 8.4.1, it is sometimes possible to evaluate the integral in (13.4) through simulation methods.

Analogously, in estimation a Bayesian decision-maker assumes that $\boldsymbol{\theta}$ is itself a random variable with a probability density function given by $\text{pr}(\boldsymbol{\theta})$. As we shall see, the Bayesian's estimation strategy recasts the information contained in this prior density in light of the acquired data.

As discussed in the Prologue, Bayesians and frequentists have vastly differing views on the relevance and interpretation of object priors. Methods for deriving and interpreting prior object information are introduced in the Prologue; a number of models for object variability are presented in Chap. 8.

Prevalence in classification tasks From a Bayesian point of view a final bit of information is needed to perform a classification task. For classification a Bayesian would need to know the prior probability or *prevalence* of the underlying classes to which the data set must be assigned, denoted $\text{Pr}(H_j) = P_j$. For example, information regarding troop and equipment movements will influence the reading of newly acquired aerial reconnaissance photographs by an expert military observer. Likewise, the prevalence of a disease will influence a radiologist's decision process when reading a set of films where the task is to determine if that disease is present or absent. There are many ways of determining prevalence, all typically frequentist in approach. Prevalence might be estimated from nationwide statistics, local community statistics, data gathered from a particular medical practice so that the demographics of that small patient population are represented, or it might even take into account patient-specific information such as age, weight, or family risk factors.

¹The integral here is, in principle, over the entire object Hilbert space \mathbb{U} . See Sec. 8.2.2 and especially (8.81) for details.

Costs and risks Costs can be associated with making correct and incorrect decisions, and a decision strategy can be designed to minimize these costs. Similarly, costs can be associated with estimation errors, and an estimator can be chosen to minimize these. The philosophy of the decision-maker greatly influences the manner by which costs are utilized in the design of an inference strategy.

For estimating a scalar parameter, we write the cost of an estimation error as $C(\hat{\theta}, \theta)$, which is a function of both the underlying parameter, θ , and its estimated value, $\hat{\theta}$. The squared distance $(\hat{\theta} - \theta)^2$ between the estimate and the actual value of the parameter is a common cost function. The *risk*, or average cost, can be defined in three ways, depending on the functional dependence we are interested in probing.

Table 13.1 Definitions of Risk

Average Cost	Functional Dependence
$\langle C(\hat{\theta}, \theta) \rangle_{\mathbf{g} \theta}$	Function of θ
$\langle C(\hat{\theta}, \theta) \rangle_{\theta \mathbf{g}}$	Function of \mathbf{g}
$\langle \langle C(\hat{\theta}, \theta) \rangle_{\mathbf{g} \theta} \rangle_{\theta} = \langle \langle C(\hat{\theta}, \theta) \rangle_{\theta \mathbf{g}} \rangle_{\mathbf{g}}$	Pure scalar

The first definition of risk in Table 13.1 is essentially frequentist, in that it averages over many realizations of the data for a particular underlying parameter θ . In contrast, a Bayesian considers only the single data set in hand to be relevant. Thus the second row in the table above, which expresses the average cost of the estimate for a particular data set \mathbf{g} , is a Bayesian measure of risk. The left-most form in the third row defines the average cost found by first averaging over all data sets conditioned on a particular parameter θ , followed by averaging over the ensemble of possible values of θ . An equivalent value is obtained by first computing the average cost of the estimate for a fixed data set and then averaging over the ensemble of possible data vectors. The resulting risk is a scalar that summarizes the overall performance of the estimator in the presence of measurement noise as well as randomness of the underlying object. This measure is commonly (but confusingly) referred to as *Bayes risk*. Hard-nosed Bayesians would resist the average over \mathbf{g} .

A similar hierarchy exists when considering classification errors. Let C_{ij} be the cost associated with making decision D_i (in favor of hypothesis H_i) when hypothesis H_j is actually true. Then $C_{ij} = C(D_i, H_j)$ is the classification analog of the estimation cost function $C(\hat{\theta}, \theta)$. In general, a cost can be assigned to a correct decision as well as an incorrect decision (a positive cost indicates a penalty). If there are L total classes, the average cost of making decision D_i is:

$$\bar{C}(D_i) = \sum_{j=1}^L C_{ij} \Pr(H_j|D_i). \tag{13.5}$$

The average cost, over all possible decisions, when hypothesis H_j is true is given by

$$\bar{C}(H_j) = \sum_{i=1}^L C_{ij} \Pr(D_i|H_j). \quad (13.6)$$

The overall average cost of a decision, also called the Bayes risk, is given by

$$\begin{aligned} \bar{C} &= \sum_{i=1}^L \sum_{j=1}^L C_{ij} \Pr(H_j, D_i) \\ &= \sum_{i=1}^L \sum_{j=1}^L C_{ij} \Pr(H_j|D_i) \Pr(D_i) = \sum_{i=1}^L \sum_{j=1}^L C_{ij} \Pr(D_i|H_j) \Pr(H_j) \\ &= \sum_{i=1}^L \bar{C}(D_i) \Pr(D_i) = \sum_{j=1}^L \bar{C}(H_j) \Pr(H_j). \end{aligned} \quad (13.7)$$

Note the parallel between the three kinds of averages represented by (13.5)–(13.7) and the three kinds of average cost functions for estimation presented in Table 13.1. We can average over the decision (estimate), the underlying truth state (underlying true parameter value), or both.

13.2 CLASSIFICATION TASKS

In this section we present a formal theory for the detection and classification of objects from data distorted by noise. We begin in Sec. 13.2.1 with the concept of classification as a partitioning of the data space. The specific case of a binary decision task is considered in Sec. 13.2.2, with methods for summarizing binary classification performance given in Secs. 13.2.3–13.2.5. Once we have defined figures of merit for task performance, we can make use of these tools in Secs. 13.2.6 and 13.2.7 to determine optimal strategies for classification. The optimal classifier for known signals on known backgrounds in Gaussian noise is treated in Sec. 13.2.8, and the non-Gaussian case is the subject of Sec. 13.2.9. Section 13.2.10 considers situations in which the signal is random; the generalization to random backgrounds is given in Sec. 13.2.11. Finally, we consider the performance of the best linear observer in Sec. 13.2.12. All these sections treat the data as discrete random vectors; continuous data sets are treated in Sec. 13.2.13. Readers already conversant with the approach to statistical decision theory found in such classic texts as Van Trees (1968), Whalen (1971), and Melsa and Cohn (1978) should be able to skim the material in Secs. 13.2.1–13.2.4.

13.2.1 Partitioning the data space

In a classification problem, an observer makes use of a data vector \mathbf{g} to infer which of the underlying classes or hypotheses was the source of the detected data. That is, given all the inputs to the process the observer makes decision D_i , deciding in favor of hypothesis H_i . We shall impose two restrictions on the manner by which the observer makes this decision. First, we allow no randomness in the decision

rule; repeated observations of the same data \mathbf{g} must result in the same decision D_i . We also assume that every observation results in a decision; we shall not allow for the possibility of an equivocal test. With these assumptions, classification is equivalent to partitioning the observation space into distinct (nonoverlapping) volumes. Combined, these regions in observation space must contain all possible observation points. (See App. C for a presentation of the basics of set theory needed to understand the concept of an observation space and its underlying probability structure.)

An example data space is shown in Fig. 13.2 with nonoverlapping partitions labeled Γ_i to indicate that a data vector in that region results in decision D_i . Regardless of the topology of the decision boundaries, the union of the partitions covers all data space \mathbb{V} :

$$\bigcup_i \Gamma_i = \mathbb{V}, \tag{13.8a}$$

where

$$\Gamma_i \cap \Gamma_j = \emptyset \quad \text{for } i \neq j. \tag{13.8b}$$

For a binary or two-class problem, the process of assigning the data to one of the decision regions is accomplished by computation of a scalar *test statistic*, t . The test statistic is related to the data through a *discriminant function* $T(\mathbf{g}) = t$. The discriminant function can be either a linear or nonlinear functional of the random data. The observer assigns a given data set to a particular decision region by comparing t to a *decision threshold* or cutoff t_c . The partition lines in Fig. 13.2 are thus contours of constant value of t .

Fig. 13.2 Example of a partitioned data space showing four decision regions.

In an L -class problem with $L > 2$, we need multiple discriminant functions and some partitioning rule. For example, we could compute a set of functions $\{T_\ell(\mathbf{g}), \ell = 1, \dots, L\}$ and assign a particular \mathbf{g} to region Γ_j if $T_j(\mathbf{g}) > T_k(\mathbf{g})$ for all $j \neq k$.

Partitioning with hyperplanes Consider the special case in which $t = T(\mathbf{g})$ is a linear function of the data. That is,

$$T(\mathbf{g}) = \mathbf{w}^t \mathbf{g}, \tag{13.9}$$

where \mathbf{w} is an $M \times 1$ vector and $\mathbf{w}^t \mathbf{g}$ is the scalar product of \mathbf{w} and \mathbf{g} . The decision boundary is an isocontour of this function, which is a hyperplane in an

M -dimensional space.² For a binary classification problem, the data space can be partitioned with a single such hyperplane, though the use of several hyperplanes to allow a region Γ_i to consist of disjoint subregions is not precluded. If there are L classes, at least $L - 1$ hyperplanes are needed.

General discriminants and their density functions More generally, the test statistic is a nonlinear function of the data, in which case the decision boundary can deviate greatly from a hyperplane. For example, when the test statistic depends quadratically on the data, the decision boundaries shown in Fig. 13.2 would be quadratic in shape.

Whatever its functional dependence on the data, the test statistic t is a random variable through its dependence on \mathbf{g} . The probability density function on t depends on the underlying hypothesis:

$$\text{pr}(t|H_j) = \int_{-\infty}^{\infty} d^M \mathbf{g} \text{pr}(t|\mathbf{g}) \text{pr}(\mathbf{g}|H_j) = \int_{-\infty}^{\infty} d^M \mathbf{g} \delta[t - T(\mathbf{g})] \text{pr}(\mathbf{g}|H_j), \quad (13.10)$$

where we have represented the deterministic function $T(\mathbf{g}) = t$ as a probabilistic mapping.

The ellipses in Figure 13.3 represent the PDFs $\text{pr}(\mathbf{g}|H_1)$ and $\text{pr}(\mathbf{g}|H_2)$ in a 2D subspace for the binary decision problem. Overlapping univariate PDFs representing $\text{pr}(g_1|H_1)$ and $\text{pr}(g_1|H_2)$ are plotted along the x axis. Similarly, overlapping univariate PDFs representing $\text{pr}(g_2|H_1)$ and $\text{pr}(g_2|H_2)$ are plotted along the y axis. A linear discriminant is also shown in the figure; the line perpendicular to the discriminant function is the t -axis. When $t \geq t_c$, H_2 is chosen; when $t < t_c$, H_1 is chosen. By varying t_c we move the line in Fig. 13.3 perpendicular to itself. In the general L -class problem, changes in decision boundaries cause the partitions in Fig. 13.2 to shrink or grow.

Fig. 13.3 Illustration of a linear discriminant for a 2-pixel (feature) problem. The ellipsoids indicate isocontours of constant joint probability density on the data values for each class. The line labeled $t = t_c$ is the linear discriminant for one threshold setting. Also shown are the marginal PDFs for each data component.

²We have assumed that both \mathbf{g} and \mathbf{w} are real vectors in (13.9), resulting in a real test statistic t . In the case of complex data, the form of the linear discriminant is generalized to $t = \text{Re}[\mathbf{w}^\dagger \mathbf{g}]$, with \mathbf{w} possibly also complex, such that t is a real scalar which is then compared to a threshold.

13.2.2 Binary decision outcomes

We again restrict our discussion to the binary decision problem depicted in Fig. 13.3, in which the object belongs to one of two classes or hypotheses: H_1 and H_2 . In the detection case the hypotheses correspond to signal present or signal absent, but the hypotheses more generally represent signal family 1 vs. signal family 2. We assume that the decision made by the observer is also binary: D_1 denotes a decision that hypothesis H_1 is true, and D_2 similarly for H_2 .

The observer’s decision is based on the data \mathbf{g} , which constitute only incomplete clues to the underlying object because they are obtained through some imaging system and contaminated by noise. Because this is the case, whatever the decision rule adopted, the decisions to which it leads cannot always be correct. Instead, as shown in Table 13.2, four scenarios exist for each experimental observation.

Table 13.2 Decision outcomes

1.	True positive (TP):	H_2 is true; observer decides H_2 is true.
2.	False positive (FP):	H_1 is true; observer decides H_2 is true.
3.	False negative (FN):	H_2 is true; observer decides H_1 is true.
4.	True negative (TN):	H_1 is true; observer decides H_1 is true.

Two of the above alternatives result in the observer correctly determining the underlying hypothesis, but we also see that two types of errors can be made. If the problem is to decide whether signal is present or absent, and the observer says a signal is present when in fact it is not, a type I error is made. In radar terminology this is called a *false alarm*, while in the medical literature it is called a *false positive*. When the signal is present, but the observer chooses the noise-only alternative, we say a *miss* or *false negative* has occurred. This is known as a Type II error.

The four scenarios for the binary detection problem can be represented by the 2×2 decision table shown in Table 13.3.

Table 13.3 Decision states

	H_2 : Signal present	H_1 : Signal absent
Decide H_2 D_2	True positive Hit Correct detection	False positive False alarm Type I error
Decide H_1 D_1	False negative Miss Type II error	True negative “good no call”

Sensitivity and specificity Let N be the total number of decisions made by an observer. Further, let N_{TP} denote the number of true positive decisions made by the observer. Similar notation can be used for the number of times a decision is made corresponding to the other three scenarios represented in the table, so that $N = N_{TP} + N_{FP} + N_{TN} + N_{FN}$. The observed fractions of correct and incorrect

decisions under each truth state are random quantities; in the limit of an infinite number of trials they yield the actual true- and false-positive fractions:

$$\text{TPF} = \Pr(D_2|H_2) = \left\langle \frac{N_{TP}}{N_{TP} + N_{FN}} \right\rangle = \lim_{N \rightarrow \infty} \left[\frac{\text{Number of true positive decisions}}{\text{Number of actually positive cases}} \right], \quad (13.11a)$$

$$\text{TNF} = \Pr(D_1|H_1) = \left\langle \frac{N_{TN}}{N_{TN} + N_{FP}} \right\rangle = \lim_{N \rightarrow \infty} \left[\frac{\text{Number of true negative decisions}}{\text{Number of actually negative cases}} \right], \quad (13.11b)$$

$$\text{FPF} = \Pr(D_2|H_1) = \left\langle \frac{N_{FP}}{N_{TN} + N_{FP}} \right\rangle = 1 - \text{TNF}, \quad (13.11c)$$

$$\text{FNF} = \Pr(D_1|H_2) = \left\langle \frac{N_{FN}}{N_{TP} + N_{FN}} \right\rangle = 1 - \text{TPF}. \quad (13.11d)$$

By definition each of these fractions has value in the range from zero to one.

We see from (13.11c) and (13.11d) that the observer's performance is fully specified by two of the fractions, *e.g.*, TPF and FPF. In the medical literature, the TPF is referred to as the *sensitivity*, since it is an indication of the sensitivity of the test to the presence of an abnormality. The TNF is commonly referred to as the *specificity*, because a test with low specificity is one where there are many false or meaningless positive decisions.

We can compute the fraction of true and false decisions for each truth state (see Table 13.2) given knowledge of the probability density functions on t , which we presume we have via (13.10). As we see in Fig. 13.4, these fractions are the areas under the appropriate PDF on t for a given threshold t_c :

$$\text{TPF} = \Pr(t \geq t_c|H_2) = \int_{t_c}^{\infty} dt \text{pr}(t|H_2), \quad (13.12a)$$

$$\text{FPF} = \Pr(t \geq t_c|H_1) = \int_{t_c}^{\infty} dt \text{pr}(t|H_1), \quad (13.12b)$$

$$\text{TNF} = 1 - \text{FPF} = \int_{-\infty}^{t_c} dt \text{pr}(t|H_1), \quad (13.12c)$$

$$\text{FNF} = 1 - \text{TPF} = \int_{-\infty}^{t_c} dt \text{pr}(t|H_2). \quad (13.12d)$$

13.2.3 The ROC curve

We see from (13.12a) and (13.12b) that the TPF and FPF depend on the decision threshold or criterion t_c . A decision-maker is said to be conservative when a strict criterion is used that results in relatively few positive decisions, some of which are correct and some of which are false. On the other hand, a lax criterion yields a higher number of positive decisions, both true and false. By varying the decision threshold, a plot showing the relationship between the TPF and the FPF can be generated. This plot, known as a *receiver operating characteristic curve*, or an ROC curve, is a method of portraying test performance that is becoming increasingly popular in the medical community. The ROC curve is an extremely useful tool because, as we shall see, it summarizes the difficulty of the task, the performance of the decision strategy, and the quality of the data for enabling the observer

to perform the specified task. Additionally, the ROC curve and figures of merit derived from it are independent of prevalence, the main complaint lodged against the use of accuracy (see Sec. 13.2.4) as a measure of classification performance.

Fig. 13.4 The probability density functions for the test statistic under the two hypotheses and one setting of the threshold, with the resulting TPF, FPF, TNF, FNF.

A sample ROC curve is shown in Fig. 13.5. There are three points on the ROC curve labeled A, B, and C. Point A corresponds to a very strict criterion level, so that the observer has very few false-positive responses, but few true-positive responses as well. As the observer’s threshold is relaxed, the number of true-positive and false-positive responses increases. The point indicated by the letter B on the graph is a moderate criterion level, and point C corresponds to a very lenient criterion. At point C the observer often says signal is present in the images, resulting in many true-positive calls, but many false-positive calls, too.

Properties of ROC curves are covered thoroughly in the three-volume series by Van Trees (1968). The application of ROC techniques to nuclear medical imaging and radiography has been discussed by Lusted (1971), Metz *et al.* (1973), and Anderson *et al.* (1973). Two early tutorial papers on ROC analysis in medical imaging were published by Metz (1978) and Turner (1978). Good general overviews have been presented by Swets (1979), Swets and Pickett (1982), Swets (1988), and Metz (1999).

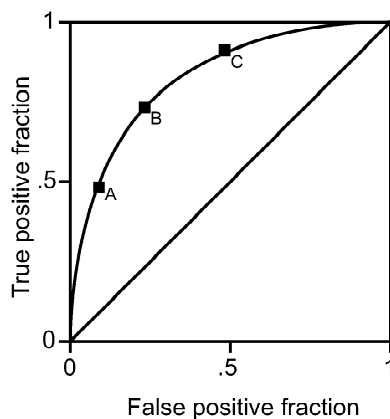

Fig. 13.5 A sample ROC curve with three threshold levels identified.

13.2.4 Performance measures for binary tasks

A variety of measures exist for summarizing task performance for a given imaging system and observer. More importantly, meaningful summary measures of task performance allow the quantitative comparison of imaging systems and observers.

Accuracy It is tempting to summarize the performance of a classification task by its *accuracy*, which is the fraction of decisions that are correct:

$$\text{accuracy} = \lim_{N \rightarrow \infty} \frac{N_{TP} + N_{TN}}{N}. \quad (13.13)$$

As mentioned briefly in Sec. 13.2.3, the problem with accuracy as a figure of merit is that it is highly dependent on the prevalence of the underlying hypotheses. Consider a physician involved in screening patients for a disease so rare it affects only 0.1% of the population [$\Pr(H_2) = 0.001$]. The physician can perform with 99.9% accuracy simply by calling all patients normal, all the while miscalling every case where disease is present, a clearly worthless strategy. Accuracy can make a bad test look good when the prevalences are unbalanced.

A similar misrepresentation of test performance occurs for any figure of merit that involves only one of the probabilities of error. Beware of studies that claim excellent performance based on high values for sensitivity or specificity alone. A test with high sensitivity could be achieved by calling all patients positive for disease, but this strategy would yield abysmal specificity.

Positive and negative predictive value Two other measures for summarizing the performance of a diagnostic test or classification task are sometimes found in the literature. These are the *positive predictive value* (PPV) and *negative predictive value* (NPV) of the test. They are defined by:

$$\text{PPV} = \Pr(H_2|D_2) = \lim_{N \rightarrow \infty} \frac{N_{TP}}{N_{TP} + N_{FP}}, \quad (13.14a)$$

and

$$\text{NPV} = \Pr(H_1|D_1) = \lim_{N \rightarrow \infty} \frac{N_{TN}}{N_{TN} + N_{FN}}. \quad (13.14b)$$

These measures have a decidedly Bayesian flavor, in that they tell us how likely an underlying condition is given that the test decides in favor of that condition.

Cost and utility We already described in Sec. 13.1 how we can characterize a decision-making strategy by associating costs with making correct and incorrect decisions. Three kinds of average classification cost are defined in (13.5)–(13.7). Any one of these average costs can be used as a summary measure of performance, though the choice among them and the assignment of costs is inherently arbitrary.

The *utility* of a classification outcome has been defined as a measure of the desirability of the outcome relative to other outcomes (Patton and Woolfenden, 1989). In medical applications the overall diagnostic utility of a test can be evaluated as an expectation of the utility of the test over the population of patients and outcomes. The cost effectiveness of a test is determined by the utility of the test and its cost (Fryback and Thornbury, 1991). Early models for analyzing the cost effectiveness of classification decisions were presented by McNeil and Adelstein (1976), Weinstein

and Fineberg (1980), and Swets and Pickett (1982). Cost-effectiveness analysis of medical imaging exams, including the determination of decision costs and the valuation of life quality with and without various medical interventions, is an area of active research (Gold *et al.*, 1996; Russell *et al.*, 1996).

TPF-FPF pairs The ROC curve suggests a number of summary measures of classification performance. The first is the TPF at a specified FPF, which is no more than a presentation of two of the elements in Table 13.2. A detection strategy that maximizes this performance measure is known as the *Neyman-Pearson criterion* (Sec. 13.2.6).

When we can make the argument that t is normally distributed, then the TPF and FPF can be derived from (13.12) to give

$$\text{TPF} = \frac{1}{2} \left[1 - \operatorname{erf} \left(\frac{t_c - \bar{t}_2}{\sqrt{2\sigma_2^2}} \right) \right], \quad (13.15a)$$

$$\text{FPF} = \frac{1}{2} \left[1 - \operatorname{erf} \left(\frac{t_c - \bar{t}_1}{\sqrt{2\sigma_1^2}} \right) \right], \quad (13.15b)$$

at each threshold level t_c . Here $\langle t \rangle_j = \bar{t}_j$ denotes the mean of the test statistic under hypothesis H_j , and σ_j^2 is the variance of the test statistic under hypothesis j , defined by

$$\sigma_j^2 = \left\langle (t - \bar{t}_j)^2 \right\rangle_j. \quad (13.16)$$

Throughout this chapter the notation $\langle \cdot \rangle_j$ indicates an average over the data when hypothesis j is true, or equivalently, an average over the density of t given that H_j is true. The *error function*, $\operatorname{erf}(z)$, is defined by (C.115)

$$\operatorname{erf}(z) = \frac{2}{\sqrt{\pi}} \int_0^z dy \exp[-y^2]. \quad (13.17)$$

Fig. 13.6 Plots of $\operatorname{pr}(t|H_1)$ and $\operatorname{pr}(t|H_2)$ for two cases. In (a) the PDFs exhibit little overlap, resulting in relatively few decision errors. In (b) the PDFs are virtually identical and the TPF and FPF are approximately equal for each value of t_c .

Figure 13.6 contains plots of $\operatorname{pr}(t|H_1)$ and $\operatorname{pr}(t|H_2)$ for two cases. In Fig. 13.6a the PDFs exhibit little overlap, enabling the observer to choose a threshold that separates the two classes quite well. Figure 13.6b shows the case where the PDFs are virtually identical. In this case, the TPF and FPF are approximately equal for

each value of t_c , and the observer using this test statistic has difficulty separating the classes. Plots of the TPF vs. FPF for these cases are shown in Fig. 13.7. Two PDFs with no overlap (perfect class separation) yield an ROC curve formed by the left and top borders of the square, while the 45° or chance line results when $\text{pr}(t|H_1) = \text{pr}(t|H_2)$ for all t .

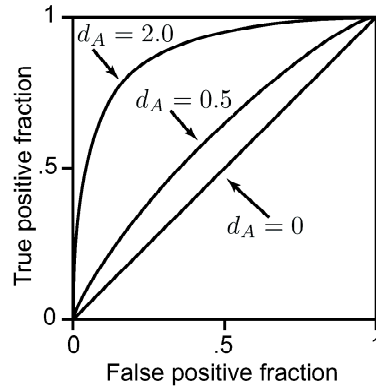

Fig. 13.7 Plots of the TPF vs. FPF for the PDFs depicted in Fig. 13.6, as well as the chance line ($d_A = 0$). The ROC curves are symmetric about the negative diagonal.

AUC Another figure of merit is the area under the ROC curve, *AUC*, defined as

$$\text{AUC} = \int_0^1 d\text{FPF} \text{TPF}(\text{FPF}). \quad (13.18)$$

Since both the FPF and the TPF range from 0 to 1, the area under the ROC curve also ranges from 0 to 1. The ROC curves shown in Fig. 13.7 are symmetric about the negative diagonal. For this special case, higher values of *AUC* indicate higher true positive fraction for any given false positive fraction; intuitively one can see that classification systems with higher *AUC* are then preferable. On the other hand, ROC curves need not be symmetric, as Fig. 13.8 illustrates. The ROC curves in Fig. 13.8 have the same area, which is the *average* TPF over all FPF. Thus the *AUC* may be the same for two imaging systems, even though one may be superior within some range of FPF values.

Fig. 13.8 Two crossing ROC curves with the same area.

SNR_t The degree of overlap of the density functions of the test statistic determines the separability of the classes in the general classification problem; in the detection problem this overlap determines the detectability of the signal. The AUC is one measure of this overlap. Another is the signal-to-noise ratio associated with t :

$$SNR_t = \frac{\langle t \rangle_2 - \langle t \rangle_1}{\sqrt{\frac{1}{2}\sigma_1^2 + \frac{1}{2}\sigma_2^2}}. \quad (13.19)$$

SNR_t should be used with caution if the test statistic is not normally distributed under both hypotheses. In particular, when the test statistic has a highly skewed PDF, the variance is not a good measure of the spread of the decision variable, and this figure of merit is not useful.

SNR under assumptions of normality When the test statistic is normally distributed under both hypotheses, the area under the ROC curve can be derived from SNR_t through the following relationship:

$$AUC = \frac{1}{2} + \frac{1}{2} \operatorname{erf} \left(\frac{SNR_t}{2} \right), \quad (13.20)$$

where $\operatorname{erf}(z)$ is defined in (13.17). A proof of this relationship is given in Sec. 13.2.5.

When the variance of a normally-distributed test statistic is the same under each hypothesis, SNR_t is granted the special name d' (Simpson and Fitter, 1973; Swets, 1979). In this particular case, the ROC curve bows upward toward the left-hand corner of the ROC plot and is symmetric about the negative diagonal. The value of d' is related monotonically to the distance between the ROC curve and the positive diagonal. Figure 13.7 contains two equal-variance ROC curves with different nonzero values of d' . When d' is zero, $\operatorname{pr}(t|H_1)$ is equal to $\operatorname{pr}(t|H_2)$, and the resulting ROC curve is the chance line. When d' is infinite, there is perfect separation between $\operatorname{pr}(t|H_2)$ and $\operatorname{pr}(t|H_1)$. Consequently, d' values range from 0 to ∞ and classification performance increases monotonically with d' .

If the test statistic is normal with unequal variance under the two hypotheses, the ROC curve will be asymmetric, like those shown in Fig. 13.8. The shape of the curve in that case is determined by the ratio of the variances under the two hypotheses (Green and Swets, 1966). In this circumstance, neither SNR_t nor AUC is sufficient to specify the system completely. Of course, we can still find an area under the ROC curve, but two skewed ROC curves may have the same area, as shown in the figure. We need another way of deciding which imaging system yields the best performance when this happens. Metz and Kronman (1980) have discussed several possible approaches. One option is to choose the system with the highest partial area under the ROC curve, given as a modified version of (13.18) involving only the portion of ROC-space thought to be most critical for the system under consideration (McClish, 1989). Another is to compare the ROC curves by considering the utility associated with their optimal operating points (Halpern *et al.*, 1996).

The estimate of AUC given in (13.20) can be grossly in error for test statistics that are far from normally distributed. In such cases, it is advisable to determine AUC directly from (13.18).

Detectability index d_A When AUC is known, it can be used to compute an effective signal-to-noise ratio simply by inverting (13.20). The resulting figure of merit is

denoted d_A and calculated via (ICRU Report 54, 1996)

$$d_A = 2 \operatorname{erf}^{-1}[2(\operatorname{AUC}) - 1]. \quad (13.21)$$

The quantity is invariant to any monotonic transformation on the test statistic used to obtain AUC.

Most experimental ROC curves from psychophysical studies of human performance can be modeled quite well with the assumption that the test statistic is normal under each hypothesis, although with unequal variance, otherwise referred to as a *binormal* model for the test statistic (Swets, 1986). In that case d_A equals the difference in means divided by the square root of the average variance under each hypothesis as given in (13.19).

Many studies of human-observer performance measure AUC directly through the use of a forced-choice technique, a method described theoretically in Sec. 13.2.5 and revisited in Sec. 14.2. Such a measurement method gives an estimate of AUC without determining the shape of the ROC curve, so no information is obtained regarding the relevance of the Gaussian model for the underlying PDFs of the observer's test statistic. Even so, the measured AUC is commonly converted to d_A for comparison with other studies (see Sec. 14.2.3).

13.2.5 Computation of AUC

We now consider various ways of computing AUC, depending on what knowledge we have of the statistics of the problem. Our treatment follows Barrett *et al.* (1998b), though each of the methods has a considerable prior literature.

Discriminant function with known probability law Consider the case where we have complete statistical descriptions $\operatorname{pr}(t|H_1)$ and $\operatorname{pr}(t|H_2)$ for the discriminant function t . First let us rewrite the expression for the area under the ROC curve in (13.18) to explicitly show the role of the threshold t_c :

$$\operatorname{AUC} = \int_0^1 d\operatorname{FPF}(t_c) \operatorname{TPF}(t_c). \quad (13.22)$$

For notational convenience, we define the shorthand $\operatorname{pr}(t|H_j) \equiv p_j(t)$. Since FPF is a monotonic function of t_c , we can change the variable of integration from $\operatorname{FPF}(t_c)$ to t_c , yielding

$$\operatorname{AUC} = - \int_{-\infty}^{\infty} dt_c \operatorname{TPF}(t_c) \frac{d}{dt_c} \operatorname{FPF}(t_c), \quad (13.23)$$

where the minus sign arises since $\operatorname{FPF}(t_c) \rightarrow 1$ as $t_c \rightarrow -\infty$.

From (13.12b) and Leibniz' rule, we have

$$\frac{d}{dt_c} \operatorname{FPF}(t_c) = -p_1(t_c), \quad (13.24)$$

so

$$\operatorname{AUC} = \int_{-\infty}^{\infty} dt_c p_1(t_c) \int_{t_c}^{\infty} dy p_2(y). \quad (13.25)$$

We can rewrite this expression in a variety of ways. One is to recognize that the cumulative probability distribution function (Sec. C.2.3) of t under H_2 is given by

$$F_2(t_c) \equiv \operatorname{Pr}(t < t_c|H_2) = \int_{-\infty}^{t_c} dy p_2(y) = 1 - \int_{t_c}^{\infty} dy p_2(y). \quad (13.26)$$

Thus

$$\text{AUC} = 1 - \int_{-\infty}^{\infty} dt_c p_1(t_c) F_2(t_c). \quad (13.27)$$

We can obtain another form for AUC by using the step function to rewrite (13.25) as

$$\text{AUC} = \int_{-\infty}^{\infty} dt_c \int_{-\infty}^{\infty} dy p_1(t_c) p_2(y) \text{step}(y - t_c). \quad (13.28)$$

With the change of variables $x = y - t_c$, we obtain

$$\text{AUC} = \int_{-\infty}^{\infty} dt_c \int_{-\infty}^{\infty} dx p_1(t_c) p_2(x + t_c) \text{step}(x) = \int_0^{\infty} dx [p_1 \star p_2](x), \quad (13.29)$$

where \star denotes a 1D correlation integral [cf. (3.115)]. Computation of AUC by this formula thus requires cross-correlating p_1 and p_2 and then integrating the result over the half line from 0 to ∞ .

The Fourier transform of the step function given in (3.163) allows us to write

$$\text{step}(x) = \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \exp(2\pi i \xi x), \quad (13.30)$$

where \mathcal{P} indicates that the singular integral must be interpreted as a Cauchy principal value (see Sec. B.3.9). Then (13.29) becomes

$$\begin{aligned} \text{AUC} &= \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \int_{-\infty}^{\infty} dt_c \int_{-\infty}^{\infty} dy p_1(t_c) p_2(y) \exp[2\pi i \xi (y - t_c)] \\ &= \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \psi_{t_1}(\xi) \psi_{t_2}^*(\xi), \end{aligned} \quad (13.31)$$

where $\psi_{t_j}(\xi) = \langle \exp(-2\pi i \xi t) | H_j \rangle$ is the characteristic function for t under hypothesis H_j [see (C.53)].

AUC with normal probability law When we know that the functions $\text{pr}_1(t)$ and $\text{pr}_2(t)$ are both univariate Gaussians, the characteristic function for t under hypothesis H_j is given by

$$\psi_{t_j}(\xi) = \exp(-2\pi i \bar{t}_j \xi - 2\pi^2 \sigma_j^2 \xi^2). \quad (13.32)$$

Then the AUC of (13.31) becomes

$$\begin{aligned} \text{AUC} &= \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \exp[-2\pi i (\bar{t}_1 - \bar{t}_2) \xi - 2\pi^2 (\sigma_1^2 + \sigma_2^2) \xi^2] \\ &= \frac{1}{2} + \frac{1}{2\pi} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \sin[2\pi (\bar{t}_2 - \bar{t}_1) \xi] \exp[-2\pi^2 (\sigma_1^2 + \sigma_2^2) \xi^2] \\ &= \frac{1}{2} + (\bar{t}_2 - \bar{t}_1) \int_{-\infty}^{\infty} d\xi \text{sinc}[2(\bar{t}_2 - \bar{t}_1) \xi] \text{gaus} \left[\sqrt{2\pi(\sigma_1^2 + \sigma_2^2)} \xi \right], \end{aligned} \quad (13.33)$$

where $\text{gaus}(\cdot)$ is defined in (3.173), and we have dropped the principal value in the third line because the integrand is now well behaved at the origin. By Parseval's

theorem we have

$$\begin{aligned} \text{AUC} &= \frac{1}{2} + \frac{1}{2\sqrt{2\pi(\sigma_1^2 + \sigma_2^2)}} \int_{-\infty}^{\infty} dx \operatorname{rect} \left[\frac{x}{2(\bar{t}_2 - \bar{t}_1)} \right] \operatorname{gaus} \left[\frac{x}{\sqrt{2\pi(\sigma_1^2 + \sigma_2^2)}} \right] \\ &= \frac{1}{2} + \frac{1}{\sqrt{2\pi(\sigma_1^2 + \sigma_2^2)}} \int_0^{(\bar{t}_2 - \bar{t}_1)} dx \exp \left[-\frac{x^2}{2(\sigma_1^2 + \sigma_2^2)} \right]. \end{aligned} \quad (13.34)$$

A change of variables then yields the error-function relationship of (13.20).

Discriminant function with unknown probability law In the last sections we assumed that the densities $p_j(t)$ were known, and we derived general expressions for AUC that are independent of the specific form of the densities and for the specific case of a normal probability law. When t is a complicated function of \mathbf{g} , we may not know its densities or even its moments. We may, however, know $\operatorname{pr}(\mathbf{g}|H_j)$ from the basic physics of the image-formation process and knowledge of the signal and background statistics. We shall now develop expressions for AUC in terms of integrals over \mathbf{g} rather than ones over t .

If we again define $\operatorname{pr}(t|H_j) \equiv p_j(t)$ and also define the shorthand $q_j(\mathbf{g}) \equiv \operatorname{pr}(\mathbf{g}|H_j)$, (13.10) becomes

$$p_j(t) = \int_{\infty} d^M g q_j(\mathbf{g}) \delta[t - T(\mathbf{g})]. \quad (13.35)$$

The 1D delta function defines an $(M-1)$ -dimensional surface in the M -dimensional data space; all points on this surface have $T(\mathbf{g}) = t$ and hence contribute to the probability density on t at the same t .

From (13.28) and (13.35), we have

$$\text{AUC} = \int_{-\infty}^{\infty} dt_c \int_{-\infty}^{\infty} dy \int_{\infty} d^M g q_1(\mathbf{g}) \delta[t_c - T(\mathbf{g})] \int_{\infty} d^M g' q_2(\mathbf{g}') \delta[y - T(\mathbf{g}')] \operatorname{step}(y - t_c). \quad (13.36)$$

The delta functions allow us to perform the integrals over t_c and y , with the result

$$\text{AUC} = \int_{\infty} d^M g \int_{\infty} d^M g' q_1(\mathbf{g}) q_2(\mathbf{g}') \operatorname{step}[T(\mathbf{g}') - T(\mathbf{g})]. \quad (13.37)$$

Note that if we replace $T(\mathbf{g})$ with $T'(\mathbf{g}) = h[T(\mathbf{g})]$, where $h(x)$ is a monotonically increasing function, then the step function remains unchanged: if $\operatorname{step}[T(\mathbf{g}') - T(\mathbf{g})] = 1$ for some set of values of \mathbf{g} and \mathbf{g}' , then $\operatorname{step}[T'(\mathbf{g}') - T'(\mathbf{g})] = 1$ for precisely this same set. Thus AUC is unchanged by a monotonic point transformation of the data.

If we express the step function in terms of its Fourier transform, as given in (3.163), we obtain

$$\begin{aligned} \text{AUC} &= \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \int_{\infty} d^M g \int_{\infty} d^M g' q_1(\mathbf{g}) q_2(\mathbf{g}') \exp\{2\pi i \xi [T(\mathbf{g}') - T(\mathbf{g})]\} \\ &= \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \langle \exp[-2\pi i \xi T(\mathbf{g})] \rangle_1 \langle \exp[2\pi i \xi T(\mathbf{g}')] \rangle_2 \\ &= \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \psi_{t_1}(\xi) \psi_{t_2}^*(\xi), \end{aligned} \quad (13.38)$$

where we have again made use of the definition of the characteristic function (C.53) in the last line. The final form of (13.38) is identical to (13.31); AUC can be obtained by computing expectations over either the probability density on \mathbf{g} or the one on t .

2AFC interpretations The area under the ROC curve has another interesting interpretation. Consider an experiment where an observer is presented with two data sets \mathbf{g} and \mathbf{g}' simultaneously, where \mathbf{g} is drawn from $\text{pr}(\mathbf{g}|H_1)$ and \mathbf{g}' is drawn from $\text{pr}(\mathbf{g}'|H_2)$. The observer's task is to choose the image from class 2. This experimental paradigm, called the *two-alternative forced-choice* method, or 2AFC procedure, is often used in studies of human performance (see Sec. 14.2.3).

To make a decision, the observer computes two test statistics $T(\mathbf{g})$ and $T(\mathbf{g}')$, and the data vector that gives the higher value is assigned to H_2 . This assignment is correct if $T(\mathbf{g}') > T(\mathbf{g})$. Thus the probability of a correct decision is

$$\text{Pr}(\text{correct}) = \text{Pr}[T(\mathbf{g}') > T(\mathbf{g})] = \int_{-\infty}^{\infty} d^M g \int_{-\infty}^{\infty} d^M g' q_1(\mathbf{g}) q_2(\mathbf{g}') \text{step}[T(\mathbf{g}') - T(\mathbf{g})], \quad (13.39)$$

which, by (13.37), is AUC. For any test statistic, the probability of a correct decision in a 2AFC experiment is the AUC for that observer.

A similar interpretation applies to (13.28). If we denote the test statistics by $t = T(\mathbf{g})$ and $y = T(\mathbf{g}')$, the 2AFC decision is correct if $t > y$, and (13.28) gives the probability of this event.

Linear discriminants When the test statistic is linear in the data, as in (13.9), (13.37) becomes

$$\text{AUC}_{lin} = \int_{-\infty}^{\infty} d^M g \int_{-\infty}^{\infty} d^M g' q_1(\mathbf{g}) q_2(\mathbf{g}') \text{step}[\mathbf{w}^t(\mathbf{g}' - \mathbf{g})]. \quad (13.40)$$

The change of variables $\mathbf{g}'' = \mathbf{g}' - \mathbf{g}$ yields

$$\begin{aligned} \text{AUC}_{lin} &= \int_{-\infty}^{\infty} d^M g \int_{-\infty}^{\infty} d^M g'' q_1(\mathbf{g}) q_2(\mathbf{g} + \mathbf{g}'') \text{step}(\mathbf{w}^t \mathbf{g}'') \\ &= \int_{-\infty}^{\infty} d^M g'' [q_1 \star q_2](\mathbf{g}'') \text{step}(\mathbf{w}^t \mathbf{g}''), \end{aligned} \quad (13.41)$$

where $[q_1 \star q_2](\mathbf{g}'')$ denotes a multidimensional cross-correlation integral with shift \mathbf{g}'' . This equation shows that AUC_{lin} can be found by cross-correlating q_1 and q_2 and then integrating the result over the half-space $\mathbf{w}^t \mathbf{g} > 0$.

The similarity in form between (13.29) and (13.41) should be noted; (13.29) holds for an arbitrary discriminant function (but requires the probability densities for that function), while (13.41) holds specifically for a linear discriminant and requires knowledge of the data densities.

With a linear discriminant, we can also relate AUC to the multivariate characteristic functions for \mathbf{g} , defined by (see Sec. 8.1.4)

$$\psi_{\mathbf{g}j}(\boldsymbol{\rho}) \equiv \int_{-\infty}^{\infty} d^M g q_j(\mathbf{g}) \exp(-2\pi i \boldsymbol{\rho}^t \mathbf{g}), \quad (13.42)$$

where $\boldsymbol{\rho}$ is the M -dimensional frequency vector conjugate to the data vector \mathbf{g} . We can relate the characteristic function for the scalar test statistic t to the characteristic function for the MD data vector \mathbf{g} via

$$\begin{aligned}\psi_{t_j}(\xi) &= \int_{-\infty}^{\infty} dt p_j(t) \exp(-2\pi i \xi t) = \int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} d^M g \delta[t - T(\mathbf{g})] \text{pr}(\mathbf{g}|H_j) \exp(-2\pi i \xi t) \\ &= \int_{-\infty}^{\infty} d^M g \text{pr}(\mathbf{g}|H_j) \exp(-2\pi i \xi \mathbf{w}^t \mathbf{g}) = \psi_{\mathbf{g}_j}(\mathbf{w}\xi),\end{aligned}\quad (13.43)$$

where we have used (13.19), (13.35), and the sifting property of the delta function. Thus, in the case of a linear discriminant, we see that the characteristic function of the test statistic is determined by the characteristic function of the data along a line through the origin and parallel to \mathbf{w} in the MD Fourier space. For linear discriminants, (13.38) becomes

$$\text{AUC}_{lin} = \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \psi_{\mathbf{g}_1}(\mathbf{w}\xi) \psi_{\mathbf{g}_2}^*(\mathbf{w}\xi). \quad (13.44)$$

Another way of interpreting this result is to say that all we need to calculate AUC_{lin} are integrals of the data densities q_1 and q_2 over $(M-1)D$ hyperplanes normal to \mathbf{w} . By the MD central-slice theorem (4.178), integral of an MD density over these hyperplanes gives information about the Fourier transform of the density along the line specified in (13.43). With nonlinear discriminants, the central-slice theorem does not provide any assistance; we need integrals over $(M-1)D$ surfaces defined by constant $T(\mathbf{g})$ rather than integrals over hyperplanes.

In practice, we can often simplify the computation of AUC_{lin} greatly by realizing that a linear discriminant $\mathbf{w}^t \mathbf{g}$ is univariate normal if \mathbf{g} is multivariate normal. Even if \mathbf{g} follows some other probability law, the output of a linear discriminant acting on the data can often be assumed to approximate a univariate normal law by the central-limit theorem (see Sec. 8.3.4). Then we can use the expression given in (13.19) for SNR_t with confidence. Thus it is almost always safe to compute AUC from SNR_t for a linear discriminant, though it is useful to check the assumption by plotting histograms of t .

Linear discriminants with independent additive noise We can be more specific about the AUC of a linear discriminant if we can assume that the noise is additive and independent of the signal. In that case, we can write:

$$\text{pr}(\mathbf{g}|H_2) = \int_{-\infty}^{\infty} d^M s \text{pr}(\mathbf{g}|H_2, \mathbf{s}) \text{pr}(\mathbf{s}) = \int_{-\infty}^{\infty} d^M s \text{pr}(\mathbf{g} - \mathbf{s}|H_1) \text{pr}(\mathbf{s}). \quad (13.45)$$

Since this is an MD convolution, its Fourier transform yields

$$\psi_{\mathbf{g}_2}(\boldsymbol{\rho}) = \psi_{\mathbf{g}_1}(\boldsymbol{\rho}) \psi_{\mathbf{s}}(\boldsymbol{\rho}), \quad (13.46)$$

where $\psi_{\mathbf{s}}(\boldsymbol{\rho})$ is the characteristic function of the signal. Thus (13.44) becomes

$$\text{AUC}_{lin} = \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \psi_{\mathbf{s}}^*(\mathbf{w}\xi) |\psi_{\mathbf{g}_1}(\mathbf{w}\xi)|^2. \quad (13.47)$$

Note that $\psi(\boldsymbol{\rho}) = \psi^*(-\boldsymbol{\rho})$ for any characteristic function since it is the Fourier transform of a real function. Thus $|\psi_{\mathbf{g}_1}(\mathbf{w}\xi)|^2$ is an even function of ξ , and the

integral in (13.47) vanishes unless $\psi_s(\mathbf{w}\xi)$ has an odd component.

One situation where we can readily identify the odd component of $\psi_s(\mathbf{w}\xi)$ is when the signal is nonrandom and known exactly. In that case,

$$\text{pr}(\mathbf{s}) = \delta(\mathbf{s} - \mathbf{s}_0), \quad \psi_s(\boldsymbol{\rho}) = \exp(-2\pi i \mathbf{s}_0^t \boldsymbol{\rho}). \quad (13.48)$$

Only the odd component of $\psi_s(\boldsymbol{\rho})$ contributes to the integral in (13.47), so

$$\text{AUC}_{lin} = \frac{1}{2} + \frac{1}{2\pi} \int_{-\infty}^{\infty} d\xi \frac{\sin(2\pi \mathbf{s}_0^t \mathbf{w}\xi)}{\xi} |\psi_{\mathbf{g}1}(\mathbf{w}\xi)|^2. \quad (13.49)$$

The principal-value indicator \mathcal{P} is no longer necessary, and the expression is patently real.

As $\mathbf{s}_0^t \mathbf{w} \rightarrow \infty$, the factor $\sin(2\pi \mathbf{s}_0^t \mathbf{w}\xi)/\xi$ approaches $\pi\delta(\xi)$ [cf. (2.44)], so $\text{AUC}_{lin} \rightarrow 1$; strong, nonrandom signals can be perfectly detected by any linear discriminant not orthogonal to the signal. If $\mathbf{s}_0^t \mathbf{w}$ is small, on the other hand, then

$$\text{AUC}_{lin} \approx \frac{1}{2} + \mathbf{s}_0^t \mathbf{w} \int_{-\infty}^{\infty} d\xi |\psi_{\mathbf{g}1}(\mathbf{w}\xi)|^2. \quad (13.50)$$

This expression shows, not surprisingly, that $\text{AUC}_{lin} \rightarrow \frac{1}{2}$ as $\mathbf{s}_0^t \mathbf{w} \rightarrow 0$, which occurs either for weak signals or for a linear discriminant orthogonal to the signal.

13.2.6 The likelihood ratio and the ideal observer

We have defined AUC and related figures of merit for classification, and these metrics provide a basis for the optimization of classification performance. We shall now explore several optimization strategies and show that all optimization roads lead to the ideal or Bayesian observer.

Minimum average cost One possible decision strategy is to formulate a test statistic that minimizes the overall average cost or Bayes risk of making a decision. The average cost given in (13.7) can be written in the binary case as

$$\begin{aligned} \bar{C} = & C_{22} \Pr(D_2|H_2) \Pr(H_2) + C_{12} \Pr(D_1|H_2) \Pr(H_2) \\ & + C_{21} \Pr(D_2|H_1) \Pr(H_1) + C_{11} \Pr(D_1|H_1) \Pr(H_1). \end{aligned} \quad (13.51)$$

The probability of making decision D_i when hypothesis H_j is true can be written as an integral over the M -dimensional data space:

$$\Pr(D_i|H_j) = \int_{\Gamma_i} d^M g \text{pr}(\mathbf{g}|H_j), \quad (13.52)$$

where Γ_i defines the observation region over which a decision is made in favor of H_i (see Fig. 13.2). The average cost can thus be written in terms of integrals over the regions Γ_1 and Γ_2 :

$$\begin{aligned} \bar{C} = & C_{22} \Pr(H_2) \int_{\Gamma_2} d^M g \text{pr}(\mathbf{g}|H_2) + C_{12} \Pr(H_2) \int_{\Gamma_1} d^M g \text{pr}(\mathbf{g}|H_2) \\ & + C_{21} \Pr(H_1) \int_{\Gamma_2} d^M g \text{pr}(\mathbf{g}|H_1) + C_{11} \Pr(H_1) \int_{\Gamma_1} d^M g \text{pr}(\mathbf{g}|H_1). \end{aligned} \quad (13.53)$$

To minimize the overall cost is to choose an optimal division between the regions Γ_1 and Γ_2 .

We can use the fact that

$$\Pr(D_2|H_2) + \Pr(D_1|H_2) = 1, \quad (13.54)$$

and that the regions are nonoverlapping and complete to say

$$\int_{\Gamma_2} d^M g \operatorname{pr}(\mathbf{g}|H_2) + \int_{\Gamma_1} d^M g \operatorname{pr}(\mathbf{g}|H_2) = 1. \quad (13.55)$$

We can then rewrite the average cost as a function of region Γ_2 only:

$$\begin{aligned} \bar{C} &= C_{12} \Pr(H_2) + C_{11} \Pr(H_1) \\ &+ \int_{\Gamma_2} d^M g [(C_{21} - C_{11}) \Pr(H_1) \operatorname{pr}(\mathbf{g}|H_1) - (C_{12} - C_{22}) \Pr(H_2) \operatorname{pr}(\mathbf{g}|H_2)]. \end{aligned} \quad (13.56)$$

The first two terms in the cost function are constants, leaving the integral to be minimized by choice of the region Γ_2 . This is done by choosing to include in the region only that portion of the observation space for which the integrand is negative. Thus the region Γ_2 , where H_2 is chosen, is the region for which

$$(C_{12} - C_{22}) \operatorname{pr}(\mathbf{g}|H_2) \Pr(H_2) > (C_{21} - C_{11}) \operatorname{pr}(\mathbf{g}|H_1) \Pr(H_1), \quad (13.57)$$

where we have assumed that the cost of making an error is greater than the cost of a correct decision, so $(C_{12} - C_{22})$ and $(C_{21} - C_{11}) > 0$, and we made use of the knowledge that all PDFs are nonnegative. The decision rule is then to choose H_2 when

$$\frac{\operatorname{pr}(\mathbf{g}|H_2)}{\operatorname{pr}(\mathbf{g}|H_1)} > \frac{(C_{21} - C_{11}) \Pr(H_1)}{(C_{12} - C_{22}) \Pr(H_2)}. \quad (13.58)$$

Otherwise, choose H_1 .

The quantity $\operatorname{pr}(\mathbf{g}|H_2)/\operatorname{pr}(\mathbf{g}|H_1)$ is called the *likelihood ratio* and is often written $\Lambda(\mathbf{g})$. It is a scalar random variable that depends on the data vector \mathbf{g} . In terms of $\Lambda(\mathbf{g})$, the decision rule becomes

$$\Lambda(\mathbf{g}) \underset{D_1}{\overset{D_2}{>}} \frac{(C_{12} - C_{22}) \Pr(H_2)}{(C_{21} - C_{11}) \Pr(H_1)}. \quad (13.59)$$

This inequality is to be read “decide hypothesis H_2 true whenever the greater-than sign holds; decide hypothesis H_1 when the less-than sign holds.”

We have found the region Γ_2 that minimizes the average cost of (13.51). The resulting minimum average cost is called the Bayes risk, and this decision criterion is called the Bayes criterion. A detector that uses this criterion to do signal detection is called a Bayesian detector.

The overall average cost is determined by repeated decision-making trials. Thus the performance of the Bayesian detector that minimizes this value is determined using frequentist methods.³ Similarly, AUC and all measures derived from it are found by keeping score in frequentist fashion.

³Recall from Sec. 13.1 that a hard-nosed Bayesian would not use the Bayes criterion. Strict Bayesians resist the last averaging step, relying instead on the cost determined from the posterior as represented in the second row of Table 13.1.

Minimum-error detector The costs C_{ij} can be quite difficult to know. Many times they are determined in some *ad hoc* manner. As a result, it is often desirable to find a decision rule that minimizes the average probability of error, which is equivalent to maximizing the AUC. The probability of error in the binary decision problem is given by

$$P_e = \Pr(D_1|H_2) \Pr(H_2) + \Pr(D_2|H_1) \Pr(H_1). \quad (13.60)$$

Comparing (13.60) to (13.51), we discover that minimizing the probability of error is equivalent to minimizing the average cost, provided no costs are associated with correct decisions, and each kind of error is assigned an equal cost. From (13.59) we ascertain that the minimum-error decision rule is written

$$\Lambda(\mathbf{g}) \underset{D_1}{\overset{D_2}{>}} \frac{\Pr(H_1)}{\Pr(H_2)}. \quad (13.61)$$

This decision rule tells us to choose H_2 when

$$\frac{\text{pr}(\mathbf{g}|H_2)}{\text{pr}(\mathbf{g}|H_1)} > \frac{\Pr(H_1)}{\Pr(H_2)}, \quad (13.62)$$

or when

$$\text{pr}(\mathbf{g}|H_2) \Pr(H_2) > \text{pr}(\mathbf{g}|H_1) \Pr(H_1), \quad (13.63)$$

since $\Pr(H_j)$ and $\text{pr}(\mathbf{g}|H_j)$ are always positive.

We can use Bayes' theorem,

$$\text{pr}(\mathbf{g}|H_j) \Pr(H_j) = \Pr(H_j|\mathbf{g}) \text{pr}(\mathbf{g}), \quad (13.64)$$

to rewrite the condition for choosing H_2 as

$$\Pr(H_2|\mathbf{g}) \text{pr}(\mathbf{g}) > \Pr(H_1|\mathbf{g}) \text{pr}(\mathbf{g}) \quad (13.65)$$

or

$$\Pr(H_2|\mathbf{g}) > \Pr(H_1|\mathbf{g}). \quad (13.66)$$

The decision rule is to choose H_2 when the *a posteriori* probability of H_2 given the data vector \mathbf{g} is greater than the *a posteriori* probability of H_1 given \mathbf{g} . For this reason the minimum-error criterion is also called the *maximum a posteriori probability*, or *MAP*, criterion.

Neyman-Pearson criterion In certain applications we may wish to constrain the false-positive fraction to be less than or equal to some level α . The Neyman-Pearson test seeks the maximum true-positive fraction given this constraint. We now derive the decision strategy that yields this outcome.

We want to impose the constraint that $\text{FPF} = \alpha' \leq \alpha$ while maximizing the TPF. We can solve this problem using Lagrange multipliers. The Lagrangian function we want to maximize is

$$\begin{aligned} F &= \text{TPF} + \gamma[\alpha' - \text{FPF}] \\ &= \int_{\Gamma_2} d^M g [\text{pr}(\mathbf{g}|H_2) - \gamma \text{pr}(\mathbf{g}|H_1)] + \gamma \alpha'. \end{aligned} \quad (13.67)$$

The problem is thus one of choosing the discriminant function such that the region Γ_2 results in maximum F , similar to the approach we used earlier to find the decision rule that gives minimum average cost. For positive γ , we obtain maximum F if we include all \mathbf{g} in Γ_2 for which $\text{pr}(\mathbf{g}|H_2) > \gamma \text{pr}(\mathbf{g}|H_1)$. In other words, the Neyman-Pearson decision boundaries are obtained by assigning to Γ_2 all data for which

$$\frac{\text{pr}(\mathbf{g}|H_2)}{\text{pr}(\mathbf{g}|H_1)} > \gamma. \quad (13.68)$$

We see that a constraint on the likelihood ratio results. When $\gamma < 0$, a likelihood-ratio constraint also results, of opposite sign in that instance. Since the probability density functions are continuous, the probability that these quantities are equal is zero, and thus we have neglected this case.

Lastly, we need a solution that satisfies the constraint $\text{FPF} = \alpha' \leq \alpha$. We can rewrite the decision rule of (13.68) in terms of the likelihood ratio as

$$\Lambda(\mathbf{g}) \underset{D_1}{\overset{D_2}{>}} \gamma, \quad (13.69)$$

whereby we see that the Lagrange multiplier plays the role of a threshold for the scalar decision variable $\Lambda(\mathbf{g})$. The FPF can thus be expressed in terms of $\Lambda(\mathbf{g})$ as

$$\text{FPF} = \int_{\gamma}^{\infty} d\Lambda \text{pr}[\Lambda(\mathbf{g})|H_1] = \alpha'. \quad (13.70)$$

Note that decreasing γ increases the region for which we decide in favor of H_2 , which thereby increases the TPF (and, of course, the FPF). Since our goal is to maximize the TPF while keeping $\text{FPF} \leq \alpha$, we continue to decrease γ until we run into the $\alpha' = \alpha$ condition (we are assuming the FPF to be a continuous function of γ). Thus the maximum TPF is obtained when the FPF equals its upper bound, α .

The particular value of α in the above derivation is arbitrary. Thus, the decision rule given by (13.69) yields maximum TPF at every predetermined FPF, and this is equivalent to a decision rule that yields maximum AUC by virtue of (13.18).

Maximum-likelihood criterion There is one last decision criterion important to us. This is the decision rule that results when the observer has no information about the *a priori* probabilities of the hypotheses, $\text{Pr}(H_2)$ and $\text{Pr}(H_1)$, which in medical imaging correspond to the probabilities of disease. When this is the case the observer has no reason not to assume they are equivalent (there is no information to the contrary, so this is the least prejudiced assumption). The decision rule under this assumption becomes

$$\Lambda(\mathbf{g}) \underset{D_1}{\overset{D_2}{>}} 1. \quad (13.71)$$

We call (13.71) a *maximum-likelihood* criterion because we choose the hypothesis which results in the greatest probability or likelihood of the data vector given that hypothesis. This is the decision strategy that results when the observer has the least amount of information about the decision problem.

The ideal observer We have described four decision strategies, all of the form

$$\text{Choose } H_2 \text{ if } \Lambda(\mathbf{g}) > \Lambda_c, \quad (13.72)$$

where $\Lambda(\mathbf{g})$ is the likelihood ratio and Λ_c is the threshold determined by the particular objective of the test. Note that the data-dependent part of the decision rule in each case is the same. Thus all four decision strategies described above yield the same ROC curve. The observers differ only in their choice of threshold, the operating point along the ROC curve.

A test that can be written in the form of (13.72) is termed a *likelihood-ratio test*. Any observer that performs a likelihood-ratio test properly is referred to as an *ideal observer*.

What is required to perform a likelihood-ratio test properly? Looking back at our four test strategies, we see that the ideal observer must have no internal noise mechanism that would further corrupt the data. It must know the threshold and maintain it exactly at that level on each trial. Most importantly, it must have all the information necessary to formulate $\text{pr}(\mathbf{g}|H_j)$, including descriptions of the objects to be classified and complete information regarding the measurement process and the noise statistics.

In the previous subsections we have seen how particular choices of threshold result in minimum-Bayes risk or minimum-error performance for the ideal observer. These are just two operating points on the same ROC curve. These operating points are determined by the particular values of the priors and decision costs that enter into the calculation of the threshold. Since the ideal observer is optimal for every choice of costs C_{ij} in (13.59), it is optimal at all operating points. In other words, the ideal observer is that observer that achieves maximum TPF for any specified FPF. It follows that the ideal observer achieves maximum AUC of all observers. AUC is a widely-used figure of merit for summarizing ideal-observer performance among scientists studying image quality, since figures of merit that require the specification of the operating point depend on the costs and priors assigned by the various users of the system and are therefore fairly arbitrary.

Monotonic transformations and performance of the ideal observer Since monotonic transformations of the discriminant function do not affect decision outcomes, an observer that uses a monotonically transformed version of the likelihood ratio is also called an ideal observer. In particular, when the data statistics are normal, the log-likelihood ratio, denoted $\lambda(\mathbf{g})$ or just λ , is often found to be an easier test statistic to work with. Since the decision outcomes are unchanged, $\text{AUC}_\lambda = \text{AUC}_\Lambda$. Therefore, d_A , as defined in (13.21), is also invariant to whether the likelihood ratio or the log-likelihood ratio is used as the test statistic. On the other hand, the SNR computed from (13.19) is very much dependent on the statistical properties of the decision variable. Thus SNR_λ may be quite different from SNR_Λ . An SNR computed from (13.19) is useful only when the decision variable is approximately Gaussian; otherwise it can be very misleading as a summary measure of observer performance.

In the same spirit, image processing does not affect the ideal observer's AUC, so long as the processing operation is invertible in the sense that the original data before processing are recoverable. When it is not invertible, the processing may reduce the ideal observer's AUC. Alternatively, post-processing cannot improve ideal-observer performance. By definition the ideal observer operates optimally on the data to achieve the maximum AUC for the specified classification task, so if any algorithm is useful, she will use it.

To see the invariance of the ideal observer to post-processing, let $\mathbf{y} = \mathbf{B}\mathbf{g}$ represent the output of an invertible processing operation applied to the data. Since the data are random, \mathbf{y} is also a random vector in the range of \mathbf{B} . The PDF on \mathbf{y} is given by

$$\text{pr}_{\mathbf{y}}(\mathbf{y}) = \text{pr}_{\mathbf{y}}(\mathbf{B}\mathbf{g}) = \frac{\text{pr}_{\mathbf{g}}(\mathbf{g})}{|J|}, \quad (13.73)$$

where J is the Jacobian of the transformation [see (C.102)], assumed to be nonzero for all \mathbf{g} .

An ideal observer who has only \mathbf{y} to perform the classification task forms the likelihood ratio in \mathbf{y} -space:

$$\Lambda(\mathbf{y}) = \frac{\text{pr}_{\mathbf{y}}(\mathbf{y}|H_2)}{\text{pr}_{\mathbf{y}}(\mathbf{y}|H_1)} = \frac{\text{pr}_{\mathbf{g}}(\mathbf{g}|H_2)}{\text{pr}_{\mathbf{g}}(\mathbf{g}|H_1)} = \Lambda(\mathbf{g}) \quad (13.74)$$

since the Jacobians cancel. Thus the performance of an ideal observer given only \mathbf{y} is identical to the performance of an ideal observer with access to the original data \mathbf{g} . This conclusion is true whether \mathbf{B} is linear or nonlinear and whether \mathbf{g} and \mathbf{y} are continuous or discrete; all we require is that the dimensionality of \mathbf{g} equal the dimensionality of \mathbf{y} and the transformation from \mathbf{g} to \mathbf{y} be invertible.

13.2.7 Statistical properties of the likelihood ratio

Knowledge of the PDFs on Λ or λ is required to calculate the TPF and FPF at each threshold and thus compute AUC. We shall now show that the particular form of the ideal observer's discriminant function leads to some interesting and useful relationships between its moments under each hypothesis.

The likelihood ratio is the ratio of the two densities $q_2(\mathbf{g})$ and $q_1(\mathbf{g})$. These same densities are the ones needed to compute moments of Λ under the two hypotheses. The general $(k+1)^{\text{th}}$ moment of Λ under H_1 is given by

$$\langle \Lambda^{k+1} \rangle_1 = \int_{\infty} d^M g q_1(\mathbf{g}) \left[\frac{q_2(\mathbf{g})}{q_1(\mathbf{g})} \right]^{k+1} = \int_{\infty} d^M g q_2(\mathbf{g}) \left[\frac{q_2(\mathbf{g})}{q_1(\mathbf{g})} \right]^k = \langle \Lambda^k \rangle_2. \quad (13.75)$$

This relationship is true for *any* task, regardless of the form of the PDF on Λ , simply by virtue of the special form of the ideal discriminant function.

It follows immediately from (13.75) that the mean of Λ under H_1 is always 1, since

$$\langle \Lambda \rangle_1 = \int_{\infty} d^M g q_1(\mathbf{g}) \frac{q_2(\mathbf{g})}{q_1(\mathbf{g})} = \int_{\infty} d^M g q_2(\mathbf{g}) = 1. \quad (13.76)$$

The variance of Λ under H_1 is given by

$$\text{Var}(\Lambda|H_1) = \langle \Lambda^2 \rangle_1 - \bar{\Lambda}_1^2 = \bar{\Lambda}_2 - 1. \quad (13.77)$$

Since $\Lambda = e^{\lambda}$, we can use (13.75) to write a similar relationship for the moments of λ :

$$\langle e^{(k+1)\lambda} \rangle_1 = \langle e^{k\lambda} \rangle_2. \quad (13.78)$$

This relationship holds for all k , including complex values, so long as the expectations exist.

From the definition of the moment-generating function (C.56), we see that the moment-generating function of λ evaluated at $k = \beta + 1$ under H_1 is the moment-generating function of λ evaluated at $k = \beta$ under H_2 :

$$M_1(\beta + 1) = M_2(\beta), \quad (13.79)$$

where β is an arbitrary complex number. This property has been shown by Swensson and Green (1977) to be unique to log-likelihood ratios. It is left as an exercise for the reader to show how $M_1(\beta)$ can be used to generate moments of both λ and Λ under both hypotheses.

A corresponding relation for the characteristic functions for λ can be found from (13.79) and (C.53) to be

$$\psi_{\lambda_1}\left(\xi + \frac{i}{2\pi}\right) = \psi_{\lambda_2}(\xi). \quad (13.80)$$

The densities $p_1(\lambda)$ and $p_2(\lambda)$ can then be related by an inverse Fourier transformation of (13.80):

$$\begin{aligned} p_2(\lambda) &= \mathcal{F}^{-1}\{\psi_{\lambda_2}(\xi)\} = \int_{-\infty}^{\infty} d\xi \psi_{\lambda_1}\left(\xi + \frac{i}{2\pi}\right) \exp(2\pi i \xi \lambda) \\ &= e^\lambda \int_{-\infty + \frac{i}{2\pi}}^{\infty + \frac{i}{2\pi}} dz \psi_{\lambda_1}(z) \exp(2\pi i z \lambda), \end{aligned} \quad (13.81)$$

where $z = \xi + i/(2\pi)$. If $\psi_{\lambda_1}(z)$ is analytic in the strip $0 \leq \text{Im}(z) \leq 1/(2\pi)$, we can shift the contour to obtain (see Barrett *et al.* 1998b, App. A)

$$p_2(\lambda) = e^\lambda \int_{-\infty}^{\infty} dz \psi_{\lambda_1}(z) \exp(2\pi i z \lambda) = e^\lambda p_1(\lambda). \quad (13.82)$$

The shift is allowed as long as $\langle \Lambda \rangle_2$ is finite.

We can now use (13.82) to find a relation between the densities for Λ under the two hypotheses. From (C.45) we know the transformation of the probability density functions is given by

$$p_j(\lambda) = \frac{\text{pr}(\Lambda|H_j)}{|d\lambda/d\Lambda|}, \quad (13.83)$$

where the Jacobian $|d\lambda/d\Lambda|$ is the same under H_1 and H_2 . Then we have

$$\text{pr}(\Lambda|H_2) = e^\lambda \text{pr}(\Lambda|H_1) = \Lambda \text{pr}(\Lambda|H_1). \quad (13.84)$$

Another way of writing (13.84) is

$$\frac{\text{pr}(\Lambda|H_2)}{\text{pr}(\Lambda|H_1)} = \Lambda. \quad (13.85)$$

Green and Swets (1966) describe this result by stating, “To paraphrase Gertrude Stein, the likelihood ratio of the likelihood ratio is the likelihood ratio.” The revelation of (13.85) is that all the information necessary for discriminating between H_2 and H_1 is contained in Λ . In statistical terminology, the likelihood ratio is said to be a *sufficient statistic* for the task.

Likelihood-generating function We have considered various ways of computing AUC, depending on the knowledge we have of the form of the probability law on the data or the test statistic. In this section we introduce the concept of the likelihood-generating function, which will provide us with another avenue for obtaining approximations for AUC.

The relationship between the density functions given in (13.82) tells us that one function is sufficient to specify both $p_2(\lambda)$ and $p_1(\lambda)$. In terms of this arbitrary function, which we shall call $f(\lambda)$, we have

$$p_2(\lambda) = e^{\lambda/2} f(\lambda) \quad \text{and} \quad p_1(\lambda) = e^{-\lambda/2} f(\lambda). \quad (13.86)$$

The characteristic function of λ can be written in terms of $f(\lambda)$:

$$\psi_{\lambda_2}(\xi) = F\left(\xi + \frac{i}{4\pi}\right) \quad \text{and} \quad \psi_{\lambda_1}(\xi) = F\left(\xi - \frac{i}{4\pi}\right). \quad (13.87)$$

The moment-generating functions on λ can be rewritten in terms of this function:

$$M_2(\beta) = F_L\left(\beta + \frac{1}{2}\right) \quad \text{and} \quad M_1(\beta) = F_L\left(\beta - \frac{1}{2}\right), \quad (13.88)$$

where $F_L(\beta)$ is the two-sided Laplace transform of $f(\lambda)$ [see (4.77) and (C.59)].

The normalization of the moment-generating function requires that $M_j(0) = 1$, so that $F_L(\pm\frac{1}{2}) = 1$. Normalization of the characteristic function requires $\psi_{\lambda_j}(0) = 1$, so that $F(\pm i/4\pi) = 1$. We can enforce these constraints by rewriting the characteristic function and moment-generating function in terms of new functions $A(\xi)$ and $G(\beta)$:

$$F(\xi) = \exp\left[\left(\xi + \frac{i}{4\pi}\right)\left(\xi - \frac{i}{4\pi}\right)A(\xi)\right] \quad (13.89)$$

and

$$F_L(\beta) = \exp\left[(\beta + \frac{1}{2})(\beta - \frac{1}{2})G(\beta)\right], \quad (13.90)$$

where $G(\beta)$ is the *likelihood-generating function*. It is straightforward to show the following relationship between these new functions:⁴

$$A(\xi) = -4\pi^2 G(2\pi i\xi). \quad (13.91)$$

In terms of $G(\beta)$ the moment-generating functions under each hypothesis are

$$M_2(\beta) = \exp\left[\beta(\beta + 1)G\left(\beta + \frac{1}{2}\right)\right] \quad \text{and} \quad M_1(\beta) = \exp\left[\beta(\beta - 1)G\left(\beta - \frac{1}{2}\right)\right]. \quad (13.92)$$

The characteristic function for λ under each hypothesis is given in terms of the likelihood-generating function by

$$\begin{aligned} \psi_{\lambda_2}(\xi) &= \exp\left[-4\pi^2\xi\left(\xi + \frac{i}{2\pi}\right)G\left(2\pi i\xi - \frac{1}{2}\right)\right] \quad \text{and} \\ \psi_{\lambda_1}(\xi) &= \exp\left[-4\pi^2\xi\left(\xi - \frac{i}{2\pi}\right)G\left(2\pi i\xi + \frac{1}{2}\right)\right]. \end{aligned} \quad (13.93)$$

⁴The difference in sign between the argument in this expression and that found in (5.7) of Barrett *et al.* (1998b) is the result of the difference between their definition of the Laplace transform and the one given in (4.77).

Fig. 13.9 The function $M_1(\beta)$, which passes through unity at $\beta = 0$ and $\beta = 1$.

Figure 13.9 contains a plot of $M_1(\beta)$ as a function of β for real β . From (13.92) we know the value of the function at $\beta = \frac{1}{2}$ defines $G(0)$.

We can make use of Marcinkiewicz’s theorem, presented in Shirayayev (1984), to draw a conclusion regarding the form of $G(\beta)$. By this theorem, when a characteristic function has the form $\exp(P)$, where P is a polynomial, the order of the polynomial cannot exceed 2. Thus $G(\beta)$ cannot be a polynomial (other than a polynomial of order 0, where $G(\beta)$ is a constant).

Since all moments of the likelihood ratio are determined by $G(\beta)$, the likelihood-generating function determines the statistics of the likelihood ratio under both hypotheses. We can apply (C.54) to (13.92) to determine the moments of λ in terms of $G(\beta)$. We leave it to the reader to show that

$$\bar{\lambda}_2 = G\left(\frac{1}{2}\right) \quad \text{and} \quad \bar{\lambda}_1 = -G\left(-\frac{1}{2}\right),$$

$$\text{Var}(\lambda|H_2) = 2 \left[G\left(\frac{1}{2}\right) + G'\left(\frac{1}{2}\right) \right] \quad \text{and} \quad \text{Var}(\lambda|H_1) = 2 \left[G\left(-\frac{1}{2}\right) - G'\left(-\frac{1}{2}\right) \right]. \tag{13.94}$$

With these moments we can write the SNR for the log-likelihood ratio in terms of $G(\beta)$:

$$\text{SNR}_\lambda^2 = \frac{\left[G\left(\frac{1}{2}\right) + G\left(-\frac{1}{2}\right) \right]^2}{G\left(\frac{1}{2}\right) + G\left(-\frac{1}{2}\right) + G'\left(\frac{1}{2}\right) - G'\left(-\frac{1}{2}\right)}. \tag{13.95}$$

For a Gaussian test statistic we can obtain AUC from (13.95) via (13.20).

Note that (13.95) takes on a particularly simple form if $G'(1/2) \approx G'(-1/2)$. When we can make this assumption,

$$\text{SNR}_\lambda^2 = G\left(-\frac{1}{2}\right) + G\left(\frac{1}{2}\right) \approx 2G(0). \tag{13.96}$$

Clarkson and Barrett (2000) have found that values of ideal-observer AUC derived from $2G(0)$ are more accurate than those derived from the SNR given in (13.19) for non-Gaussian noise models, including Poisson, and one- and two-sided exponential models.

Setting $\beta = \frac{1}{2}$ in (13.92) gives $G(0) = -4 \ln M_1\left(\frac{1}{2}\right)$. Thus the SNR of (13.96) can be computed directly from the probability density functions on the data ac-

cording to

$$\begin{aligned} G(0) &= -4 \ln M_1 \left(\frac{1}{2} \right) = -4 \ln \langle \Lambda^{\frac{1}{2}}(\mathbf{g}) \rangle_1 \\ &= -4 \ln \left\{ \int d^M g \left[\frac{q_2(\mathbf{g})}{q_1(\mathbf{g})} \right]^{\frac{1}{2}} q_1(\mathbf{g}) \right\} = -4 \ln \left\{ \int d^M g [q_1(\mathbf{g}) q_2(\mathbf{g})]^{\frac{1}{2}} \right\} \equiv 4d_B, \end{aligned} \quad (13.97)$$

where d_B is the *Bhattacharyya distance* between the probability densities on the data under the two hypotheses (Bhattacharyya, 1943).

A complete description of the performance of any observer is contained in the general expression for AUC of (13.38), which holds for any test statistic. For the special case of the ideal observer, we can rewrite this expression in terms of the characteristic function for the log-likelihood ratio under H_1 :

$$\text{AUC} = \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \psi_{\lambda 1}(\xi) \psi_{\lambda 1} \left(-\xi + \frac{i}{2\pi} \right), \quad (13.98)$$

where we have made use of (13.80) and the Hermiticity of the characteristic function. By moving the contour of integration, (13.98) becomes (Barrett *et al.*, 1998b)

$$\text{AUC} = 1 + \frac{1}{2\pi i} \int_{-\infty}^{\infty} \frac{d\xi}{\xi + \frac{i}{4\pi}} \psi_{\lambda 1} \left(\xi + \frac{i}{4\pi} \right) \psi_{\lambda 1} \left(-\xi + \frac{i}{4\pi} \right). \quad (13.99)$$

We can write (13.99) in terms of $F(\xi)$ using (13.87):

$$\text{AUC} = 1 + \frac{1}{2\pi i} \int_{-\infty}^{\infty} \frac{d\xi}{\xi + \frac{i}{4\pi}} F(\xi) F(-\xi). \quad (13.100)$$

Substituting the expression for $F(\xi)$ given in (13.89) and doing some algebra yields

$$\text{AUC} = 1 + \frac{1}{2\pi i} \int_{-\infty}^{\infty} \frac{d\xi}{\xi + \frac{i}{4\pi}} \exp \left\{ \left(\xi^2 + \frac{1}{16\pi^2} \right) 2 \operatorname{Re}[A(\xi)] \right\}, \quad (13.101)$$

where we have made use of the fact that $A(-\xi) + A(\xi) = 2 \operatorname{Re}[A(\xi)]$. The relationship between $A(\xi)$ and $G(\xi)$ given in (13.91) leads finally to

$$\text{AUC} = 1 + \frac{1}{2\pi i} \int_{-\infty}^{\infty} \frac{d\xi}{\xi + \frac{i}{4\pi}} \exp \left\{ -8\pi^2 \left(\xi^2 + \frac{1}{16\pi^2} \right) 2 \operatorname{Re}[G(2\pi i \xi)] \right\}. \quad (13.102)$$

Thus the values of the likelihood-generating function along the imaginary axis determine AUC.

Bounds on AUC We have seen that the single value $G(0)$ can be used to derive AUC with the approximation above (13.96). It has also been shown that $G(0)$ establishes a lower bound on AUC with no approximation (Barrett *et al.*, 1998b). Additional bounds on AUC have been derived that may help to bracket ideal-observer performance for tasks where exact calculation of AUC is difficult (Shapiro, 1999; Clarkson, 2002). An active area of research continues to be the development of approximations and bounds for AUC for use in system optimization for more realistic noise and object models.

13.2.8 Ideal observer with Gaussian statistics

We now consider the decision problem of discriminating between two nonrandom signals in additive Gaussian noise. This is the so-called SKE/BKE (signal-known-exactly/background-known-exactly) problem. While this level of knowledge about the object is unrealistic in practice, it provides a useful starting place for understanding the theory of signal detection and the calculation of ideal decision strategies.

Let the first hypothesis, H_1 , denote that a single, nonrandom object \mathbf{f}_1 is present at the input. Under the second hypothesis, H_2 , a different, but nonrandom, object \mathbf{f}_2 is present. Under each hypothesis we then have:

$$\begin{aligned} H_1 : \mathbf{g} &= \mathcal{H}\mathbf{f}_1 + \mathbf{n} = \mathbf{s}_1 + \mathbf{n} \\ H_2 : \mathbf{g} &= \mathcal{H}\mathbf{f}_2 + \mathbf{n} = \mathbf{s}_2 + \mathbf{n}, \end{aligned} \quad (13.103)$$

where the signal \mathbf{s}_j is the MD data-space vector resulting from the imaging operator acting on the object-space vector \mathbf{f}_j . These signals are assumed to be real and known (though it is not known which of the two is present), and they are nonrandom since the two possible objects are nonrandom.

We shall now derive expressions for the ideal-observer test statistic and associated figures of merit for this problem for both correlated and uncorrelated Gaussian noise. Non-Gaussian noise is treated in Sec. 13.2.9.

Independent, identically distributed Gaussian noise As a simple example, assume that the noise corrupting the data is zero-mean, independent, identically distributed (i.i.d.) Gaussian with variance σ^2 for each data component. The conditional probability density function for each component is then

$$\text{pr}(g_m|H_j) = \left(\frac{1}{2\pi\sigma^2}\right)^{\frac{1}{2}} \exp\left[-\frac{(g_m - s_{jm})^2}{2\sigma^2}\right]. \quad (13.104)$$

The noise samples are statistically independent, which tells us that the conditional PDF on the data vector \mathbf{g} is simply the product of the densities of the components. Thus the PDF on the data vector under the j^{th} hypothesis can be written as follows:

$$\text{pr}(\mathbf{g}|H_j) = \left(\frac{1}{2\pi\sigma^2}\right)^{\frac{M}{2}} \prod_{m=1}^M \exp\left[-\frac{(g_m - s_{jm})^2}{2\sigma^2}\right]. \quad (13.105)$$

Using this expression for the conditional PDF on the data vector and the definition of the likelihood ratio below (13.58), we can write $\Lambda(\mathbf{g})$ as

$$\Lambda(\mathbf{g}) = \frac{\text{pr}(\mathbf{g}|H_2)}{\text{pr}(\mathbf{g}|H_1)} = \frac{\prod_{m=1}^M \sqrt{2\pi\sigma^2} \exp\left[-\frac{(g_m - s_{2m})^2}{2\sigma^2}\right]}{\prod_{m=1}^M \sqrt{2\pi\sigma^2} \exp\left[-\frac{(g_m - s_{1m})^2}{2\sigma^2}\right]}. \quad (13.106)$$

The ideal decision rule is to evaluate this expression and compare it to a threshold Λ_c . We can simplify this expression by first cancelling the common terms in the numerator and denominator to get

$$\Lambda(\mathbf{g}) = \prod_{m=1}^M \exp\left[\frac{(s_{2m} - s_{1m})g_m}{\sigma^2} - \frac{s_{2m}^2 - s_{1m}^2}{2\sigma^2}\right] \underset{D_1}{\overset{D_2}{>}} \Lambda_c. \quad (13.107)$$

Since the natural logarithm is a monotonic function, we can construct an equivalent test by taking the log of both sides of this expression to give

$$\ln \Lambda(\mathbf{g}) = \lambda(\mathbf{g}) = \sum_{m=1}^M \frac{(s_{2m} - s_{1m})g_m}{\sigma^2} - \frac{s_{2m}^2 - s_{1m}^2}{2\sigma^2} \underset{D_1}{\overset{D_2}{>}} \ln \Lambda_c = \lambda_c. \quad (13.108)$$

The threshold is the logarithm of Λ_c , which we have rewritten as λ_c . We can go one step further and combine the constant term relating the nonrandom difference in the signal energies into the threshold, giving the new decision rule:

$$\sum_{m=1}^M (s_{2m} - s_{1m})g_m \underset{D_1}{\overset{D_2}{>}} \lambda'_c. \quad (13.109)$$

This expression gives the well-known “matched-filter” discriminator in which the expected signal is used as a filter that is correlated⁵ with the data. Since the signal is known exactly, the filtering operation is performed with the data and the filter perfectly aligned; no relative shift between filter and data is implied. Matched filtering has long been known as the optimal strategy for the detection of known signals buried in Gaussian noise (North, 1943; Van Vleck and Middleton, 1946; Zadeh and Ragazzini, 1952).

We can rewrite (13.109) using vector notation as

$$\Delta \mathbf{s}^t \mathbf{g} \underset{D_1}{\overset{D_2}{>}} \lambda'_c, \quad (13.110)$$

where $\Delta \mathbf{s}$ is the expected difference signal $\mathbf{s}_2 - \mathbf{s}_1$, and we have assumed that the data and expected signals are real.

Correlated Gaussian noise The covariance matrix under the j^{th} hypothesis is defined to be

$$\mathbf{K}_j = \langle (\mathbf{g} - \mathbf{s}_j)(\mathbf{g} - \mathbf{s}_j)^t | H_j \rangle = \langle \mathbf{nn}^t \rangle, \quad (13.111)$$

where the angle brackets denote an average over all possible noise realizations for a given hypothesis with known signal \mathbf{s}_j , and we have again assumed that the noise and signals are real. We see immediately from (13.111) that $\mathbf{K}_1 = \mathbf{K}_2$, because the noise is independent of the signal.⁶ We can therefore drop the hypothesis-specific subscript on the covariance matrix in the discussion that follows and refer to it as \mathbf{K}_n , where the subscript \mathbf{n} refers to the noise.

The probability density function on \mathbf{g} under the j^{th} hypothesis is the multivariate Gaussian [cf. (8.185)]

$$\text{pr}(\mathbf{g} | H_j) = [(2\pi)^M \det(\mathbf{K}_n)]^{-\frac{1}{2}} \exp \left[-\frac{1}{2} (\mathbf{g} - \mathbf{s}_j)^t \mathbf{K}_n^{-1} (\mathbf{g} - \mathbf{s}_j) \right], \quad (13.112)$$

⁵Though the term “correlation filter” is commonly used for a matched filter, we note that (13.109) is just a scalar product, not a correlation. The confusion arises since scanning matched filters are often used with signals whose form is known but whose spatial or temporal location is not. In that case, the matched filter is not optimal, even with i.i.d. Gaussian noise. For more details see Sec. 13.2.10.

⁶Two random variables that have the same variance, or two random vectors that have the same covariance, are said to be *homoscedastic*. The word derives from the ancient Greek verb *skedanumi* (*σκεδανουμι*), meaning “scatter.” A related word is *diaskedanumi*, which can mean “throw the troubles out, entertain, have fun.” In many statistical problems, homoscedasticity is more fun than heteroscedasticity. (Thanks to Mary Ruddick for assistance with ancient Greek etymology.)

where $\det(\mathbf{K}_n)$ is the determinant of the matrix \mathbf{K}_n .

The likelihood ratio test follows:

$$\Lambda(\mathbf{g}) = \frac{\exp\left[-\frac{1}{2}(\mathbf{g} - \mathbf{s}_2)^t \mathbf{K}_n^{-1}(\mathbf{g} - \mathbf{s}_2)\right]}{\exp\left[-\frac{1}{2}(\mathbf{g} - \mathbf{s}_1)^t \mathbf{K}_n^{-1}(\mathbf{g} - \mathbf{s}_1)\right]} \underset{D_1}{\overset{D_2}{>}} \Lambda_c. \quad (13.113)$$

The log-likelihood ratio is then

$$\begin{aligned} \lambda(\mathbf{g}) &= \frac{1}{2}(\mathbf{g} - \mathbf{s}_1)^t \mathbf{K}_n^{-1}(\mathbf{g} - \mathbf{s}_1) - \frac{1}{2}(\mathbf{g} - \mathbf{s}_2)^t \mathbf{K}_n^{-1}(\mathbf{g} - \mathbf{s}_2) \\ &= \frac{1}{2} [\mathbf{g}^t \mathbf{K}_n^{-1}(\mathbf{s}_2 - \mathbf{s}_1) + (\mathbf{s}_2 - \mathbf{s}_1)^t \mathbf{K}_n^{-1} \mathbf{g} + \mathbf{s}_1^t \mathbf{K}_n^{-1} \mathbf{s}_1 - \mathbf{s}_2^t \mathbf{K}_n^{-1} \mathbf{s}_2]. \end{aligned} \quad (13.114)$$

The ideal observer evaluates this expression and compares it to the threshold λ_c to make its decision. We can form an equivalent test by incorporating the last two terms into the threshold, since they are scalars independent of the data, and make use of the fact that the covariance matrix is symmetric, to obtain this form for the ideal decision strategy:

$$\Delta \mathbf{s}^t \mathbf{K}_n^{-1} \mathbf{g} = \lambda'(\mathbf{g}) \underset{D_1}{\overset{D_2}{>}} \lambda'_c. \quad (13.115)$$

Equation (13.115) describes the operations an ideal observer would perform to decide which hypothesis was responsible for the received data. First the data vector is filtered by the inverse of the covariance matrix. The output of this operation is then correlated with the difference signal, $\Delta \mathbf{s}$, a matched-filter operation like that found in (13.110). The correlation function is evaluated at zero shift because the ideal observer makes use of the *a priori* information that the signal is at a known location in the object; we can assume without loss of generality that the signal location is the origin.

SNR and AUC in the Gaussian case The expression for the log-likelihood ratio in (13.115) was derived under the assumption that the data are multivariate normal with \mathbf{K}_1 and \mathbf{K}_2 equal. The decision variable is a linear transformation of the data, and since linear transformations of Gaussian random variables are Gaussian random variables, we conclude that $\lambda'(\mathbf{g})$ must also be Gaussian. Thus we can confidently use the expression for SNR given in (13.19) as a measure of the test performance. We shall now determine the SNR for this case, dropping the prime on the decision variable to avoid clutter in the equations that follow.

To derive SNR_λ , we must first find the mean of $\lambda(\mathbf{g})$ under each hypothesis:

$$\langle \lambda(\mathbf{g}) | H_j \rangle = \langle \Delta \mathbf{s}^t \mathbf{K}_n^{-1} \mathbf{g} | H_j \rangle = \Delta \mathbf{s}^t \mathbf{K}_n^{-1} \mathbf{s}_j. \quad (13.116)$$

The variance of $\lambda(\mathbf{g})$ under the j^{th} hypothesis is

$$\begin{aligned} \sigma_\lambda^2 &= \langle [|\lambda(\mathbf{g}) - \langle \lambda(\mathbf{g}) | H_j \rangle|^2 | H_j] \rangle = \langle \lambda^2(\mathbf{g}) | H_j \rangle - \langle \lambda(\mathbf{g}) | H_j \rangle^2 \\ &= \langle \Delta \mathbf{s}^t \mathbf{K}_n^{-1} \mathbf{g} \mathbf{g}^t \mathbf{K}_n^{-1} \Delta \mathbf{s} | H_j \rangle - \Delta \mathbf{s} \mathbf{K}_n^{-1} \mathbf{s}_j \mathbf{s}_j^t \mathbf{K}_n^{-1} \Delta \mathbf{s} \\ &= \Delta \mathbf{s}^t \mathbf{K}_n^{-1} \Delta \mathbf{s}, \end{aligned} \quad (13.117)$$

which is independent of the hypothesis, as we would expect.

Now we can put all the pieces together to write down the expression for SNR_λ^2 :

$$\text{SNR}_\lambda^2 = \frac{[\Delta \mathbf{s}^t \mathbf{K}_n^{-1} \mathbf{s}_2 - \Delta \mathbf{s}^t \mathbf{K}_n^{-1} \mathbf{s}_1]^2}{\sigma_\lambda^2} = \frac{[\Delta \mathbf{s}^t \mathbf{K}_n^{-1} \Delta \mathbf{s}]^2}{\Delta \mathbf{s}^t \mathbf{K}_n^{-1} \Delta \mathbf{s}} = \Delta \mathbf{s}^t \mathbf{K}_n^{-1} \Delta \mathbf{s}. \quad (13.118)$$

As we should expect, the performance of the observer depends only on the difference in the two signals and the noise covariance.

In the special case where the noise in the data is uncorrelated, the covariance matrix can be written $[K_{\mathbf{n}}]_{mm'} = \sigma_m^2 \delta_{mm'}$ and the SNR becomes

$$\text{SNR}_\lambda^2 = \sum_{m=1}^M \frac{[\Delta \mathbf{s}_m]^2}{\sigma_m^2}. \quad (13.119)$$

If, in addition, the noise variance is uniform ($\sigma_m = \sigma$ for all m), this expression further simplifies to

$$\text{SNR}_\lambda^2 = \frac{1}{\sigma^2} \sum_{m=1}^M [\Delta \mathbf{s}_m]^2 = \frac{\|\Delta \mathbf{s}\|^2}{\sigma^2}. \quad (13.120)$$

In this case the form of the signal does not enter into the SNR expression; all that matters is the norm of the difference signal relative to the noise variance.

Likelihood-generating function for Gaussian data The SNR given in (13.118) can be used to determine AUC exactly via (13.20) in this Gaussian case. Moreover, the approximation based on $G(0)$ given in (13.96) gives precisely the same SNR values. These approximations are all exact for Gaussian data.

For Gaussian data the log-likelihood ratio is Gaussian because of its linear relationship with \mathbf{g} . Thus its characteristic function takes the form given in (C.116) for scalar Gaussian random variables (although with a constant phase factor determined by the mean of λ under each hypothesis). When we revisit the general forms for the characteristic function for λ given in (13.93), we see that $G(\beta)$ must therefore be independent of β . Thus the likelihood-generating function is a constant in the Gaussian case. All the information needed to describe the performance of the ideal observer is contained in one number, $2G(0)$.

KL formulation for SKE/BKE tasks Equivalent expressions for the SNRs given in the previous section can be written in terms of the Karhunen-Loève expansion of the signal and data vectors. From (8.58) we can write the data as

$$\mathbf{g} = \sum_{m=1}^M \beta_m \phi_m = \Phi \boldsymbol{\beta}, \quad (13.121)$$

where, by (8.59), the vector of coefficients is given by $\boldsymbol{\beta} = \Phi^\dagger \mathbf{g}$. For any set of expansion vectors the $\boldsymbol{\beta}$ would be random variables through their linear relationship to \mathbf{g} . In the special case where we use a KL expansion, so that the ϕ_m are the eigenvectors of the covariance matrix of the data, we know by (8.62) that the coefficients are uncorrelated random variables. Thus we can write the covariance matrix for the coefficients as $\mathbf{K}_\beta = \mathbf{M}$, with diagonal elements μ_m .

We can similarly define the mean difference in the data under each hypothesis by

$$\Delta \mathbf{s} = \Delta \bar{\mathbf{g}} = \Phi \Delta \bar{\boldsymbol{\beta}}. \quad (13.122)$$

We can use (13.122) and (8.64) to rewrite (13.118) as

$$\begin{aligned} \text{SNR}_\lambda^2 &= \Delta \mathbf{s}^t \mathbf{K}_n^{-1} \Delta \mathbf{s} = [\Phi \Delta \bar{\boldsymbol{\beta}}]^t [\Phi \mathbf{M}^{-1} \Phi^\dagger] [\Phi \Delta \bar{\boldsymbol{\beta}}] \\ &= \sum_{m=1}^M \frac{[\Delta \bar{\beta}_m]^2}{\mu_m} = \sum_{m=1}^M \frac{|(\boldsymbol{\phi}_m, \Delta \mathbf{s})|^2}{\mu_m}. \end{aligned} \quad (13.123)$$

The last form is analogous to the result we found in (13.119) for data contaminated by uncorrelated Gaussian noise. The KL domain is defined to be the domain where the random vectors are uncorrelated, so the SNR in that domain always has the form of (13.119).

Prewhitening matched filter If the noise covariance matrix \mathbf{K}_n is nonsingular, we can make use of (8.66) and (8.67) to define a new random variable \mathbf{z} in terms of the square-root matrix $\mathbf{K}_n^{-\frac{1}{2}}$:

$$\mathbf{z} = \mathbf{K}_n^{-\frac{1}{2}} \mathbf{g}. \quad (13.124)$$

Similarly,

$$\bar{\mathbf{z}}_j = \mathbf{K}_n^{-\frac{1}{2}} \bar{\mathbf{g}}_j, \quad (13.125)$$

so that

$$\Delta \bar{\mathbf{z}} = \mathbf{K}_n^{-\frac{1}{2}} \Delta \bar{\mathbf{g}} = \mathbf{K}_n^{-\frac{1}{2}} \Delta \mathbf{s}, \quad (13.126)$$

and the test statistic of (13.115) becomes

$$\lambda = \Delta \mathbf{s}^t \mathbf{K}_n^{-1} \mathbf{g} = [\mathbf{K}_n^{-\frac{1}{2}} \Delta \mathbf{s}]^t [\mathbf{K}_n^{-\frac{1}{2}} \mathbf{g}] = \Delta \bar{\mathbf{z}}^t \mathbf{z}. \quad (13.127)$$

The covariance of \mathbf{z} is given by

$$\mathbf{K}_z = \left\langle [\mathbf{K}_n^{-\frac{1}{2}} \Delta \mathbf{g}] [\mathbf{K}_n^{-\frac{1}{2}} \Delta \mathbf{g}]^t \right\rangle = \mathbf{K}_n^{-\frac{1}{2}} \mathbf{K}_n \mathbf{K}_n^{-\frac{1}{2}} = \mathbf{I}. \quad (13.128)$$

We see that \mathbf{z} is an uncorrelated Gaussian random variable with unit variance in each element. The process represented by (13.124) is called *prewhitening*; it yields a Gaussian random variable whose correlation matrix has a flat, or white, eigen-spectrum. From (13.127) we see that the ideal decision strategy is to first prewhiten the data and then perform a filtering operation with a prewhitened version of the expected difference signal. This observer is therefore referred to as the *prewhitening matched filter* or PWMF.

The simple form for the covariance of \mathbf{z} leads to a particularly simple form for the SNR given in (13.118) when it is written in terms of \mathbf{z} :

$$\text{SNR}_\lambda^2 = \|\Delta \bar{\mathbf{z}}\|^2. \quad (13.129)$$

13.2.9 Ideal observer with non-Gaussian data

So far we have restricted our attention to the SKE/BKE classification task in additive Gaussian noise. We now consider the SKE/BKE classification problem for other statistical descriptions of the measurement noise that might arise in imaging.

Poisson noise In many photon-limited imaging situations, the probability law on the data is Poisson (see Chap. 11). If the task is the discrimination between two exactly-specified signals in a radiological image with only Poisson noise, the conditional PDF of the data under hypothesis H_j is given by [cf. (11.40)]

$$\text{pr}(\mathbf{g}|H_j) = \prod_{m=1}^M \frac{e^{-\bar{g}_{jm}} [\bar{g}_{jm}]^{g_m}}{(g_m)!}, \quad (13.130)$$

where \bar{g}_{jm} is the mean of the m^{th} element of the data vector when hypothesis H_j is true. When we form the likelihood ratio using (13.130) for the two hypotheses, we find the ideal observer's test statistic to be (Helstrom, 1964)

$$\lambda(\mathbf{g}) = \sum_{m=1}^M g_m \ln \frac{\bar{g}_{2m}}{\bar{g}_{1m}}. \quad (13.131)$$

We see that in the Poisson case the optimum operation on the data is again a linear filtering operation, only now the filter is a nonlinear functional of the expected signals under the two hypotheses.

We can use (13.131) to determine the signal-to-noise ratio associated with the test statistic, according to (13.19) (Cunningham *et al.*, 1976; Wagner *et al.*, 1981)

$$\text{SNR}^2 = \frac{\left[\sum_{m=1}^M (\bar{g}_{2m} - \bar{g}_{1m}) \ln \left(\frac{\bar{g}_{2m}}{\bar{g}_{1m}} \right) \right]^2}{\frac{1}{2} \sum_{m=1}^M (\bar{g}_{2m} + \bar{g}_{1m}) \ln^2 \left(\frac{\bar{g}_{2m}}{\bar{g}_{1m}} \right)}. \quad (13.132)$$

The derivation of (13.132) makes use of a definition for SNR that is relevant whenever the test statistic is a Gaussian random variable. While the data are not assumed here to be Gaussian, the fact that λ as defined in (13.131) is a weighted sum of random variables implies that the assumption of Gaussianity is often valid owing to the central-limit theorem.

It is illustrative to consider the behavior of the ideal observer when certain pixels in the image are known to have expected values equal to zero for one hypothesis and nonzero for the other. From (13.131) we see that the test statistic becomes infinite when the data in those elements are nonzero. The SNR is infinite as well, as (13.132) confirms. This example demonstrates the tremendous power of such complete prior information regarding the expected values in a particular pixel in the image, information that is possible only for contrived problems in which there is no uncertainty in the expected images under each hypothesis.

An approximation to the SNR for the Poisson noise case can be obtained by utilizing the SNR expression for the multivariate Gaussian case given in (13.118). Poisson noise results in a diagonal covariance matrix in which the mean of each element specifies the variance:

$$[\mathbf{K}_{\mathbf{n}}]_{mm'} = \sigma_m^2 \delta_{mm'} = \bar{g}_m \delta_{mm'}, \quad (13.133)$$

where we have assumed that the signal is of sufficiently low contrast that the variance in each detector element is independent of hypothesis. Substituting this form for $\mathbf{K}_{\mathbf{n}}$ into (13.118) yields

$$\text{SNR}^2 = \sum_{m=1}^M \frac{(\bar{g}_{2m} - \bar{g}_{1m})^2}{\bar{g}_m} = \sum_{m=1}^M \frac{\Delta \bar{g}_m^2}{\bar{g}_m}, \quad (13.134)$$

similar to (13.119). To make use of (13.118) in deriving (13.134) we are assuming that the number of counts in each detector is greater than about 10, so that a Gaussian approximation to the Poisson law on the data can be made (Barrett and Swindell, 1981, 1996).

Perhaps surprisingly, even in the absence of a large number of counts per detector element, we can obtain the same expression for the SNR given in (13.134), provided we again assume that the signal is weak. To see this, consider the task of detecting a low-contrast signal, in which case we can write the expected data under hypothesis H_2 as $\bar{g}_{2m} = \bar{g}_{1m} + s_m$, with $s_m \ll \bar{g}_{1m}$ for all m . Then a Taylor expansion of the logarithms in (13.132) through terms linear in the signal yields

$$\text{SNR}_\lambda^2 \approx \sum_{m=1}^M \frac{s_m^2}{\bar{g}_m}, \quad (13.135)$$

where \bar{g}_m can be either \bar{g}_{1m} or \bar{g}_{2m} to this approximation.

Exponential noise Speckle noise, found in coherent imaging applications involving ultrasound or laser sources, is characterized by an exponential probability density function (see Chap. 18 for more detail). If the task is the detection of a known signal in speckle noise, where the signal affects only the mean, the conditional PDF on the data is written [cf. (C.118)]

$$\text{pr}(\mathbf{g}|H_j) = \prod_{m=1}^M \frac{1}{\bar{g}_{jm}} \exp\left[-\frac{g_m}{\bar{g}_{jm}}\right]. \quad (13.136)$$

This expression is valid in the idealized case in which the detectors are small relative to a speckle cell and separated by a distance greater than a speckle cell, such that the data elements are uncorrelated.

The log-likelihood ratio for this case can be shown to be

$$\lambda(\mathbf{g}) = \sum_{m=1}^M \left(\frac{\Delta \bar{g}_m}{\bar{g}_{1m} \bar{g}_{2m}} \right) g_m, \quad (13.137)$$

where we have dropped all terms that are independent of the data. We see that the ideal observer again performs a matched filter on the detected data, only now the filter is the expected difference signal normalized by the square of the geometric mean.

We can find SNR_λ by direct calculation of the relevant expectations. The mean of λ under hypothesis H_j is

$$\langle \lambda(\mathbf{g}) \rangle_j = \sum_{m=1}^M \left(\frac{\Delta \bar{g}_m}{\bar{g}_{1m} \bar{g}_{2m}} \right) \bar{g}_{jm}. \quad (13.138)$$

The variance of λ under the j^{th} hypothesis is

$$\sigma_j^2 = \sum_{m=1}^M \left(\frac{\Delta \bar{g}_m}{\bar{g}_{1m} \bar{g}_{2m}} \right)^2 (\bar{g}_{jm})^2, \quad (13.139)$$

since we have assumed there are no correlations between the data components. The SNR is thus

$$\text{SNR}_\lambda^2 = \frac{\left[\sum_m \frac{\Delta \bar{g}_m^2}{\bar{g}_{1m} \bar{g}_{2m}} \right]^2}{\frac{1}{2} \sum_m \frac{\Delta \bar{g}_m^2 (\bar{g}_{2m}^2 + \bar{g}_{1m}^2)}{\bar{g}_{1m}^2 \bar{g}_{2m}^2}}. \quad (13.140)$$

An interesting limit is the one in which $\bar{g}_{1m} \approx \bar{g}_{2m} = \bar{g}_m$. Then (13.140) becomes

$$\text{SNR}_\lambda^2 = \sum_m \frac{\Delta \bar{g}_m^2}{\bar{g}_m^2}. \quad (13.141)$$

There is an interesting difference between this expression and that obtained in the low-contrast limit for Poisson noise [see (13.135)]. For exponential noise there is no SNR increase to be found by increasing the exposure, because this affects both the numerator and the denominator equally. This is in contrast to the behavior found for the low-contrast Poisson case, where an increase in exposure yields a linear improvement in SNR^2 with count density.

Log-normal In some circumstances the data can be modeled as log-normally distributed. For example, log-normal statistics have been shown to describe the statistics of images that have been reconstructed from projections using nonlinear algorithms (Barrett *et al.*, 1994; see also Sec. 15.4.7).

Independent log-normal data are described by

$$\text{pr}(\mathbf{g}|H_j) = \prod_m \frac{1}{\sqrt{2\pi} \sigma_{jm} g_m} \exp \left[-\frac{(\ln g_m - \ln A_m - \bar{x}_{jm})^2}{2\sigma_{jm}^2} \right], \quad (13.142)$$

assuming the density for the random variable g_m is determined by the two parameters \bar{x}_{jm} and σ_{jm} under hypothesis j (see Sec. C.5.9).

The log-likelihood ratio can be shown to be

$$\lambda(\mathbf{g}) = \sum_m \ln g_m \left[\frac{\ln A_m + \bar{x}_{2m}}{\sigma_{2m}^2} - \frac{\ln A_m + \bar{x}_{1m}}{\sigma_{1m}^2} \right] + \sum_m (\ln g_m)^2 \left[\frac{1}{2\sigma_{1m}^2} - \frac{1}{2\sigma_{2m}^2} \right], \quad (13.143)$$

where we have again combined all terms independent of the data into the threshold. If we can assume $\sigma_{1m} \approx \sigma_{2m}$, the optimal decision variable is linear in the logarithm of each data element. In this case the log-likelihood ratio takes the form of a matched filter operation acting on the elements of $\ln \mathbf{g}$, which is intuitively sensible since the log operation recovers Gaussian data.

13.2.10 Signal variability and the ideal observer

In the previous section we assumed that the signals to be classified were known exactly, so that the only limitation to task performance by the ideal observer was the randomness in the data resulting from measurement noise. Let us now consider the case where the task is the detection of a signal which is in some way random. Under the two hypotheses the data are now given by

$$H_1 : \mathbf{g} = \mathcal{H}\mathbf{f}_1 + \mathbf{n} = \mathbf{b} + \mathbf{n} \quad (13.144a)$$

and

$$H_2 : \mathbf{g} = \mathcal{H}\mathbf{f}_2 + \mathbf{n} = \mathbf{s} + \mathbf{b} + \mathbf{n}. \quad (13.144b)$$

In this model, when the signal is absent the data are the sum of two components: the nonrandom (but not necessarily uniform) background \mathbf{b} and the measurement noise \mathbf{n} . The background \mathbf{b} is the image that would be obtained in the signal-absent case in the limit of an infinite exposure time. The signal present under H_2 is whatever represents the distinguishing image feature(s) between class 1 and class 2. We assume here that the presence of the signal does not occlude or alter the background.

Both \mathbf{b} and \mathbf{s} are defined in the data space \mathbb{V} . They are the result of some unspecified deterministic mapping \mathcal{H} that maps each object, either background-only or signal-plus-background, to the data domain. For example, the signal might be the image of a nodule to be detected in a detection task. The background is whatever is left that makes up the image of the object, for example, the ribs and other “non-nodule” structures in a chest film.

One approach to the problem of signal variability is to let \mathbf{s} be characterized by randomness in P of its defining parameters (Sec. 8.4). For example, \mathbf{s} might have known shape, but unknown amplitude or location or the signal might be a sinusoidal pattern of unknown frequency and phase. We can define a P -dimensional vector of random parameters $\boldsymbol{\theta}$ with probability density $\text{pr}_{\boldsymbol{\theta}}(\boldsymbol{\theta})$. Then

$$H_2 : \mathbf{g} = \mathbf{s}(\boldsymbol{\theta}) + \mathbf{b} + \mathbf{n}. \quad (13.145)$$

We assume that the statistics of \mathbf{n} and $\boldsymbol{\theta}$ are independent.

The ideal observer uses the likelihood ratio as a test statistic. To compute this statistic we must first determine the conditional PDF of the data under each hypothesis. The PDF of the data under the signal-absent condition is given by

$$\text{pr}(\mathbf{g}|H_1) = \text{pr}_{\mathbf{n}}(\mathbf{g} - \mathbf{b}), \quad (13.146)$$

which is the noise probability density function centered on the background \mathbf{b} . The PDF of the data under the signal-present condition is a weighted average of the noise probability density function shifted to each signal-plus-background combination, with the weighting given by the probability of each signal as described by $\text{pr}_{\boldsymbol{\theta}}(\boldsymbol{\theta})$:

$$\text{pr}(\mathbf{g}|H_2) = \int_{\infty} d^P\theta \text{pr}_{\mathbf{n}}[\mathbf{g} - \mathbf{b} - \mathbf{s}(\boldsymbol{\theta})|\boldsymbol{\theta}] \text{pr}_{\boldsymbol{\theta}}(\boldsymbol{\theta}) = \langle \text{pr}(\mathbf{g}|H_2, \boldsymbol{\theta}) \rangle_{\boldsymbol{\theta}}. \quad (13.147)$$

The likelihood ratio is thus given by

$$\Lambda(\mathbf{g}) = \frac{\text{pr}(\mathbf{g}|H_2)}{\text{pr}(\mathbf{g}|H_1)} = \frac{\langle \text{pr}(\mathbf{g}|H_2, \boldsymbol{\theta}) \rangle_{\boldsymbol{\theta}}}{\text{pr}(\mathbf{g}|H_1)} = \left\langle \frac{\text{pr}(\mathbf{g}|H_2, \boldsymbol{\theta})}{\text{pr}(\mathbf{g}|H_1)} \right\rangle_{\boldsymbol{\theta}} = \langle \Lambda_{\text{SKE}}(\mathbf{g}, \boldsymbol{\theta}) \rangle_{\boldsymbol{\theta}} \quad (13.148)$$

in the case where the signal depends on a random parameter vector.

Consider the case of independent, identically distributed Gaussian noise, so that $\mathbf{K}_{\mathbf{n}} = \sigma^2 \mathbf{I}$. Then

$$\begin{aligned} \Lambda_{\text{SKE}}(\mathbf{g}, \boldsymbol{\theta}) &= \frac{\left(\frac{1}{2\pi\sigma^2}\right)^{\frac{M}{2}} \exp\left\{-\frac{1}{2}[\mathbf{g} - \mathbf{b} - \mathbf{s}(\boldsymbol{\theta})]^t \mathbf{K}_{\mathbf{n}}^{-1}[\mathbf{g} - \mathbf{b} - \mathbf{s}(\boldsymbol{\theta})]\right\}}{\left(\frac{1}{2\pi\sigma^2}\right)^{\frac{M}{2}} \exp\left[-\frac{1}{2}(\mathbf{g} - \mathbf{b})^t \mathbf{K}_{\mathbf{n}}^{-1}(\mathbf{g} - \mathbf{b})\right]} \\ &= \exp\left\{\frac{1}{\sigma^2}[\mathbf{s}(\boldsymbol{\theta})]^t(\mathbf{g} - \mathbf{b}) - \frac{1}{2\sigma^2}\|\mathbf{s}(\boldsymbol{\theta})\|^2\right\}. \end{aligned} \quad (13.149)$$

When we average (13.149) over the distribution of random parameters we obtain

$$\Lambda(\mathbf{g}) = \int_{\infty} d^P \theta \operatorname{pr}_{\theta}(\boldsymbol{\theta}) \exp \left\{ \frac{1}{\sigma^2} [\mathbf{s}(\boldsymbol{\theta})]^t (\mathbf{g} - \mathbf{b}) - \frac{1}{2\sigma^2} \|\mathbf{s}(\boldsymbol{\theta})\|^2 \right\}. \quad (13.150)$$

We see from (13.150) that the decision function is no longer a linear function of the data, even in this i.i.d. Gaussian-noise case, and the log-likelihood function is not linear in the data either. In general, when the signal is random, the ideal observer performs a nonlinear operation on the data.

An exception to this general rule can be found for the case of weak signals or large noise. Suppose the energy of the signal is independent of $\boldsymbol{\theta}$, so that $\|\mathbf{s}(\boldsymbol{\theta})\|^2 = \|\mathbf{s}_0\|^2$. This holds, for example, if the random parameter is location and the signal is large with respect to the detector elements. Now let the signal be sufficiently weak that it satisfies

$$\frac{1}{\sigma^2} [\mathbf{s}(\boldsymbol{\theta})]^t (\mathbf{g} - \mathbf{b}) \ll 1. \quad (13.151)$$

In this case we can rewrite (13.150) as

$$\begin{aligned} \Lambda(\mathbf{g}) &= \exp \left\{ -\frac{1}{2\sigma^2} \|\mathbf{s}_0\|^2 \right\} \int_{\infty} d^P \theta \operatorname{pr}_{\theta}(\boldsymbol{\theta}) \left\{ 1 + \frac{1}{\sigma^2} [\mathbf{s}(\boldsymbol{\theta})]^t (\mathbf{g} - \mathbf{b}) \right\} \\ &= \exp \left\{ -\frac{1}{2\sigma^2} \|\mathbf{s}_0\|^2 \right\} \left\{ 1 + \frac{1}{\sigma^2} \bar{\mathbf{s}}^t (\mathbf{g} - \mathbf{b}) \right\}, \end{aligned} \quad (13.152)$$

where $\bar{\mathbf{s}} = \langle \mathbf{s}(\boldsymbol{\theta}) \rangle_{\boldsymbol{\theta}}$ is the average signal. When we incorporate all additive and multiplicative constants into the threshold, we find the ideal observer's decision function to be

$$\Lambda(\mathbf{g}) = \bar{\mathbf{s}}^t (\mathbf{g} - \mathbf{b}). \quad (13.153)$$

The strategy is a matched filter with the expected average signal, once the known background has been subtracted from the data. Note that this matched filter yields the likelihood ratio, not the log-likelihood ratio as found in (13.110) and (13.115).

Example: Weak sinusoid of random frequency If the task is the detection of a weak grating pattern of uncertain frequency, the signal contribution to the m^{th} detector element is given by

$$[\mathbf{s}(\theta)]_m = \cos(2\pi i \theta x_m) \quad (13.154)$$

when the pattern has frequency θ . If the PDF on θ is a Gaussian centered at frequency θ_0 and with variance σ_{θ}^2 , the average signal is given by

$$\begin{aligned} \bar{\mathbf{s}}_m &= \left(\frac{1}{2\pi\sigma_{\theta}^2} \right)^{\frac{1}{2}} \int_{-\infty}^{\infty} d\theta \cos(2\pi i \theta x_m) \exp \left[-\frac{(\theta - \theta_0)^2}{2\sigma_{\theta}^2} \right] \\ &= \cos(2\pi\theta_0 x_m) \exp \left[-2\pi^2 x_m^2 \sigma_{\theta}^2 \right], \end{aligned} \quad (13.155)$$

which has the form of a Gabor function centered at frequency θ_0 , with width dictated by σ_{θ} . It is this average signal that the ideal observer would use as a template in the matched filter expression of (13.153). As we shall discuss in greater detail in Chap. 14, the visual system has been shown to have frequency-selective filters or channels of the form given in (13.155). It has been suggested that the evolution of such channels was motivated by the need for a mechanism for detecting weak signals of unknown scale, leading to Gabor-like channels in the visual system.

Example: Location uncertainty Consider the problem of detecting a signal with unknown location in uncorrelated Gaussian measurement noise. The task is to determine whether the data do or do not contain the signal, without needing to determine its location. Under H_1 the signal is absent, and the conditional PDF of the data (13.146) is equivalent to (13.105), where the nonrandom signal component in that expression is now given by \mathbf{b} . Under H_2 the underlying continuous signal $s(\mathbf{r})$ is parameterized by a random location vector \mathbf{r}_s such that when the signal is present at location \mathbf{r}_s , its contribution to the m^{th} data element is

$$s_m(\mathbf{r}_s) = \int_m d^2r s(\mathbf{r} - \mathbf{r}_s), \quad (13.156)$$

where the subscripted integral denotes an integration over the sensitive area of the m^{th} detector element. Using (13.105) and (13.147), the PDF of the data under H_2 is given by

$$\text{pr}(\mathbf{g}|H_2) = \left(\frac{1}{2\pi\sigma^2}\right)^{\frac{M}{2}} \int_{\infty} d^2r_s \text{pr}_{\mathbf{r}}(\mathbf{r}_s) \exp\left\{-\frac{1}{2\sigma^2} \sum_{m=1}^M [g_m - s_m(\mathbf{r}_s) - b_m]^2\right\}. \quad (13.157)$$

The likelihood ratio is thus given by

$$\Lambda(\mathbf{g}) \propto \int_{\infty} d^2r_s \text{pr}_{\mathbf{r}}(\mathbf{r}_s) \exp\left\{\frac{1}{\sigma^2} \sum_{m=1}^M [g_m - b_m] s_m(\mathbf{r}_s)\right\}, \quad (13.158)$$

where we have dropped all factors that are independent of the data. We see from this expression that the ideal decision strategy in the location-uncertain problem is to subtract the known background contribution from each pixel value, correlate with the signal for a particular location \mathbf{r}_s , and exponentiate. The observer performs this set of operations for each possible signal shift and averages with respect to the prior density on signal locations.

The generalization of (13.158) to correlated Gaussian noise is straightforward, leading to

$$\Lambda(\mathbf{g}) \propto \int_{\infty} d^2r_s \text{pr}_{\mathbf{r}}(\mathbf{r}_s) \exp\left[(\mathbf{g} - \mathbf{b})^t \mathbf{K}_n^{-1} \mathbf{s}(\mathbf{r}_s)\right]. \quad (13.159)$$

It is interesting to consider the weak-signal case in the presence of location uncertainty. If the signal is equally likely to be located anywhere in the data, the average signal is a uniform gray level. For i. i. d. Gaussian noise we see from (13.153) or (13.159) that ideal observer uses this template to detect the signal, meaning it simply computes the sum of the data elements to determine the total number of counts collected and compares this to a threshold.

The decision strategy represented by (13.158) was explored by Nolte and Jaarsma (1967), who also considered several approximations to this expression. They showed that the integral is dominated by the point of maximum correlation with the signal, provided the signal is equally likely at all locations [uniform $\text{pr}(\boldsymbol{\theta})$] and the noise variance is small. The ideal observer is approximated quite well by a cross-correlator that compares the maximum output to a threshold in this case.

More recently, Brown *et al.* (1995) revisited the location-uncertainty problem and showed that the likelihood ratio has a very non-Gaussian probability density function, rendering the SNR expression of (13.19) invalid as a measure of performance. Subsequently, Barrett *et al.* (1998a) showed that this problem is resolved if

one makes use of the log-likelihood ratio as the ideal observer's test statistic. They also demonstrated that the likelihood-generating function can be used to determine the ideal observer's SNR for this task in terms of $G(0)$.

One caution should be observed in making use of (13.158), in that we have dropped a data-independent term in the exponent that is proportional to s_m^2 , the energy of the signal in each pixel. This quantity is independent of \mathbf{r}_s provided the signal is large relative to the detector pixels and always within the field of view; otherwise this quantity becomes random with signal position. When this is the case, another component of uncertainty must be incorporated into the ideal observer's decision rule.

We have considered the ideal-observer strategy in the location-uncertain problem in which the task is to decide whether signal is present or absent without providing an indication of signal position. When the location of the signal must also be reported, the strategies discovered above are no longer optimal. The detection of a signal in one of many possible signal locations can be considered to be an L -class task, with hypotheses connected with each of the location alternatives (potentially an infinite number of them). The ideal observer would then determine the signal location with the greatest likelihood and compare this to the likelihood that signal is absent in all locations, choosing to report the signal as present in location \mathbf{r}_s or absent, depending on the observer's threshold.

Example: Location and scale uncertainty A signal with random location \mathbf{r}_s and random scale parameter θ can be represented by

$$[\mathbf{s}(\theta, \mathbf{r}_s)]_m = \int_m d^2r \left(\frac{1}{\theta^2} \right) s_m \left(\frac{\mathbf{r} - \mathbf{r}_s}{\theta} \right). \quad (13.160)$$

Scaling the signal amplitude by $1/\theta^2$ ensures that all signals have the same integrated value regardless of their size. The likelihood ratio in this case is given by

$$\Lambda(\mathbf{g}) \propto \int_{-\infty}^{\infty} d^2r_s \int_0^{\infty} d\theta \text{pr}_{\theta}(\theta) \text{pr}_{\mathbf{r}}(\mathbf{r}_s) \exp [(\mathbf{g} - \mathbf{b})^t \mathbf{K}_{\mathbf{n}}^{-1} \mathbf{s}(\theta, \mathbf{r}_s)]. \quad (13.161)$$

We see that in this case the ideal observer performs the following steps:

1. Subtract the known background from the image.
2. Prewhiten with the noise covariance matrix $\mathbf{K}_{\mathbf{n}}^{-\frac{1}{2}}$.
3. Compute the inner product with the shifted, scaled, prewhitened signal.
4. Exponentiate.
5. Average over all shifts and scales.
6. Compare to a threshold.

Unequal variance and the quadratic discriminant Another model for variability in the object is to consider a signal with known mean $\bar{\mathbf{s}}$, and covariance given by $\mathbf{K}_{\mathbf{s}}$. This might be a reasonable model for a signal with known position, shape, and scale

and random amplitude described by a Gaussian PDF. The likelihood ratio for the detection of such a signal is [cf. (13.113)]

$$\Lambda = \frac{\exp\left[-\frac{1}{2}(\mathbf{g} - \bar{\mathbf{s}})^t \mathbf{K}_2^{-1}(\mathbf{g} - \bar{\mathbf{s}})\right]}{\exp\left[-\frac{1}{2}\mathbf{g}^t \mathbf{K}_1^{-1}\mathbf{g}\right]}, \quad (13.162)$$

where we have dropped the normalizing constants out front, since they are independent of the data and will therefore only affect the operating point of the observer and not the form of the discriminant function. We have also assumed the signal-absent image has zero mean; a nonzero mean simply requires the addition of a background term as in previous examples. The covariance matrix on the data is now different under the two hypotheses so we have used subscripts to label them; $\mathbf{K}_1 = \mathbf{K}_n$ and $\mathbf{K}_2 = \mathbf{K}_s + \mathbf{K}_n$. Note that we are again describing the signal as a vector in the data space.

The log-likelihood ratio test can be shown to be

$$\lambda(\mathbf{g}) = -\frac{1}{2}\mathbf{g}^t(\mathbf{K}_2^{-1} - \mathbf{K}_1^{-1})\mathbf{g} + \bar{\mathbf{s}}^t \mathbf{K}_2^{-1} \mathbf{g} \underset{D_1}{\overset{D_2}{>}} \lambda_c, \quad (13.163)$$

where we have incorporated all data-independent terms into the threshold. We see that the inequality of the data covariance under the hypotheses results in a decision function that is no longer linear in the data. The discriminant contains a term that is quadratic in the data in addition to the prewhitening matched filter term.

The L-class problem Another approach to signal variability is to consider the task to be the classification of the data into L distinct classes. For example, the classes might represent L different signal shapes or locations. One of the L classes might be a signal-absent alternative, but this is not required. For each random data set, the observer chooses in favor of D_ℓ , indicating the decision that hypothesis H_ℓ is true,⁷ without equivocation or randomness in the decision process.

The ideal observer is defined as that observer who makes optimal use of the available information to perform this task. Not surprisingly, the optimal strategy in this L -class paradigm is to choose the hypothesis H_ℓ associated with a likelihood $\text{pr}(\mathbf{g}|H_\ell)$ that is higher than the likelihood of the data conditioned on all competing hypotheses (Melsa and Cohn, 1978). More generally, the ideal observer decides in favor of the hypothesis with greatest utility, which can be defined as minimization of Bayes risk if the costs and prevalences are known, or as maximum likelihood if this information is not to be used.

While the optimal strategy is straightforward (in principle) in the L -class problem, the full ROC curve is an $(L^2 - L - 1)$ -parameter hypersurface in an $(L^2 - L)$ -dimensional probability space. Thus an analog to the area under the ROC curve is harder to determine. AUC is an appealing summary measure of binary classification performance because it is a scalar figure of merit that is independent of prevalence and threshold; these attributes are difficult to capture in L -class problems. As an alternative metric, some investigators have made use of the percent of correct responses in an L -alternative forced-choice experiment (Goodenough, 1975; Burgess

⁷This is in contrast to the binary task of the previous section, in which the observer chose between 2 hypotheses, signal present (with random parameters) versus signal absent.

and Ghandeharian, 1984). Another approach is to compute the original Bayes risk, recognizing that this figure of merit depends on prevalence and threshold. In Chap. 14 we shall discuss the experimental use of L -alternative tasks for measurement of human performance.

13.2.11 Background variability and the ideal observer

Up to this point we have assumed that the background is a known, nonrandom quantity. In most instances this is an unrealistic model for the imaging task. We now remove the restriction that the background be nonrandom and consider the effect this has on the ideal observer's decision function.

Under the signal-absent hypothesis, the presence of a random background results in a data vector with a probability density given by

$$\text{pr}(\mathbf{g}|H_1) = \int_{\infty} d^M b \text{pr}(\mathbf{g}|H_1, \mathbf{b}) \text{pr}_{\mathbf{b}}(\mathbf{b}). \quad (13.164)$$

Similarly, the signal-present density is given by

$$\text{pr}(\mathbf{g}|H_2) = \int_{\infty} d^M b \text{pr}(\mathbf{g}|H_2, \mathbf{b}) \text{pr}_{\mathbf{b}}(\mathbf{b}). \quad (13.165)$$

Note that we have assumed that the background density is the same under both hypotheses.

The likelihood ratio now becomes

$$\Lambda(\mathbf{g}) = \frac{\int_{\infty} d^M b \text{pr}(\mathbf{g}|H_2, \mathbf{b}) \text{pr}_{\mathbf{b}}(\mathbf{b})}{\int_{\infty} d^M b' \text{pr}(\mathbf{g}|H_1, \mathbf{b}') \text{pr}_{\mathbf{b}}(\mathbf{b}')} = \frac{\langle \text{pr}(\mathbf{g}|H_2, \mathbf{b}) \rangle_{\mathbf{b}}}{\langle \text{pr}(\mathbf{g}|H_1, \mathbf{b}) \rangle_{\mathbf{b}}}. \quad (13.166)$$

The quantities $\text{pr}(\mathbf{g}|H_j, \mathbf{b})$ in this expression are usually easy to compute from the physics of the measurement noise, at least when the signal is nonrandom. In some problems we will also be able to perform the average over \mathbf{b} either analytically or numerically by drawing samples as discussed in Sec. 8.4, but in other problems this will prove difficult.

To get a useful alternative form for the likelihood ratio, we multiply and divide the integrand in the numerator by $\text{pr}(\mathbf{g}|H_1, \mathbf{b})$ and regroup terms,⁸ yielding

$$\Lambda(\mathbf{g}) = \int_{\infty} d^M b \frac{\text{pr}(\mathbf{g}|H_2, \mathbf{b})}{\text{pr}(\mathbf{g}|H_1, \mathbf{b})} \left[\frac{\text{pr}(\mathbf{g}|H_1, \mathbf{b}) \text{pr}_{\mathbf{b}}(\mathbf{b})}{\int_{\infty} d^M b' \text{pr}(\mathbf{g}|H_1, \mathbf{b}') \text{pr}_{\mathbf{b}}(\mathbf{b}')} \right]. \quad (13.167)$$

The factor in square brackets is recognized as the posterior density on the background after observation of \mathbf{g} under the no-signal hypothesis:

$$\frac{\text{pr}(\mathbf{g}|H_1, \mathbf{b}) \text{pr}_{\mathbf{b}}(\mathbf{b})}{\int_{\infty} d^M b' \text{pr}(\mathbf{g}|H_1, \mathbf{b}') \text{pr}_{\mathbf{b}}(\mathbf{b}')} = \frac{\text{pr}(\mathbf{g}|H_1, \mathbf{b}) \text{pr}_{\mathbf{b}}(\mathbf{b})}{\text{pr}(\mathbf{g}|H_1)} = \text{pr}(\mathbf{b}|\mathbf{g}, H_1). \quad (13.168)$$

Thus we can write the likelihood ratio as

$$\Lambda(\mathbf{g}) = \langle \Lambda_{\text{BKE}}(\mathbf{g}, \mathbf{b}) \rangle_{\mathbf{b}|\mathbf{g}, H_1}, \quad (13.169)$$

⁸The authors thank Brandon D. Gallas for suggesting this approach and Hongbin Zhang for demonstrating its practicality.

where the subscript BKE indicates *background known exactly*, and

$$\Lambda_{\text{BKE}}(\mathbf{g}, \mathbf{b}) \equiv \frac{\text{pr}(\mathbf{g}|H_2, \mathbf{b})}{\text{pr}(\mathbf{g}|H_1, \mathbf{b})}. \quad (13.170)$$

The interpretation is that $\Lambda_{\text{BKE}}(\mathbf{g}, \mathbf{b})$ is the likelihood that we would have if we knew the background exactly; since we don't, we must average over the backgrounds, but with the posterior density $\text{pr}(\mathbf{b}|H_1, \mathbf{g})$ rather than the prior $\text{pr}(\mathbf{b})$ as in (13.166). Note also that (13.166) uses separate averages of numerator and denominator, while (13.169) averages the ratio.

For nonrandom signals, $\Lambda_{\text{BKE}}(\mathbf{g}, \mathbf{b})$ is easy to compute since numerator and denominator are just noise densities for a specified object. The average over the posterior in (13.169) can often be performed by Markov-chain Monte Carlo methods, especially in simulation studies. (See Secs. 14.3.3 and 15.4.8 for more on Markov-chain Monte Carlo methods.)

When the signal has parameter uncertainty in addition to randomness in the background, the signal-present density is given by

$$\text{pr}(\mathbf{g}|H_2) = \int_{-\infty}^{\infty} d^P\theta \int_{-\infty}^{\infty} d^M b \text{pr}_{\mathbf{n}}[\mathbf{g} - \mathbf{b} - \mathbf{s}(\theta)|\mathbf{b}] \text{pr}_{\mathbf{b}}(\mathbf{b}) \text{pr}_{\theta}(\theta). \quad (13.171)$$

Now the likelihood ratio is given by

$$\Lambda(\mathbf{g}) = \langle \Lambda_{\text{SKE}}(\mathbf{g}, \theta) \rangle_{\theta}, \quad (13.172)$$

where the SKE likelihood ratio must first be computed by taking the background variability into account for each possible signal, as is done in (13.169). Then an average over all possible signals is performed.

Gaussian random backgrounds Several models for random backgrounds were presented in Sec. 8.4. One useful model for a statistically defined background is a multivariate Gaussian with mean $\bar{\mathbf{b}}$ and covariance matrix $\mathbf{K}_{\mathbf{b}}$ in the image domain.⁹ If the noise covariance matrix is also Gaussian, the data are described by a form similar to that given in (13.112):

$$\text{pr}(\mathbf{g}|H_1) = [(2\pi)^M \det(\mathbf{K}_{\mathbf{g}})]^{\frac{1}{2}} \exp \left[-\frac{1}{2}(\mathbf{g} - \bar{\mathbf{b}})^t \mathbf{K}_{\mathbf{g}}^{-1}(\mathbf{g} - \bar{\mathbf{b}}) \right], \quad (13.173)$$

where the overall data covariance matrix $\mathbf{K}_{\mathbf{g}} = \mathbf{K}_{\mathbf{b}} + \mathbf{K}_{\mathbf{n}}$. Similarly, if the signal is known exactly, then

$$\text{pr}(\mathbf{g}|H_2) = [(2\pi)^M \det(\mathbf{K}_{\mathbf{g}})]^{\frac{1}{2}} \exp \left[-\frac{1}{2}(\mathbf{g} - \bar{\mathbf{b}} - \mathbf{s})^t \mathbf{K}_{\mathbf{g}}^{-1}(\mathbf{g} - \bar{\mathbf{b}} - \mathbf{s}) \right]. \quad (13.174)$$

When the signal is nonrandom the data covariance matrix is the same under the two hypotheses and the likelihood ratio can be determined in the same fashion by which (13.115) was derived; the ideal observer is again a prewhitening matched filter, this time applied to the image once the mean background has been subtracted.

⁹The process of integrating a 2D stationary Gaussian process over a finite detector element is one way to obtain the Gaussian random background vector model in data space, although other forms for the background in object space can also yield a Gaussian random vector when mapped through an imaging system by virtue of the central-limit theorem.

Random signals on Gaussian backgrounds It is straightforward to incorporate a Gaussian random background into the previous variable-signal examples in which the signal is a function of one or more random parameters. The randomness in the signal results in a data covariance matrix that is no longer the same under the two hypotheses. For this reason the ideal observer's discriminant function is no longer linear in the data. Barrett and Abbey (1997) give specific forms for the likelihood ratio for the cases of random signal location and scale on a Gaussian background.

Random signals on non-Gaussian random backgrounds Non-Gaussian statistical forms for a random background can be incorporated into the general framework of (13.164) and (13.165). All that is required to make use of these expressions is an analytical form for $\text{pr}(\mathbf{g}|H_1) = \text{pr}_{\mathbf{b}+\mathbf{n}}(\mathbf{g}|H_1)$. The likelihood ratio can be written again as in (13.148), with the randomness in the background implicitly included in the randomness in \mathbf{g} . The likelihood ratio is thus written

$$\Lambda(\mathbf{g}) = \frac{\langle \text{pr}(\mathbf{g}|H_2, \boldsymbol{\theta}) \rangle_{\boldsymbol{\theta}}}{\text{pr}(\mathbf{g}|H_1)} = \left\langle \frac{\text{pr}_{\mathbf{b}+\mathbf{n}}[\mathbf{g} - \mathbf{s}(\boldsymbol{\theta})]}{\text{pr}_{\mathbf{b}+\mathbf{n}}(\mathbf{g})} \right\rangle_{\boldsymbol{\theta}} = \langle \Lambda_{\text{BKS}}(\mathbf{g}, \boldsymbol{\theta}) \rangle_{\boldsymbol{\theta}}, \quad (13.175)$$

where the subscript BKS indicates *background known statistically*. This expression tells us that for a general random background model the ideal detection strategy is to

1. Compute the signal-absent density function on the data for the given background model, $\text{pr}(\mathbf{g}|H_1)$.
2. Shift by $\mathbf{s}(\boldsymbol{\theta})$ for particular $\boldsymbol{\theta}$.
3. Compute $\Lambda_{\text{BKS}}(\mathbf{g}, \boldsymbol{\theta})$, the conditional likelihood ratio for that $\boldsymbol{\theta}$.
4. Average over all $\boldsymbol{\theta}$.
5. Compare to a threshold.

Many useful models for non-Gaussian backgrounds are described in Chap. 8, which presents a variety of analytical models for random background as well as suggestions for their simulation.

13.2.12 The optimal linear discriminant

We began this chapter with a discussion of figures of merit for discriminant functions of arbitrary form. We then considered the particular form and behavior of the ideal observer, which requires full knowledge of the density function of the data for each hypothesis. In this section we consider discriminant functions that are optimal amongst all discriminant functions constrained to be linear in the data. As we shall see, linear discriminant functions are easy to compute, their performance is easy to summarize, and far less information regarding the data statistics is needed along the way.

Linear discriminants have the general form [cf. (13.9)]

$$T(\mathbf{g}) = \mathbf{w}^t \mathbf{g}, \quad (13.176)$$

where \mathbf{g} and \mathbf{w} are assumed to be real. We define the optimal linear discriminant as the $T(\mathbf{g})$ that maximizes a certain measure of class separability, to be discussed below.

In the binary classification problem, a measure of separability is the SNR defined in (13.19). As we shall demonstrate below, the linear discriminant that maximizes this measure takes the form

$$\mathbf{w}_{opt\ lin} = \mathbf{K}_{\mathbf{g}}^{-1} \Delta \bar{\mathbf{g}} \quad (13.177)$$

when the data have equal covariance $\mathbf{K}_{\mathbf{g}}$ under each hypothesis. The resulting SNR is then given by

$$\text{SNR}_{opt\ lin}^2 = \Delta \bar{\mathbf{g}}^t \mathbf{K}_{\mathbf{g}}^{-1} \Delta \bar{\mathbf{g}} = \text{tr} [\mathbf{K}_{\mathbf{g}}^{-1} \Delta \bar{\mathbf{g}} \Delta \bar{\mathbf{g}}^t], \quad (13.178)$$

where $\Delta \bar{\mathbf{g}}$ is the average difference in the data under the two hypotheses, averaged over all sources of variability, and $\text{tr}[\cdot]$ denotes the trace of the matrix.

An expression very similar to (13.178) (albeit with sample means and covariances instead of population quantities) was first given by the American statistician Harold Hotelling (Hotelling, 1931). By extension, $\mathbf{w}_{opt\ lin}$ has been called the *Hotelling discriminant*, though in fact it is the population equivalent of the familiar Fisher linear discriminant, introduced five years after Hotelling's 1931 paper (Fisher, 1936).¹⁰ Similarly, an observer who implements the optimal linear discriminant has been called the *Hotelling observer*. We shall adopt that terminology here and replace the subscript *opt lin* with *Hot* henceforth.

Relation between Hotelling and ideal observers We have already seen in Sec. 13.2.8 that the optimal discriminant *is* linear in the data whenever the data are Gaussian distributed with the same covariance matrix under the two hypotheses, as is the case when the signal is known exactly and the background is either known exactly or random but Gaussian under both hypotheses. The ideal observer's SNR is then [cf. (13.118)]

$$\text{SNR}_{\lambda}^2 = \Delta \mathbf{s}^t \mathbf{K}_{\mathbf{g}}^{-1} \Delta \mathbf{s} = \text{tr} [\mathbf{K}_{\mathbf{g}}^{-1} \Delta \mathbf{s} \Delta \mathbf{s}^t]. \quad (13.179)$$

The significant difference between the Hotelling SNR of (13.178) and this expression is that the former allows for signal variability through its reference to the mean data vector $\Delta \bar{\mathbf{g}}$. The ideal observer's SNR takes the form given in (13.179) only when the signals to be discriminated are known exactly; hence it is written in terms of $\Delta \mathbf{s}$.

When the data are Gaussian, with equal covariance for the classes, the Hotelling observer is equal to the ideal observer for the task. When the data are not Gaussian, due to signal variability or non-Gaussian noise or both, the ideal observer can be (usually is) nonlinear in the data. Calculation of the likelihood ratio requires knowledge of the full probability density functions for the data; this requirement can be a major impediment to calculation of the ideal discriminant function for more realistic tasks. The advantage of the Hotelling approach is that it requires knowledge of only the first- and second-order statistics of the data. In essence, the Hotelling approach models the data as Gaussian, regardless of the data's true

¹⁰Hotelling is credited with establishing one of the first statistics departments in the United States at the University of North Carolina in 1946. Before World War II, many statisticians, including Fisher, had worked in eugenics departments.

statistics. Moreover, as we shall discuss in Chap. 14, the Hotelling observer has been found to be a useful predictor of human performance for a variety of discrimination tasks. Another advantage to the Hotelling formalism is that, as we shall see below, it readily leads to a scalar figure of merit for the L -class problem.

Demonstration of optimality We now demonstrate that the Hotelling template of (13.177) is indeed optimal in an SNR sense. To do this, we must show that the Hotelling observer achieves equal or better SNR than that achieved by an arbitrary template \mathbf{w} . An arbitrary template would yield an SNR according to (13.19) of

$$\text{SNR}_{\mathbf{w}}^2 = \frac{(\mathbf{w}^t \Delta \bar{\mathbf{g}})^2}{\mathbf{w}^t \mathbf{K}_{\mathbf{g}} \mathbf{w}}. \quad (13.180)$$

Thus we must show that

$$\frac{(\mathbf{w}^t \Delta \bar{\mathbf{g}})^2}{\mathbf{w}^t \mathbf{K}_{\mathbf{g}} \mathbf{w}} \leq \Delta \bar{\mathbf{g}}^t \mathbf{K}_{\mathbf{g}}^{-1} \Delta \bar{\mathbf{g}} \quad (13.181)$$

or

$$(\mathbf{w}^t \Delta \bar{\mathbf{g}})^2 \leq (\mathbf{w}^t \mathbf{K}_{\mathbf{g}} \mathbf{w})(\Delta \bar{\mathbf{g}}^t \mathbf{K}_{\mathbf{g}}^{-1} \Delta \bar{\mathbf{g}}), \quad (13.182)$$

where we have used the positive-definiteness of the denominator in the first line to move it to the right-hand side in the second line.

We can insert an identity in the form of the product of the square root of the covariance matrix and its inverse, and then make use of the triangle inequality, to write the left-hand side as

$$(\mathbf{w}^t \Delta \bar{\mathbf{g}})^2 = \left[\mathbf{w}^t \mathbf{K}_{\mathbf{g}}^{1/2} \mathbf{K}_{\mathbf{g}}^{-1/2} \Delta \bar{\mathbf{g}} \right]^2 \leq \|\mathbf{w}^t \mathbf{K}_{\mathbf{g}}^{1/2}\|^2 \|\mathbf{K}_{\mathbf{g}}^{-1/2} \Delta \bar{\mathbf{g}}\|^2. \quad (13.183)$$

Now we write the norms of the vectors as inner products and we have

$$(\mathbf{w}^t \Delta \bar{\mathbf{g}})^2 \leq (\mathbf{K}_{\mathbf{g}}^{1/2} \mathbf{w})^t (\mathbf{K}_{\mathbf{g}}^{1/2} \mathbf{w}) (\mathbf{K}_{\mathbf{g}}^{-1/2} \Delta \bar{\mathbf{g}})^t (\mathbf{K}_{\mathbf{g}}^{-1/2} \Delta \bar{\mathbf{g}}) = (\mathbf{w}^t \mathbf{K}_{\mathbf{g}} \mathbf{w}) (\Delta \bar{\mathbf{g}}^t \mathbf{K}_{\mathbf{g}}^{-1} \Delta \bar{\mathbf{g}}). \quad (13.184)$$

This is what we set out to show in (13.182). Thus the template given in (13.177) indeed achieves the maximum SNR of all linear observers when $\mathbf{K}_1 = \mathbf{K}_2 = \mathbf{K}_{\mathbf{g}}$.

It is left to the reader to show that a template given by $\mathbf{w} = [\frac{1}{2}(\mathbf{K}_1 + \mathbf{K}_2)]^{-1} \Delta \bar{\mathbf{g}}$ achieves maximum SNR in the binary classification problem when $\mathbf{K}_1 \neq \mathbf{K}_2$. As we shall soon demonstrate, this is the Hotelling template for this case.

L-class problem The beauty of the Hotelling figure of merit is that it is readily extended to the L -class problem, where $L > 2$. To describe the performance of the optimal linear discriminant in the L -class problem, we first define two scatter matrices. The *interclass scatter matrix*,

$$\mathbf{S}_1 = \frac{1}{L} \sum_{\ell=1}^L (\bar{\mathbf{g}}_{\ell} - \bar{\mathbf{g}})(\bar{\mathbf{g}}_{\ell} - \bar{\mathbf{g}})^t, \quad (13.185)$$

describes the average distance between the means of the distributions of the data under each hypothesis from the overall mean $\bar{\mathbf{g}} = (1/L) \sum_{\ell} \bar{\mathbf{g}}_{\ell}$. The rank of \mathbf{S}_1 is $L - 1$, owing to the relationship of the class means to the overall mean. In the 2-class problem, the interclass scatter matrix reduces to:

$$\mathbf{S}_1 = \frac{1}{4} \Delta \bar{\mathbf{g}} \Delta \bar{\mathbf{g}}^t. \quad (13.186)$$

The *intra-class scatter matrix*, \mathbf{S}_2 , is given by

$$\mathbf{S}_2 = \frac{1}{L} \sum_{\ell=1}^L \langle (\mathbf{g} - \bar{\mathbf{g}}_\ell)(\mathbf{g} - \bar{\mathbf{g}}_\ell)^t \rangle_\ell = \frac{1}{L} \sum_{\ell=1}^L \mathbf{K}_{\mathbf{g}|\ell}, \quad (13.187)$$

and describes the average covariance matrix of the data, found by averaging the covariance matrices of the L classes.

We assume knowledge of the ensemble mean and covariance of the data under each hypothesis in writing (13.185) and (13.187). The Hotelling observer is the linear observer that makes use of this knowledge to achieve maximum discrimination performance of all linear observers. The generalized measure of class separability in the L -class problem is referred to as the *Hotelling trace* and often given the label J :

$$J = \text{tr} [\mathbf{S}_2^{-1} \mathbf{S}_1]. \quad (13.188)$$

For a binary classification task, this reduces to

$$J = \frac{1}{4} \Delta \bar{\mathbf{g}}^t \mathbf{S}_2^{-1} \Delta \bar{\mathbf{g}} = \frac{1}{4} \text{SNR}_{\text{Hot}}^2 \quad (13.189)$$

by (13.186).

Note that the scatter matrices of (13.186) and (13.187) often are written as sums of class contributions weighted by class prevalence, even in literature from the authors. We have deliberately defined the scatter matrices here with equally weighted contributions from the L classes so that the Hotelling observer's discriminant function is independent of prevalence. With this formulation the Hotelling observer achieves maximum SNR and maximum J .

Finding the optimal linear discriminant Given the scatter matrices above, we wish to determine the linear discriminant in the L -class problem that achieves maximum J . We follow the derivation given by Fukunaga (1990).

The key to finding the optimal linear discriminant is the knowledge that we can simultaneously diagonalize two noncommuting Hermitian matrices by the process outlined in Sec. 1.4.6. The simultaneous diagonalization of $\mathbf{S}_{2\mathbf{g}}$ and $\mathbf{S}_{1\mathbf{g}}$ is written [cf. (1.100)]

$$\mathbf{W}^\dagger \mathbf{S}_{2\mathbf{g}} \mathbf{W} = \mathbf{I} \quad \text{and} \quad \mathbf{W}^\dagger \mathbf{S}_{1\mathbf{g}} \mathbf{W} = \mathbf{D}, \quad (13.190)$$

where \mathbf{D} is diagonal. Note that this transformation whitens the intra-class scatter matrix. It is shown in Sec. 1.4.6 that an equivalent eigenvalue problem is given by [cf. (1.110)]

$$\mathbf{S}_{2\mathbf{g}}^{-1} \mathbf{S}_{1\mathbf{g}} \mathbf{W} = \mathbf{W} \mathbf{D}. \quad (13.191)$$

Thus \mathbf{W} is the matrix of eigenvectors of the product $\mathbf{S}_{2\mathbf{g}}^{-1} \mathbf{S}_{1\mathbf{g}}$, and \mathbf{D} is the diagonal matrix of eigenvalues. We shall call the M eigenvalues $\{\mu_m\}$ and the eigenvectors $\{\mathbf{w}_m\}$.

Recall that the trace of a matrix is equal to the sum of its eigenvalues. Thus the Hotelling trace for the data has these equivalent forms:

$$J_{\mathbf{g}} = \text{tr} [\mathbf{S}_{2\mathbf{g}}^{-1} \mathbf{S}_{1\mathbf{g}}] = \text{tr} [\mathbf{D}] = \sum_{m=1}^M \mu_m. \quad (13.192)$$

The m^{th} eigenvalue measures the separability associated with a projection of the data along the direction in feature space defined by \mathbf{w}_m . Since the rank of $\mathbf{S}_{1\mathbf{g}}$ is

$(L-1)$, where L is the number of classes, the ranks of $\mathbf{S}_{2\mathbf{g}}^{-1}\mathbf{S}_{1\mathbf{g}}$ and \mathbf{D} are also $(L-1)$. There are therefore only $(L-1)$ nonzero eigenvalues in the sum; all the separability in the data is carried by these eigenvalues. Projection of the data onto the subspace spanned by the eigenvectors of $\mathbf{S}_{2\mathbf{g}}^{-1}\mathbf{S}_{1\mathbf{g}}$ results in no loss of discriminability.

The optimal linear discriminant is thus found by solving the eigenvalue equation of (13.191). The Hotelling observer classifies the data using the feature vector

$$\mathbf{t} = \mathbf{W}^t \mathbf{g}, \quad (13.193)$$

where \mathbf{W} is the matrix whose columns are the eigenvectors of $\mathbf{S}_{2\mathbf{g}}^{-1}\mathbf{S}_{1\mathbf{g}}$. We shall label the m^{th} column vector \mathbf{w}_m , corresponding to the eigenvalue μ_m . Then

$$t_m = \mathbf{w}_m^t \mathbf{g}. \quad (13.194)$$

In the binary classification problem the separability inherent in an M -dimensional data set is preserved in a 1D feature space, and (13.191) reduces to

$$\mathbf{S}_{2\mathbf{g}}^{-1}\mathbf{S}_{1\mathbf{g}}\mathbf{w}_{Hot} = \mu\mathbf{w}_{Hot}. \quad (13.195)$$

The reader can show that this equation is satisfied when

$$\mathbf{w}_{Hot} = \mathbf{S}_{2\mathbf{g}}^{-1}\Delta\bar{\mathbf{g}}, \quad (13.196)$$

which is a generalized form for the optimal feature vector of (13.177) when the covariances under the hypotheses are unequal. The binary discriminant is thus given by

$$t = \mathbf{w}_{Hot}^t \mathbf{g}, \quad (13.197)$$

and the resulting Hotelling trace is given by μ .

Fukunaga (1990) also addresses the question of the best linear transformation that yields an ND feature vector, where $N < (L-1)$. It can be shown that this *inefficient* transformation, so named because it does not preserve the separability in the original data, is again obtained by solving the eigenvector problem of (13.191), only now the transformation matrix is composed of the N eigenvectors with the largest eigenvalues as its columns.

From features to classification In the binary decision problem the connection between feature extraction and classification is straightforward. The Hotelling observer forms the single test statistic of (13.197) and compares this value to a threshold to decide between hypothesis 1 and 2. The test statistic t can be thought of as a single feature derived from a given image; that feature is used to classify the image.

The relationship between feature extraction and classification in the L -class task is more complex. Comparing each of the $L-1$ features to a threshold is equivalent to using $L-1$ hyperplanes to partition the feature space, which can lead to regions of ambiguous class assignment.

A number of options are available for avoiding the problem of ambiguous areas in the decision space (Duda *et al.*, 2001). We shall consider one option, inspired by the approach taken by the ideal observer in the L -class problem as described in Sec. 13.2.10. Recall that the ideal observer selects the hypothesis associated with the greatest likelihood of the data. Analogously, one option for the Hotelling observer's

strategy is to choose the hypothesis that gives the largest probability of obtaining the data, only now under Gaussian assumptions for each $\text{pr}(\mathbf{g}|H_\ell)$.

Under the Gaussian assumption, $\text{pr}(\mathbf{t}|H_\ell)$ is a multivariate Gaussian PDF as given in (13.112), with $\bar{\mathbf{t}}_\ell = \mathbf{W}^t \bar{\mathbf{g}}_\ell$ and $\mathbf{K}_{\mathbf{t}|\ell} = \mathbf{W}^t \mathbf{K}_{\mathbf{g}|\ell} \mathbf{W}$. The Hotelling observer chooses the hypothesis that gives maximum

$$\bar{\mathbf{t}}_\ell^t \mathbf{K}_{\mathbf{t}|\ell}^{-1} \mathbf{t} = \bar{\mathbf{g}}_\ell^t \mathbf{W} [\mathbf{W}^t \mathbf{K}_{\mathbf{g}|\ell} \mathbf{W}]^{-1} \mathbf{W}^t \mathbf{g}. \quad (13.198)$$

When $\mathbf{K}_{\mathbf{g}|\ell}$ is approximately independent of ℓ , then by (13.190)

$$[\mathbf{W}^t \mathbf{K}_{\mathbf{g}} \mathbf{W}]^{-1} = \mathbf{I}. \quad (13.199)$$

With (13.199) we can rewrite the Hotelling observer's decision strategy of (13.198) as

$$\text{Choose } H_\ell \text{ that gives max } [\bar{\mathbf{g}}_\ell^t \mathbf{W}] [\mathbf{W}^t \mathbf{g}] = \bar{\mathbf{t}}_\ell^t \mathbf{t}. \quad (13.200)$$

This is a matched filter applied to the feature vector; no prewhitening is required because the covariance of the feature vectors is already white by (13.199).

Thus, in the L -class classification problem, the Hotelling observer forms the matched filter output for each possible signal in the reduced-dimensionality feature space and chooses the alternative that gives the maximum value. No ambiguity in the decision space arises. Furthermore, the Hotelling trace describes the performance of the Hotelling observer in this L -class problem, providing a useful scalar measure of performance for system optimization.

Post-processing and feature extraction We found in Sec. 13.2.6 that digital image processing does not affect the ideal observer, so long as the processing operation is invertible in the sense that the original digital data before processing is recoverable. The same can be said for linear post-processing and the performance of the Hotelling observer. Any nonsingular $M \times M$ linear transformation \mathbf{A} preserves the separability in the data because if

$$\mathbf{y} = \mathbf{A}^t \mathbf{g}, \quad (13.201)$$

then

$$J_{\mathbf{y}} = \text{tr}[(\mathbf{A}^t \mathbf{S}_{2\mathbf{g}} \mathbf{A})^{-1} \mathbf{A}^t \mathbf{S}_{1\mathbf{g}} \mathbf{A}] = \text{tr}[\mathbf{S}_{2\mathbf{g}} \mathbf{S}_{1\mathbf{g}}] = J_{\mathbf{g}}. \quad (13.202)$$

Similarly, a nonsingular linear transformation can be applied to the features \mathbf{t} of (13.197); the inherent discriminability of the data is preserved by these features, and an invertible transformation applied to \mathbf{t} will still yield $J_{\mathbf{t}} = J_{\mathbf{g}}$ by the logic of (13.202).

We have seen that the dimensionality of the data can be reduced and yet maintain the separability inherent in the data. Suppose instead that the post-processing resulted in an increase in dimensionality. For example, linear image reconstruction algorithms process the raw data to yield a number of features N (pixel values) that can be greater than M . We now show under what conditions the resulting features preserve the separability of the data.

Let the post-processing operation again be written as (13.201), with \mathbf{A} now an $M \times N$ post-processing matrix, $N > M$. Then

$$J_{\mathbf{y}} = \text{tr}[(\mathbf{A}^t \mathbf{S}_{2\mathbf{g}} \mathbf{A})^{-1} \mathbf{A}^t \mathbf{S}_{1\mathbf{g}} \mathbf{A}] = \text{tr}[\mathbf{A} (\mathbf{A}^t \mathbf{S}_{2\mathbf{g}} \mathbf{A})^{-1} \mathbf{A}^t \mathbf{S}_{1\mathbf{g}}]. \quad (13.203)$$

However, we cannot equate $J_{\mathbf{y}}$ with $J_{\mathbf{g}}$ as we did in (13.202) because in the current example \mathbf{A}^{-1} does not exist.

Now form the $M \times M$ matrix $\mathbf{L} = \mathbf{A}\mathbf{A}^t$. If we assume that \mathbf{A} has a left inverse (that is, L is nonsingular; see Sec. 1.7.2), we can insert the identity $\mathbf{S}_{2\mathbf{g}}^{-1}\mathbf{L}^{-1}\mathbf{L}\mathbf{S}_{2\mathbf{g}}$ inside the trace in (13.203) to find

$$\begin{aligned} J_{\mathbf{y}} &= \text{tr}[\mathbf{S}_{2\mathbf{g}}^{-1}\mathbf{L}^{-1}\mathbf{L}\mathbf{S}_{2\mathbf{g}}\mathbf{A}(\mathbf{A}^t\mathbf{S}_{2\mathbf{g}}\mathbf{A})^{-1}\mathbf{A}^t\mathbf{S}_{1\mathbf{g}}] \\ &= \text{tr}[\mathbf{S}_{2\mathbf{g}}^{-1}\mathbf{L}^{-1}\mathbf{A}\mathbf{A}^t\mathbf{S}_{2\mathbf{g}}\mathbf{A}(\mathbf{A}^t\mathbf{S}_{2\mathbf{g}}\mathbf{A})^{-1}\mathbf{A}^t\mathbf{S}_{1\mathbf{g}}] = \text{tr}[\mathbf{S}_{2\mathbf{g}}^{-1}\mathbf{L}^{-1}\mathbf{A}\mathbf{A}^t\mathbf{S}_{1\mathbf{g}}] \\ &= \text{tr}[\mathbf{S}_{2\mathbf{g}}^{-1}\mathbf{S}_{1\mathbf{g}}] = J_{\mathbf{g}}. \end{aligned} \quad (13.204)$$

We have thus demonstrated that the features preserve the inherent discriminability in the original data so long as a left inverse of the post-processing matrix exists.

The effect associated with nonlinear processing is more subtle. Appropriately chosen nonlinear processing or feature extraction can improve Hotelling observer performance by rendering the data more separable by a linear discriminant. For example, consider the case of a binary detection task in which the signal can have either a positive amplitude a or negative amplitude $-a$ with equal probability. Since the mean data vector under each hypothesis is zero, a linear observer would yield an SNR of zero for this problem. The reader can show that, for additive multivariate Gaussian noise, use of (13.112) and (13.148) to compute the log-likelihood ratio yields the following optimal strategy:

$$\lambda = \mathbf{g}^t \mathbf{K}_{\mathbf{n}}^{-1} \mathbf{g}. \quad (13.205)$$

When the noise is independent and identically distributed, the ideal observer's decision variable reduces to

$$\lambda = \sum_{m=1}^M g_m^2. \quad (13.206)$$

We see that the ideal observer uses a decision variable that is quadratic in the data. Taking inspiration from the ideal observer, the application of a point-wise absolute-value operator to each data element, $\mathbf{y} = |\mathbf{g}|$, improves the performance of the Hotelling observer in that $\text{SNR}_{\mathbf{y}}^2 > \text{SNR}_{\mathbf{g}}^2 = 0$.

More generally, for any task where the ideal observer's decision strategy is nonlinear, it is possible to improve a linear observer's AUC by nonlinear preprocessing of the data. As demonstrated in the previous example, the optimal nonlinear processing takes the form of computing the likelihood ratio. Designing post-processing to improve the Hotelling trace, however, is trickier business, requiring an improvement in the difference in class means relative to their average variance, as quantified by (13.178). This point is particularly relevant to the performance of human observers. There are some tasks for which the human and Hotelling SNRs are well below the detectability achievable by an ideal observer [computed from AUC via (13.21)]. In such circumstances, preprocessing of the data may improve human observer performance by better matching the data to the abilities of the human visual system. This has implications for image processing and computer-aided diagnosis.

Signal variability and the Hotelling observer The Hotelling approach allows arbitrary variability in the data resulting from random signals and/or random backgrounds.

If the task is discrimination between two classes with statistically defined signals, the Hotelling template is given by

$$\mathbf{w} = \mathbf{S}_2^{-1} \Delta \bar{\mathbf{g}} = \mathbf{S}_2^{-1} \Delta \bar{\mathbf{s}}, \quad (13.207)$$

requiring the mean of the variable signal under each hypothesis to calculate $\Delta \bar{\mathbf{s}}$. This linear discriminant may work very well in the presence of signal variability, especially for compact signals (Eckstein and Abbey, 2001).

Then again, the Hotelling observer may be quite challenged by the presence of signal uncertainty, particularly when it leads to highly non-Gaussian data. We shall illustrate this challenge by considering the problem of detection of a signal with large location uncertainty. Let H_1 denote the absence of a signal and H_2 denote the signal-present hypothesis, with signal of known shape and amplitude in any one of L nonoverlapping locations on the detector. The task of the observer is to decide whether or not a signal is present. Figure 13.10 is a simplistic representation of the data PDFs for this task in a two-dimensional subspace. Under H_1 , the data are centered on the origin with circular isocontours of constant probability density. Under H_2 the data are distributed equally into L regions of data space, two of which are shown in the plot. The circular isocontours show the scatter about these two locations due to the additive Gaussian noise. The overall density function of the data in the signal-present case is highly non-Gaussian and multimodal. The ideal observer decision variable for this problem, quite nonlinear in the data, is given in (13.150). The Hotelling observer attempts to separate the data from the two hypotheses using features derived from the eigenanalysis of (13.191). It has been shown that in the limit of a very large number of locations, the linear discriminant is not an effective classifier for this task (Brown *et al.*, 1995). However, this binary detection example can be reformulated as a $(L + 1)$ -hypothesis classification task, with H_0 : signal absent and H_ℓ : signal present at location ℓ . Then a set of linear discriminants will separate the data quite nicely.

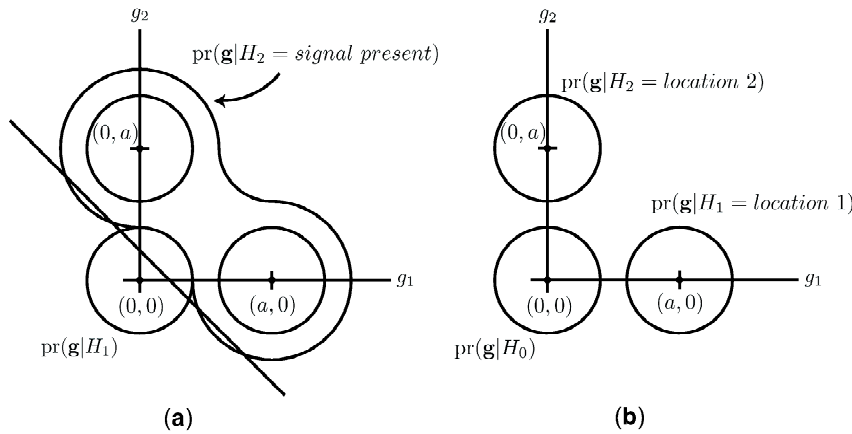

Fig. 13.10 Isocontours of the data in the random-location problem with signal-present contours centered on $\bar{\mathbf{s}}_1 = (a, 0)$ and $\bar{\mathbf{s}}_2 = (0, a)$; a noise-only contour is centered on $(0, 0)$. (a) The data PDFs when the problem is formulated as binary discrimination; the linear discriminant is shown for one threshold setting. (b) The data PDFs when the problem is reformulated as L -class discrimination; now the data are Gaussian distributed under each class.

Note that a similar reformulation can be imposed on the bipolar-signal example discussed above in the context of post-processing. Splitting the signal-present hypothesis into two, where one is that the signal is present with amplitude $+a$ and the other is that the signal is present with amplitude $-a$, yields improved performance over the 2-class problem (as measured by the Hotelling trace in each case).

More generally, situations in which signal uncertainty produces a data space populated by multiple approximately Gaussian clouds, such as occurs in the detection of a signal in one of L orthogonal locations, or the detection of one of L orthogonal signal profiles (*e.g.*, sinusoids of different phase, or multiple Hadamard signals) often yield improved Hotelling performance when the number of candidate hypotheses is increased. In these cases the signal is defined in terms of a vector of random parameters $\boldsymbol{\theta}$ as in (13.145), where $\text{pr}_{\boldsymbol{\theta}}(\boldsymbol{\theta})$ takes on the special form of a finite set of delta functions. Increasing the number of hypotheses reduces the contribution from signal variability to the intraclass scatter matrix, leaving measurement noise (which is often well modeled by a Gaussian PDF) as the dominant source of variability in the data. The data are thus characterized by localized Gaussian distributions such that a set of linear discriminants can be used to partition the space.

Not all decision problems with signal-parameter uncertainty may be reformulated to suit the Hotelling observer so readily. When the signal uncertainty does not take the form of a finite set of delta functions, the Hotelling observer's efficiency relative to the ideal observer can decrease dramatically, and no amount of fiddling with the number of hypotheses will help. For example, discrimination of texture differences is often cited as a decision task that requires nonlinear strategies. The choice of observer (Hotelling or ideal) used to design or evaluate an imaging system will be driven by the information available regarding the task and the observer for which the system is being optimized.

Detectability maps Another approach to tasks with randomness in the signal is to compute the optimum linear test statistic for the SKE case as a function of the random parameters:

$$\mathbf{w}(\boldsymbol{\theta}) = [\mathbf{S}_2(\boldsymbol{\theta})]^{-1} \Delta \mathbf{s}(\boldsymbol{\theta}). \quad (13.208)$$

The SNR for the Hotelling observer for each value of the random parameter vector is thus given by

$$\text{SNR}_{Hot}^2(\boldsymbol{\theta}) = \frac{\{[\mathbf{w}(\boldsymbol{\theta})]^t \Delta \mathbf{s}(\boldsymbol{\theta})\}^2}{[\mathbf{w}(\boldsymbol{\theta})]^t \mathbf{S}_2(\boldsymbol{\theta}) \mathbf{w}(\boldsymbol{\theta})} = [\mathbf{w}(\boldsymbol{\theta})]^t \mathbf{s}(\boldsymbol{\theta}). \quad (13.209)$$

Using this expression, detectability maps showing sensitivity of SNR to $\boldsymbol{\theta}$, *e.g.*, location, can be made (Pineda, 2000). The beauty of (13.208) is that in many cases the linear observer is the ideal observer for fixed signal parameters, because the randomness in the data from measurement noise (and even background variability in some cases) is well approximated by a Gaussian.

Signal known exactly, but variable The SNR of (13.209) gives the Hotelling observer's performance for a particular value of the random parameter $\boldsymbol{\theta}$. A summary measure of observer performance can be obtained by averaging this expression over $\boldsymbol{\theta}$. System optimization can thus be pursued with this overall measure of performance as the figure of merit, so that the system is "best" for the set of all possible

signals. We refer to this assessment method as *signal known exactly, but variable (SKEV)*.

Detection in a random background We found previously that a Gaussian random background results in an ideal decision strategy that is linear in the data. The ideal observer and the Hotelling observer are thus equivalent for this special case. Other statistical models for random backgrounds may yield nonlinear optimal discriminant functions; the exact form of the optimal discriminant given in (13.175) may not even be calculable in many cases. We are not without resources, though, because calculation of the Hotelling SNR requires only knowledge of the first- and second-order statistics of the data, and often we have knowledge of these.

We can characterize a general random background in terms of its mean contribution to detector element m , denoted \bar{b}_m and its covariance matrix

$$[\mathbf{K}_b]_{ij} = \langle (b_i - \bar{b}_i)(b_j - \bar{b}_j) \rangle_{\mathbf{b}}. \quad (13.210)$$

In the weak-signal approximation, the covariance of the data is the same under each hypothesis and equal to

$$[\mathbf{K}_g]_{ij} = \langle \langle (g_i - \bar{b}_i)(g_j - \bar{b}_j) \rangle_{\mathbf{n}|\mathbf{b}} \rangle_{\mathbf{b}} = \bar{b}_i \delta_{ij} + [\mathbf{K}_b]_{ij}, \quad (13.211)$$

where we have assumed Poisson noise in writing the last result. The Hotelling observer's discriminant is given by (13.208) (presuming some randomness in the signal) with \mathbf{S}_2 equal to \mathbf{K}_g of (13.211).

A uniform background model with a random level can be considered as the limit of a random background model in which the mean background is the same in all detector elements, and the background variation is completely correlated across the detector. Let \bar{b} be the average level of the uniform background, with variance σ_b^2 . The covariance matrix for the data in this case is given by

$$[\mathbf{K}_g]_{ij} = \bar{b} \delta_{ij} + \sigma_b^2$$

or

$$\mathbf{K}_g = \bar{b}\mathbf{I} + \mathbf{u}\mathbf{u}^t, \quad (13.212)$$

where \mathbf{u} is an $M \times 1$ column vector in which each element is equal to σ_b . The inverse of \mathbf{K}_g can be determined via (A.55):

$$\mathbf{K}_g^{-1} = (\bar{b})^{-1}\mathbf{I} - \frac{\mathbf{u}\mathbf{u}^t}{\bar{b}^2 + M\bar{b}\sigma_b^2}. \quad (13.213)$$

The Hotelling observer's test statistic for discriminating between two known signals on a flat background of random level is then given by:

$$\begin{aligned} t &= \Delta \mathbf{s}^t \mathbf{K}_g^{-1} \mathbf{g} = \sum_{n=1}^M \sum_{m=1}^M \Delta s_n \left[\frac{\delta_{nm}}{\bar{b}} - \frac{[\mathbf{u}\mathbf{u}^t]_{nm}}{\bar{b}^2 + M\bar{b}\sigma_b^2} \right] g_m \\ &= (\bar{b})^{-1} \sum_{n=1}^M \Delta s_n \left[g_n - \frac{\sigma_b^2 \sum_m g_m}{\bar{b} + M\sigma_b^2} \right] = (\bar{b})^{-1} \sum_{n=1}^M \Delta s_n \left[g_n - \frac{M\sigma_b^2 \hat{b}}{\bar{b} + M\sigma_b^2} \right], \end{aligned} \quad (13.214)$$

where $\hat{b} = \frac{1}{M} \sum_m g_m$ is an estimate of the background level formed from the data set in hand. Note that as $\sigma_b^2 \rightarrow 0$ the Hotelling observer approaches the background-known-exactly matched filter result. Alternatively, for large σ_b^2 , the Hotelling test statistic approaches

$$t = \frac{1}{\bar{b}} \sum_{n=1}^M \Delta s_n (g_n - \hat{b}). \quad (13.215)$$

In this case the Hotelling observer estimates the background from the data prior to applying a matched filter.

The Hotelling observer's performance in the random-background-level task is summarized by

$$\begin{aligned} \text{SNR}_{Hot}^2 &= \Delta \mathbf{s}^t \mathbf{K}_{\mathbf{g}}^{-1} \Delta \mathbf{s} = \sum_{n=1}^M \sum_{m=1}^M \Delta s_n \left[\frac{\delta_{nm}}{\bar{b}} - \frac{[\mathbf{u}\mathbf{u}^t]_{nm}}{\bar{b}^2 + M\bar{b}\sigma_b^2} \right] \Delta s_m \\ &= \frac{\|\Delta \mathbf{s}\|^2}{\bar{b}} - \frac{[\Delta \mathbf{s}^t \mathbf{u}]^2}{\bar{b}^2 + M\bar{b}\sigma_b^2}. \end{aligned} \quad (13.216)$$

The Hotelling observer's SNR in the presence of a more general background is found by an extension to the approach that led to (13.216); in particular, a more general background model would give a more general expression for the data covariance of (13.212). Of note are models for statistically defined backgrounds with known first- and second-order statistics such as the lumpy and clustered-lumpy backgrounds (described in Sec. 8.4.4) that allow for task-based assessment through exact computation of Hotelling-observer performance even though the ideal observer's strategy is unknown. Figure 13.11 shows the radial profile of the Hotelling template for classification of a known Gaussian signal on a Gaussian lumpy background of known correlation length. The Hotelling observer attempts to match the signal in the expected location, while subtracting off an estimate of the local surrounding background.

Fig. 13.11 Radial profile of the Hotelling template for detection of a Gaussian signal on a lumpy background.

Practical issues related to the use of random backgrounds in system evaluation will be discussed further in Chap. 14.

Non-Gaussian noise and the Hotelling observer The Hotelling observer results in a suboptimal AUC whenever the statistics of the data are non-Gaussian. Even when the statistics on the data are Gaussian, the Hotelling observer achieves suboptimal AUC for situations where data covariance matrices are unequal across hypotheses; the ideal-observer's discriminant is a nonlinear functional of the data in that case.

In Sec. 13.2.9 we determined the ideal observer's decision strategy for several examples involving non-Gaussian data.¹¹ While the ideal observer's test statistic can be highly nonlinear in the data for non-Gaussian statistics, recall that certain non-Gaussian statistics yield a linear ideal decision surface. We found this to be the case for Poisson noise (13.131) as well as exponential noise (13.137). Nevertheless, the ideal observer's linear strategy and that of the Hotelling observer can differ because the Hotelling observer uses only first- and second-order statistics to describe the data and not the complete joint density function.

As an example, consider the problem of detection in speckle noise, for which the log-likelihood ratio gives a linear filtering operation with the following template [*cf.* (13.137)]:

$$[\mathbf{w}_{ideal}]_m = \frac{\Delta \bar{g}_m}{\bar{g}_{1m} \bar{g}_{2m}}. \quad (13.217)$$

The Hotelling observer makes use of the fact that the mean in the m^{th} detector element under hypothesis j is \bar{g}_{jm} and its variance is \bar{g}_{jm}^2 to yield

$$[\mathbf{w}_{Hot}]_m = [\mathbf{S}_2^{-1} \Delta \bar{\mathbf{g}}]_m = \frac{\Delta \bar{g}_m}{\frac{1}{2}(\bar{g}_{1m}^2 + \bar{g}_{2m}^2)}. \quad (13.218)$$

The numerators are the same, but the ideal observer divides by the geometric mean of the variances while the Hotelling observer divides by the arithmetic mean. The resulting decision surface for each observer is a hyperplane in data space, although with different orientation. As a result, the Hotelling observer attains maximum SNR, while the ideal observer attains maximum AUC. The observer with the higher AUC is preferred, of course, since AUC is a more accurate measure of observer performance for arbitrary data statistics.

A similar set of calculations can be performed to compare the Hotelling observer to the ideal observer for other non-Gaussian data distributions. In particular, since Poisson noise is well approximated by a Gaussian PDF when the number of counts per detector element is greater than about ten, the Hotelling observer is asymptotically optimal in both AUC and SNR in that limit. Both the ideal observer and the Hotelling observer are linear in the data for Poisson noise; the orientation of their decision surfaces converges as the count rate increases.

AUC-optimal linear discriminants As we have just seen, there are some cases where the log-likelihood is a linear discriminant but not equivalent to the Hotelling discriminant. This raises two questions: 1) In general, what linear discriminant is optimal in the sense of maximizing AUC? 2) When is the log-likelihood a linear discriminant? We shall address the former question here and the latter below.

¹¹Note that these strategies do not necessarily yield maximum SNR as computed from (13.19). Rather, they are optimal in the attributes relevant to the ideal observer: maximum AUC and thus maximum d_A , minimum decision error, and minimum Bayes risk.

Our starting point for finding the linear discriminant that maximizes AUC is (13.47), which gives the AUC for an arbitrary linear discriminant when the noise is additive and independent of the signal. As that equation shows, only the odd part of the signal characteristic function $\psi_{\mathbf{s}}^*(\mathbf{w}\xi)$ contributes to AUC_{lin} . Since $\psi_{\mathbf{s}}^*(\mathbf{w}\xi) = \psi_{\mathbf{s}}(-\mathbf{w}\xi)$, the odd part of $\psi_{\mathbf{s}}^*(\mathbf{w}\xi)$ is i times its imaginary part, and the AUC for a linear discriminant is optimized by

$$\mathbf{w}_{opt} = \underset{\mathbf{w}}{\operatorname{argmax}} \left\{ \int_{-\infty}^{\infty} \frac{d\xi}{\xi} |\psi_{\mathbf{g}1}(\mathbf{w}\xi)|^2 \operatorname{Im} [\psi_{\mathbf{s}}^*(\mathbf{w}\xi)] \right\}. \quad (13.219)$$

For SKE problems [cf. (13.49) and (13.50)],

$$\begin{aligned} \mathbf{w}_{opt} &= \underset{\mathbf{w}}{\operatorname{argmax}} \left\{ \int_{-\infty}^{\infty} \frac{d\xi}{\xi} |\psi_{\mathbf{g}1}(\mathbf{w}\xi)|^2 \sin(2\pi\mathbf{s}_0^t\mathbf{w}\xi) \right\} \\ &= \underset{\mathbf{w}}{\operatorname{argmax}} \left\{ \mathbf{s}_0^t\mathbf{w} \int_{-\infty}^{\infty} d\xi |\psi_{\mathbf{g}1}(\mathbf{w}\xi)|^2 \operatorname{sinc}(2\mathbf{s}_0^t\mathbf{w}\xi) \right\} \\ &\approx \underset{\mathbf{w}}{\operatorname{argmax}} \left\{ \mathbf{s}_0^t\mathbf{w} \int_{-\infty}^{\infty} d\xi |\psi_{\mathbf{g}1}(\mathbf{w}\xi)|^2 \right\}, \end{aligned} \quad (13.220)$$

where the last form holds for weak signals. Note that the magnitude of \mathbf{w} does not affect the quantity being maximized; if $\mathbf{w} \rightarrow \alpha\mathbf{w}$, the integrals in the last two forms scale as $1/\alpha$, $\mathbf{s}_0^t\mathbf{w}$ scales as α , and the quantity in curly brackets remains constant.

As applications of these results, the reader can rederive the linear discriminants for uncorrelated Poisson or exponential noise, as well as the prewhitening matched filter for correlated Gaussian noise.

When is the log-likelihood ratio linear? Now we address the second question posed above: When is the AUC-optimal linear discriminant in fact the log-likelihood ratio? We require that

$$\lambda(\mathbf{g}) = \ln \left[\frac{\operatorname{pr}(\mathbf{g}|H_2)}{\operatorname{pr}(\mathbf{g}|H_1)} \right] = \mathbf{w}^t\mathbf{g} + c, \quad (13.221)$$

where c is a constant that can be lumped into the decision threshold. This condition implies that

$$\operatorname{pr}(\mathbf{g}|H_j) = A_j d(\mathbf{g}) \exp(\mathbf{b}_j^t\mathbf{g}), \quad (13.222)$$

where A_j and \mathbf{b}_j are independent of the data \mathbf{g} , and $d(\mathbf{g})$ is independent of the hypothesis j . The constants \mathbf{b}_j are related to the discriminant function by

$$\mathbf{w} = \mathbf{b}_2 - \mathbf{b}_1. \quad (13.223)$$

As a point of terminology, (13.222) is a *multivariate linear exponential-type distribution*. The general form for such a PDF is (Kotz *et al.*, 2000)

$$\operatorname{pr}(\mathbf{g}|\boldsymbol{\theta}) = d(\mathbf{g}) \exp[\mathbf{b}^t\mathbf{g} - q(\boldsymbol{\theta})]. \quad (13.224)$$

Rather than a continuous parameter $\boldsymbol{\theta}$, (13.222) has a discrete index, but (13.222) and (13.224) are essentially the same form. The reader can show that (13.222) holds

for several SKE problems we have encountered: multivariate Gaussian, Poisson and exponential PDFs, all of which are exponential families.

We can recast (13.222) in terms of the characteristic functions:

$$\psi_{\mathbf{g}_j}(\boldsymbol{\xi}) = A_j \int_{-\infty}^{\infty} d^M g \, d(\mathbf{g}) \exp \left[(\mathbf{b}_j - 2\pi i \boldsymbol{\xi})^t \mathbf{g} \right]. \quad (13.225)$$

A little algebra shows that

$$\psi_{\mathbf{g}_2}(\boldsymbol{\xi}) = \frac{A_2}{A_1} \psi_{\mathbf{g}_1} \left(\boldsymbol{\xi} + \frac{i}{2\pi} \mathbf{w} \right). \quad (13.226)$$

Note that \mathbf{b}_j and hence \mathbf{w} have to be real since PDFs are real; thus, in order for the log-likelihood ratio to be a linear discriminant, $\psi_{\mathbf{g}_2}(\boldsymbol{\xi})$ must be proportional to $\psi_{\mathbf{g}_1}(\boldsymbol{\xi})$ with each component shifted along the imaginary axis; the shift is immediately the ideal-observer discriminant function.

13.2.13 Detectability in continuous data

The previous sections assumed that the data were a discrete set of M measurements, relevant to a digital imaging system. We can conceive of two scenarios in which we might be willing to analyze an imaging system using a continuous framework. The first would be the case where the data are indeed continuous, as would be found when the detection system is film-based. The second scenario would be when we have a sufficiently large number of discrete detector elements that we are tempted to consider the limit of an infinite number of infinitely fine samples. We shall treat the true continuous detection system here. Our treatment is inspired by that of Helstrom (1995).

SKE/BKE tasks in Gaussian noise Consider first the problem of binary classification in Gaussian noise, and assume that the signal and background are both exactly known. We write the continuous data set as a linear functional of the known object under each hypothesis:

$$H_j : g(\mathbf{r}) = \int_{-\infty}^{\infty} d^q r' h(\mathbf{r}, \mathbf{r}') f_j(\mathbf{r}') + n(\mathbf{r}) \equiv s_j(\mathbf{r}) + n(\mathbf{r}). \quad (13.227)$$

Because the noise is a zero-mean Gaussian random process, $E[g(\mathbf{r})|H_j] = s_j(\mathbf{r})$. The noise is described by the continuous autocovariance function $K_{\mathbf{n}}$, which is assumed to be independent of the underlying hypothesis:

$$K_{\mathbf{n}}(\mathbf{r}, \mathbf{r}') = \langle n(\mathbf{r}) n^*(\mathbf{r}') \rangle. \quad (13.228)$$

From Sec. 8.2.7 we know that the noise autocovariance operator $\mathcal{K}_{\mathbf{n}}$, whose kernel is the noise autocovariance function $K_{\mathbf{n}}(\mathbf{r}, \mathbf{r}')$, is a compact Hermitian operator provided $\mathcal{K}_{\mathbf{n}}$ is Hilbert-Schmidt. The conditions for compactness are further detailed in Sec. 1.3.3; from that discussion we know that if the random variable \mathbf{g} has finite support, then $\mathcal{K}_{\mathbf{n}}$ is Hilbert-Schmidt and hence has a denumerable eigenfunction expansion. The eigenfunctions of $\mathcal{K}_{\mathbf{n}}$ can be used as an infinite series of orthonormal expansion functions for $g(\mathbf{r})$, which is written analogously to (13.121) as

$$\mathbf{g} = \sum_{m=1}^{\infty} \beta_m \boldsymbol{\phi}_m. \quad (13.229)$$

Using these expansion functions as a basis for the data $g(\mathbf{r})$ allows us to follow the same steps that led to the SNR given in (13.123), giving

$$\text{SNR}_\lambda^2 = \sum_{m=1}^{\infty} \frac{[\Delta\bar{\beta}_m]^2}{\sigma_m^2} = \sum_{m=1}^{\infty} \frac{|(\phi_m, \Delta\mathbf{s})|^2}{\mu_m}. \quad (13.230)$$

The infinite sums in (13.230) cannot diverge so long as the discrimination task cannot be done perfectly.

Stationarity Let us now assume that the autocovariance function is wide-sense stationary: $K_{\mathbf{n}}(\mathbf{r}, \mathbf{r}') = K_{\mathbf{n}}(\mathbf{r} - \mathbf{r}')$. Note that to make this assumption we are abandoning the requirement stated in the previous paragraph that the data have finite support. The data are thus no longer square-integrable, the Hilbert-Schmidt condition is gone, and the eigenvalues are no longer denumerable. In Chap. 8 we showed that the eigenfunctions of the autocorrelation operator of a stationary random process are the Fourier expansion functions. The eigenfunctions of $\mathcal{K}_{\mathbf{n}}$ are thus

$$\phi_{\boldsymbol{\rho}}(\mathbf{r}) = \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}), \quad (13.231)$$

where $\boldsymbol{\rho}$ is the continuous vector spatial-frequency index. With these expansion functions we can write the data as

$$g(\mathbf{r}) = \int_{\infty} d^q \boldsymbol{\rho} G(\boldsymbol{\rho}) \phi_{\boldsymbol{\rho}}(\mathbf{r}) = \int_{\infty} d^q \boldsymbol{\rho} G(\boldsymbol{\rho}) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \quad (13.232)$$

The inner product of the Fourier expansion functions and the expected difference signal is given by

$$(\phi_{\boldsymbol{\rho}}, \Delta\mathbf{s}) = \int_{\infty} d^q r \Delta\bar{g}(\mathbf{r}) \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) = \Delta\bar{G}(\boldsymbol{\rho}); \quad (13.233)$$

and thus

$$|(\phi_{\boldsymbol{\rho}}, \Delta\mathbf{s})|^2 = |\Delta\bar{G}(\boldsymbol{\rho})|^2. \quad (13.234)$$

From (8.181) we know that the autocovariance function in the Fourier basis becomes

$$\langle [\mathcal{F}_2\{n(\mathbf{r})\}] [\mathcal{F}_2\{n(\mathbf{r}')\}]^\dagger \rangle = [\mathcal{F}_2 \mathcal{K}_{\mathbf{n}} \mathcal{F}_2^\dagger](\boldsymbol{\rho}, \boldsymbol{\rho}') = W_{\mathbf{n}}(\boldsymbol{\rho}) \delta(\boldsymbol{\rho} - \boldsymbol{\rho}'), \quad (13.235)$$

where $W_{\mathbf{n}}(\boldsymbol{\rho})$ is the power spectral density of the noise. The noise autocorrelation function is diagonalized by the Fourier operator, so that the components are delta-correlated in that domain.

We now have all the pieces in place for writing the ideal observer's SNR by analogy with (13.230). The numerator is given in (13.234). By (8.178), the eigenvalues in the denominator are given by the power spectral density $W_{\mathbf{n}}(\boldsymbol{\rho})$. Thus, for the continuous, stationary case the SNR is given by

$$\text{SNR}_\lambda^2 = \int_{\infty} d^q \boldsymbol{\rho} \frac{|\Delta\bar{G}(\boldsymbol{\rho})|^2}{W_{\mathbf{n}}(\boldsymbol{\rho})}. \quad (13.236)$$

For a linear, shift-invariant imaging system, we can rewrite the expected difference in the data as (see Sec. 7.2.6)

$$|\Delta\bar{G}(\boldsymbol{\rho})|^2 = |H(\boldsymbol{\rho}) \Delta F(\boldsymbol{\rho})|^2, \quad (13.237)$$

where $H(\boldsymbol{\rho})$ is the transfer function of the system and $\Delta F(\boldsymbol{\rho})$ is the difference object, $f_2(\mathbf{r}) - f_1(\mathbf{r})$, in the Fourier domain. By (7.154) and (7.155) we can factor $H(\boldsymbol{\rho})$ into two components and thus rewrite the SNR of (13.236) as

$$\text{SNR}_\lambda^2 = \int_\infty d^q \rho |\Delta F(\boldsymbol{\rho})|^2 \left\{ \frac{|H(0)|^2 \text{MTF}^2(\boldsymbol{\rho})}{W_n(\boldsymbol{\rho})} \right\}, \quad (13.238)$$

where $\text{MTF}(\boldsymbol{\rho})$ is the modulation transfer function of the imaging system. The integrand of (13.238) is the product of two factors, one specifying the objects to be discriminated and the other (in curly brackets) characterizing the performance of the imaging system. We shall have more to say about (13.238) after we consider the effects of quantum noise.

Quantum noise: The weak-signal limit Just as we did in the SKE/BKE task for Gaussian noise, we can consider the limit of an infinite number of infinitely fine samples to reach the limit of a continuous data set for Poisson noise. In this limit, the SNR of (13.135) becomes

$$\text{SNR}_\lambda^2 \approx \int_\infty d^2 r \frac{s^2(\mathbf{r})}{\bar{g}(\mathbf{r})} = \int_\infty d^2 r \frac{s^2(\mathbf{r})}{b(\mathbf{r})} \quad (13.239)$$

in the 2D case, where $b(\mathbf{r})$ is the background fluence that describes the mean background image at each location [*cf.* (11.84) and (11.94)].

The SNR of (13.239) is the continuous formulation of the SNR of (13.135), which was derived for the case of a weak signal. Note that for the current problem — the limit of infinitely fine detector elements — it cannot be the case that each mean data component \bar{g}_m is much greater than 1. Thus the weak-signal limit must be achieved by requiring that the signal have low amplitude relative to the background. Even so, the SNR may still be large since it is computed as an integral over a large area.

Poisson noise plus additive Gaussian noise Suppose the data have an additional noise contribution that can be modeled as an additive Gaussian random process, e.g., the excess noise due to dark current or noisy amplification. Then the data covariance is given by [*cf.* (12.159)]

$$K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = K^{\text{phot}}(\mathbf{r}, \mathbf{r}') + K^{\text{exc}}(\mathbf{r}, \mathbf{r}') = b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') + K^{\text{exc}}(\mathbf{r}, \mathbf{r}'), \quad (13.240)$$

where the first term is the delta-correlated photon noise and the second term is the excess Gaussian noise. For this form to be valid, the excess noise must have the same units as the Poisson random process, namely fluence or inverse area. For example, suppose there is a noisy gain mechanism that senses the Poisson process and produces a random output voltage. If the mean conversion gain (from fluence to voltage) is denoted G_{conv} , then the voltage must be divided by G_{conv} before calculating $K^{\text{exc}}(\mathbf{r}, \mathbf{r}')$ in (13.240). Thus $K^{\text{exc}}(\mathbf{r}, \mathbf{r}') = (G_{\text{conv}})^{-2} K_V^{\text{exc}}(\mathbf{r}, \mathbf{r}')$, where $K_V^{\text{exc}}(\mathbf{r}, \mathbf{r}')$ is the autocovariance function of the voltage random process. We say that the excess noise has been *referred back to the input*.

With the noise described by (13.240), we seek to derive a Fourier-domain extension to (13.239) to describe the SNR for detection of a weak signal. To do so, we again need to impose the assumptions of a linear, shift-invariant imaging system and wide-sense stationary noise. The Fourier-domain counterpart of the numerator

is then $|H(\boldsymbol{\rho})F(\boldsymbol{\rho})|^2$, where $F(\boldsymbol{\rho})$ is the Fourier transform of the weak signal to be detected. Noise stationarity requires that the background be flat, that is, $b(\mathbf{r}) = b_0$. Then the mean image and the variance in the data due to the quantum fluctuations are independent of position (in this weak-signal case). The Fourier-domain noise description under the present model then becomes $W_{\mathbf{g}}(\boldsymbol{\rho}) = b_0 + W_{exc}(\boldsymbol{\rho})$.

We can rewrite (13.239) for the current problem in the Fourier domain as

$$\text{SNR}_{\lambda}^2 = \int_{\infty} d^2\rho \frac{|H(\boldsymbol{\rho})F(\boldsymbol{\rho})|^2}{W_{\mathbf{g}}(\boldsymbol{\rho})} = \int_{\infty} d^2\rho |F(\boldsymbol{\rho})|^2 \left\{ \frac{|H(0)|^2 \text{MTF}^2(\boldsymbol{\rho})}{W_{\mathbf{g}}(\boldsymbol{\rho})} \right\}. \quad (13.241)$$

We define the relative object $\Delta f_{rel}(\mathbf{r}) = s(\mathbf{r})/b_0$, so that $F(\boldsymbol{\rho}) = b_0[\Delta F_{rel}(\boldsymbol{\rho})]$. Then

$$\begin{aligned} \text{SNR}_{\lambda}^2 &= |H(0)|^2 \int_{\infty} d^2\rho |\Delta F_{rel}(\boldsymbol{\rho})|^2 \left\{ \frac{b_0^2 \text{MTF}^2(\boldsymbol{\rho})}{W_{\mathbf{g}}(\boldsymbol{\rho})} \right\} \\ &\equiv |H(0)|^2 \int_{\infty} d^2\rho |\Delta F_{rel}(\boldsymbol{\rho})|^2 \text{NEQ}(\boldsymbol{\rho}), \end{aligned} \quad (13.242)$$

where

$$\text{NEQ}(\boldsymbol{\rho}) = \frac{b_0^2 \text{MTF}^2(\boldsymbol{\rho})}{W_{\mathbf{g}}(\boldsymbol{\rho})} = \frac{b_0^2 \text{MTF}^2(\boldsymbol{\rho})}{b_0 + W_{exc}(\boldsymbol{\rho})}. \quad (13.243)$$

The expression in (13.243) is referred to as the *noise equivalent quanta*, or NEQ of the system. Its name originates in the historical interpretation of NEQ as the equivalent number of input quanta per unit area required by an ideal imaging system to give the same SNR achieved by an actual system whose output is an image degraded by measurement noise and blur. Shaw (1963) proposed the frequency decomposition of system performance measures of (13.243) in response to the problems that were being encountered at the time when evaluating detector performance using finite apertures. Dainty and Shaw (1974) explored the NEQ concept in great detail for photographic processes.

NEQ and signal-detection theory The ideal-observer SNR of (13.242) is an elegant factorization of hardware characteristics, bundled into NEQ, and the signal to be detected, expressed in terms of its Fourier spectrum. Thus $\text{NEQ}(\boldsymbol{\rho})$ can be interpreted as the weight applied to each frequency component of the signal in computing the ideal observer's SNR for an LSIV imaging system on an SKE/BKE task when there is quantum noise and possibly also some excess noise mechanism. $\text{NEQ}(\boldsymbol{\rho})$ is a function of the system MTF, which describes the resolution properties of the imaging system in terms of how well each exponential eigenfunction of an LSIV system is transferred by the system; the noise power spectrum $W_{\mathbf{g}}(\boldsymbol{\rho})$, which characterizes the noise variance in the data as a function of spatial frequency, and finally, the fluence of the uniform input exposure level, b_0 , also referred to as the operating point of interest. Since the MTF is dimensionless, $\text{NEQ}(\boldsymbol{\rho})$ has dimensions of fluence (quanta per unit area).

Wagner and his colleagues were the first to show this connection between NEQ and ideal-observer SNR (Wagner, 1978; Wagner *et al.*, 1979). Soon after, Wagner and Brown (1985) developed expressions for NEQ as a function of spatial frequency for a variety of medical imaging modalities, including radiography, CT, PET, and NMR.

It would appear from (13.242) that system optimization could be performed via maximization of NEQ. However, very restrictive assumptions regarding the deterministic and stochastic properties of the imaging system were required to derive this SNR form, as well as strong assumptions regarding the task. As Wagner and Brown point out in their 1985 paper, their treatment is strictly valid only when the signal is low contrast and the noise is additive and Gaussian. As we shall see, more complicated tasks, or imaging systems in which the assumptions of shift invariance and stationarity are violated, rarely yield such an elegant factorization for SNR as found in (13.242).

Relationship between NEQ and DQE The *detective quantum efficiency*, or DQE, was first encountered in Chap. 12 as a measure of detector performance (without any discussion of tasks or observers) for the case of a single photodiode [*cf.* (12.24)]. The nonimaging DQE of (12.24) is in keeping with the basic definition of DQE given by Rose (1948), who compared the noise level of an actual radiation detector with that of an ideal one. Rose applied this concept to the determination of the efficiency of the eye as a photoreceptor.

Dainty and Shaw (1974) explored the Rose concept of DQE in great detail. One of the ways in which they interpreted DQE was as a ratio of squared SNRs, so that the DQE described the transfer of SNR in photographic processes. From there it was a simple step to relate the squared input and output SNRs to the ratio of the ideal and effective number of counts, and Dainty and Shaw's NEQ was born.

Consider the DQE we obtain when we form the ratio of the frequency-dependent NEQ of (13.243) with the actual number of quanta (per unit area) at the input.

$$\text{DQE}(\rho) = \frac{\text{NEQ}(\rho)}{b_0} = \left[\frac{b_0}{b_0 + W_{exc}(\rho)} \right] \text{MTF}^2(\rho). \quad (13.244)$$

We see that this frequency-dependent DQE is dimensionless, as we would expect. Note also the similarity between the DQE expressions of Chap. 12 and that obtained here in the context of the performance of the ideal observer on a specific imaging task. The denominator is again the sum of two terms representing the photon and excess noise contributions. Furthermore, (13.244) has the limiting behavior we would expect for a perfect system: as the excess noise and blur approach zero, $\text{DQE} \rightarrow 1$.

However, the expression for DQE given in (13.244) is limited in that it is suitable for characterization of an imaging system only when $\text{NEQ}(\rho)$ is an appropriate measure of system performance. Specifically, this definition of DQE is not appropriate when the system is shift variant, or the noise is nonstationary, or the task is not SKE/BKE.

In order for the DQE concept to be applicable to more realistic systems and tasks, we must return to its original definition in terms of a ratio of squared detector SNRs. To generalize this definition, we define a task-dependent DQE as the squared SNR at the output of an imaging system or component divided by the squared SNR at the input, for a given task and observer. This ratio describes the degree to which the SNR has been degraded by the system, in terms of observer performance. Thus this definition is relevant to the usefulness of the system for its intended task, as Wagner and Brown advocated, while going beyond the limitations of $\text{NEQ}(\rho)$. Since the numerator and denominator are SNRs, and not in units of quanta, we call this ratio simply the detection efficiency, η . As we shall see in Chap.

14, a similar efficiency measure is often used to describe the performance of the human observer relative to a model observer for a given task.

We shall now relate (13.244) to a ratio of observer SNRs. The squared SNR of an ideal system can be obtained by considering (13.242) in the limit of a perfect MTF and no excess noise:

$$[\text{SNR}_{\lambda, \text{ideal system}}]^2 \equiv |H(0)|^2 b_0 \int_{\infty} d^2\rho |\Delta F_{rel}(\boldsymbol{\rho})|^2, \quad (13.245)$$

where we use subscripts to label the observer as well as the system. The efficiency of the system in presenting information to the ideal observer is then

$$\begin{aligned} \eta &= \frac{[\text{SNR}_{\lambda}]^2}{[\text{SNR}_{\lambda, \text{ideal system}}]^2} = \frac{|H(0)|^2 \int_{\infty} d^2\rho |\Delta F_{rel}(\boldsymbol{\rho})|^2 \text{NEQ}(\boldsymbol{\rho})}{|H(0)|^2 b_0 \int_{\infty} d^2\rho |\Delta F_{rel}(\boldsymbol{\rho})|^2} \\ &= \frac{\int_{\infty} d^2\rho |\Delta F(\boldsymbol{\rho})|^2 \text{DQE}(\boldsymbol{\rho})}{\int_{\infty} d^2\rho |\Delta F(\boldsymbol{\rho})|^2}. \end{aligned} \quad (13.246)$$

To interpret these results, consider the detection of a sinusoidal signal of the form

$$\Delta f(\mathbf{r}) = \frac{A}{L} \text{rect}\left(\frac{x}{L}\right) \text{rect}\left(\frac{y}{L}\right) \cos(2\pi\boldsymbol{\rho}_0 \cdot \mathbf{r}). \quad (13.247)$$

It follows from (2.86) and (3.255) that

$$\lim_{L \rightarrow \infty} |\Delta F(\boldsymbol{\rho})|^2 = \frac{1}{2} A^2 [\delta(\boldsymbol{\rho} - \boldsymbol{\rho}_0) + \delta(\boldsymbol{\rho} + \boldsymbol{\rho}_0)]. \quad (13.248)$$

We note that $\text{NEQ}(\boldsymbol{\rho})$ depends only on the MTF and the noise power spectrum, both of which are even functions of $\boldsymbol{\rho}$. Hence $\text{DQE}(\boldsymbol{\rho})$ is also even, and in the limit $L \rightarrow \infty$, (13.246) becomes

$$\eta = \text{DQE}(\boldsymbol{\rho}_0). \quad (13.249)$$

For this highly specialized signal, the efficiency of the system is directly its DQE evaluated at the frequency of the signal. For more realistic signals, $\text{DQE}(\boldsymbol{\rho})$ is best interpreted as the weighting factor giving the contribution of each frequency component of $|\Delta F(\boldsymbol{\rho})|^2$ to the efficiency η . We reiterate, however, that the whole formalism rests on the assumptions of continuous data, a linear, shift-invariant imaging system, and stationary noise. The concept of detective quantum efficiency and its application to digital radiography are treated further in Sec. 16.1.6.

Random backgrounds and generalized NEQ The concept of NEQ was presented in (13.243) in the context of detection SNRs for classification tasks limited by stationary noise processes and for which the imaging system was assumed to be linear and shift-invariant (LSIV). Both the signals to be classified and the background were assumed to be known exactly. The NEQ concept can be generalized to the detection of known signals on Gaussian random backgrounds (Barrett *et al.*, 1989; Barrett *et al.*, 1995); to do this we again assume the imaging system to be LSIV and the random background to be stationary in the wide sense.

In the analysis of NEQ for the SKE problem we modeled the data as having two sources of randomness, one due to the quantum fluctuations in the incoming photons and the other resulting from an excess noise source [see (13.240)]. To generalize that derivation to incorporate a Gaussian random background, we add another term to the autocovariance function for the data:

$$K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = K^{\text{phot}}(\mathbf{r}, \mathbf{r}') + K^{\text{exc}}(\mathbf{r}, \mathbf{r}') + K^{\text{bg}}(\mathbf{r}, \mathbf{r}'), \quad (13.250)$$

where the third term is the contribution to the covariance of the data from the random background. For a particular background, the data have a covariance given by (13.240). In the limit of no excess noise, and for a fixed background, the data are Poisson.

Now let us make the assumption that the random background can be described by a 2D stationary Gaussian random process in the object domain with power spectral density $W_{\mathbf{f}_b}(\boldsymbol{\rho})$. We assume that the mean image averaged over all random backgrounds is independent of location and denoted by \bar{b}_0 . When we also make the assumption that the excess noise contributions are stationary, the Fourier domain expression for (13.250) is written [*cf.* above (13.241)]:

$$W_{\mathbf{g}}(\boldsymbol{\rho}) = \bar{b}_0 + W_{exc}(\boldsymbol{\rho}) + |H(0)|^2 \text{MTF}^2(\boldsymbol{\rho}) W_{\mathbf{f}_b}(\boldsymbol{\rho}). \quad (13.251)$$

The factors describing the imaging system transfer characteristics impact only the background power spectral density; they represent the mapping of the background randomness from object space to image space.

Given the Fourier description for the data covariance of (13.251), we can write the SNR for the random-background detection problem analogously to (13.242):

$$\text{SNR}_{\lambda}^2 = |H(0)|^2 \int d^2\rho |\Delta F_{rel}(\boldsymbol{\rho})|^2 \left\{ \frac{\bar{b}_0^2 \text{MTF}^2(\boldsymbol{\rho})}{\bar{b}_0 + W_{exc}(\boldsymbol{\rho}) + |H(0)|^2 \text{MTF}^2(\boldsymbol{\rho}) W_{\mathbf{f}_b}(\boldsymbol{\rho})} \right\}. \quad (13.252)$$

We identify the quantity in brackets as the generalized NEQ:

$$\text{GNEQ}(\boldsymbol{\rho}) = \frac{\bar{b}_0^2 \text{MTF}^2(\boldsymbol{\rho})}{\bar{b}_0 + W_{exc}(\boldsymbol{\rho}) + |H(0)|^2 \text{MTF}^2(\boldsymbol{\rho}) W_{\mathbf{f}_b}(\boldsymbol{\rho})}. \quad (13.253)$$

The important attribute of this result is that, even when the imaging system is LSIV and the background process is Gaussian and stationary, we find that object variability results in an SNR that couples together task and hardware contributions in a complicated fashion. Simple measures of the properties of the imaging system alone cannot be reported as measures of system performance across all tasks.

A more meaningful approach would be to a) compute the SNR of a specified observer at the input to the system, taking into account the background randomness as well as the quantum fluctuations; b) determine the same observer's SNR at the output of the system; and c) compute the ratio of those squared measures, the detection efficiency η . This quantity describes the efficiency of the imaging system in transferring the information to the observer for performing the specified task.

Hotelling SNR in the continuous limit The SNR given in (13.178) is maximum over all possible linear decision strategies without making any assumptions regarding the stationarity of the data statistics. For continuous data (13.178) becomes

$$\text{SNR}_{Hot}^2 = \int d^2r \int d^2r' \Delta \bar{g}(\mathbf{r}) S_2^{(-1)}(\mathbf{r}, \mathbf{r}') \Delta \bar{g}(\mathbf{r}'), \quad (13.254)$$

where $S_2(\mathbf{r}, \mathbf{r}')$ is the average of the data autocovariance functions, and $S_2^{(-1)}(\mathbf{r}, \mathbf{r}')$ satisfies

$$\int d^2r S_2^{(-1)}(\mathbf{r}'', \mathbf{r}) S_2(\mathbf{r}, \mathbf{r}') = \delta(\mathbf{r}'' - \mathbf{r}'). \quad (13.255)$$

The superscript -1 is in parentheses here to indicate that $S_2^{(-1)}(\mathbf{r}'', \mathbf{r})$ is the kernel of the operator \mathbf{S}_2^{-1} , not the reciprocal of the function $S_2(\mathbf{r}'', \mathbf{r})$.

If we assume that the autocovariance functions are stationary, we can follow the derivation that led to the ideal observer's SNR in the Fourier domain given in (13.242). The Hotelling observer's SNR is given by

$$\text{SNR}_{Hot}^2 = \int_{\infty} d^2\rho \frac{|\Delta\bar{G}(\boldsymbol{\rho})|^2}{W_{\mathbf{g}}(\boldsymbol{\rho})}, \tag{13.256}$$

where $\Delta\bar{G}(\boldsymbol{\rho})$ is the Fourier transform of the average signal and $W_{\mathbf{g}}(\boldsymbol{\rho})$ is the power spectral density determined from the stationary average autocovariance function. While the SNR given in (13.242) holds for the ideal observer in the case of stationary Gaussian noise and signal known exactly, (13.256) holds more generally for the Hotelling observer. The signal may be random and the data statistics may be non-Gaussian. All that is required is that the data covariance be stationary under each hypothesis, and that the mean signal under each hypothesis be known.

Quasistationary noise We now consider the form of the SNR that results when the task is the detection of a known signal on a quasistationary background. We shall continue to assume that the data are continuous in order to make use of the Fourier descriptors developed in Sec. 8.2.5 for quasistationary random processes.

We assume the signal is spatially compact and localized at \mathbf{r}_0 , so that $\Delta\bar{g}(\mathbf{r}) = 0$ if $|\mathbf{r} - \mathbf{r}_0| > R$. As in (8.120), we can make use of the following coordinate transformation:

$$\bar{\mathbf{r}} = \frac{1}{2}(\mathbf{r} + \mathbf{r}'), \quad \Delta\mathbf{r} = \mathbf{r} - \mathbf{r}' \tag{13.257}$$

so that

$$\mathbf{r} = \bar{\mathbf{r}} + \frac{1}{2}\Delta\mathbf{r}, \quad \mathbf{r}' = \bar{\mathbf{r}} - \frac{1}{2}\Delta\mathbf{r}. \tag{13.258}$$

Note that the Jacobian of this transformation is unity.

We assume the autocovariance function of the background $K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}')$ is the same under each hypothesis. When we rewrite the autocovariance function using the transformation of (13.258) we obtain

$$K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = K_{\mathbf{g}}(\bar{\mathbf{r}} + \frac{1}{2}\Delta\mathbf{r}, \bar{\mathbf{r}} - \frac{1}{2}\Delta\mathbf{r}) \equiv \tilde{K}_{\mathbf{g}}(\bar{\mathbf{r}}, \Delta\mathbf{r}). \tag{13.259}$$

We can similarly transform $K_{\mathbf{g}}^{-1}(\mathbf{r}, \mathbf{r}')$ or any other function of \mathbf{r} and \mathbf{r}' . Thus the SNR of (13.254) becomes

$$\text{SNR}_{Hot}^2 = \int d^2\bar{\mathbf{r}} \int d^2\Delta\mathbf{r} \Delta\bar{g}(\bar{\mathbf{r}} + \frac{1}{2}\Delta\mathbf{r}) \tilde{K}_{\mathbf{g}}^{(-1)}(\bar{\mathbf{r}}, \Delta\mathbf{r}) \Delta\bar{g}(\bar{\mathbf{r}} - \frac{1}{2}\Delta\mathbf{r}), \tag{13.260}$$

where $\tilde{K}_{\mathbf{g}}^{(-1)}(\bar{\mathbf{r}}, \Delta\mathbf{r})$ is the kernel of the operator $\tilde{\mathbf{K}}_{\mathbf{g}}^{-1}$. We have made a coordinate transformation, but no approximations thus far.

The compact support of the signal implies that $\Delta\bar{g}(\bar{\mathbf{r}} + \frac{1}{2}\Delta\mathbf{r}) \Delta\bar{g}(\bar{\mathbf{r}} - \frac{1}{2}\Delta\mathbf{r}) = 0$ unless $|\bar{\mathbf{r}} - \mathbf{r}_0| < 2R$. If we can assume that $\tilde{K}_{\mathbf{g}}^{(-1)}(\bar{\mathbf{r}}, \Delta\mathbf{r})$ is a slowly varying

function of the $\bar{\mathbf{r}}$ variable, so that it is approximately constant over this range, then $\tilde{K}_{\mathbf{g}}^{(-1)}(\bar{\mathbf{r}}, \Delta\mathbf{r}) \approx \tilde{K}_{\mathbf{g}}^{(-1)}(\mathbf{r}_0, \Delta\mathbf{r})$. Then the SNR becomes

$$\begin{aligned} \text{SNR}_{Hot}^2(\mathbf{r}_0) &\approx \int d^2\Delta r \tilde{K}_{\mathbf{g}}^{(-1)}(\mathbf{r}_0, \Delta\mathbf{r}) \int d^2\bar{\mathbf{r}} \Delta\bar{g}(\bar{\mathbf{r}} + \frac{1}{2}\Delta\mathbf{r}) \Delta\bar{g}(\bar{\mathbf{r}} - \frac{1}{2}\Delta\mathbf{r}) \\ &= \int d^2\Delta r \tilde{K}_{\mathbf{g}}^{(-1)}(\mathbf{r}_0, \Delta\mathbf{r}) [\Delta\bar{g} \star \Delta\bar{g}](\Delta\mathbf{r}), \end{aligned} \quad (13.261)$$

where $[\Delta\bar{g} \star \Delta\bar{g}]$ is the spatial autocorrelation function of the known signal, and the argument indicates that the SNR depends on the signal location \mathbf{r}_0 .

The SNR expression above is ripe for transformation to the Fourier domain. We know that $\mathcal{F}_2\{\Delta\bar{g}(\mathbf{r})\} = \Delta\bar{G}(\boldsymbol{\rho})$ and $\mathcal{F}_2\{[\Delta\bar{g} \star \Delta\bar{g}](\Delta\mathbf{r})\} = |\Delta\bar{G}(\boldsymbol{\rho})|^2$. We define $\mathcal{F}_2\{\tilde{K}_{\mathbf{g}}^{(-1)}(\mathbf{r}_0, \Delta\mathbf{r})\} = C(\mathbf{r}_0, \boldsymbol{\rho})$. By Parseval's rule (13.261) can be rewritten as

$$\text{SNR}_{Hot}^2(\mathbf{r}_0) = \int d^2\rho C(\mathbf{r}_0, \boldsymbol{\rho}) |\Delta\bar{G}(\boldsymbol{\rho})|^2. \quad (13.262)$$

To better understand (13.262), we must determine the relationship between $C(\mathbf{r}_0, \boldsymbol{\rho})$ and the autocovariance of the quasistationary noise, $\tilde{K}_{\mathbf{g}}(\bar{\mathbf{r}}, \Delta\mathbf{r})$. To ascertain this relationship, we rewrite the defining equation (13.255) for the inverse of $K_{\mathbf{g}}$ with the approximation $\frac{1}{2}(\mathbf{r} + \mathbf{r}') \approx \frac{1}{2}(\mathbf{r} + \mathbf{r}'') \approx \mathbf{r}_0$, yielding

$$\int d^2r K_{\mathbf{g}}^{(-1)}(\mathbf{r}'', \mathbf{r}) K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') \approx \int d^2r \tilde{K}_{\mathbf{g}}^{(-1)}(\mathbf{r}_0, \mathbf{r}'' - \mathbf{r}) \tilde{K}_{\mathbf{g}}(\mathbf{r}_0, \mathbf{r} - \mathbf{r}') = \delta(\mathbf{r}'' - \mathbf{r}'). \quad (13.263)$$

With the change of variables¹² $\Delta\mathbf{r} = \mathbf{r} - \mathbf{r}'$, this relation becomes

$$\int d^2\Delta r \tilde{K}_{\mathbf{g}}^{(-1)}(\mathbf{r}_0, \mathbf{r}'' - \Delta\mathbf{r} - \mathbf{r}') \tilde{K}_{\mathbf{g}}(\mathbf{r}_0, \Delta\mathbf{r}) = \delta(\mathbf{r}'' - \mathbf{r}'). \quad (13.264)$$

Since (13.264) is a convolution integral, taking the Fourier transform of both sides produces

$$\mathcal{F}_2\{\tilde{K}_{\mathbf{g}}^{(-1)}(\mathbf{r}_0, \Delta\mathbf{r})\} \mathcal{F}_2\{\tilde{K}_{\mathbf{g}}(\mathbf{r}_0, \Delta\mathbf{r})\} = \mathcal{F}_2\{\delta(\Delta\mathbf{r})\} = 1$$

or

$$\mathcal{F}_2\{\tilde{K}_{\mathbf{g}}^{(-1)}(\mathbf{r}_0, \Delta\mathbf{r})\} = C(\mathbf{r}_0, \boldsymbol{\rho}) = \frac{1}{\mathcal{F}_2\{\tilde{K}_{\mathbf{g}}(\mathbf{r}_0, \Delta\mathbf{r})\}} = \frac{1}{W_{\Delta\mathbf{g}}(\mathbf{r}_0, \boldsymbol{\rho})}, \quad (13.265)$$

where $W_{\Delta\mathbf{g}}(\mathbf{r}_0, \boldsymbol{\rho})$ is the stochastic Wigner distribution function [*cf.* (5.54) and (8.140)] for the zero-mean process $\Delta g(\mathbf{r})$.

Thus the SNR in (13.262) in the quasistationary approximation is

$$\text{SNR}_{Hot}^2(\mathbf{r}_0) = \int d^2\rho \frac{|\Delta\bar{G}(\boldsymbol{\rho})|^2}{W_{\Delta\mathbf{g}}(\mathbf{r}_0, \boldsymbol{\rho})}. \quad (13.266)$$

This expression is strikingly similar to the one found in (13.256), only now we have the Wigner distribution function in place of the power spectral density of the stationary noise, $W_{\mathbf{n}}(\boldsymbol{\rho})$. For stationary noise, (13.266) reduces to (13.256).

¹²Note that \mathbf{r}' is simply a constant here, independent of the variable of integration.

Factorable quasistationarity and prewhitening As we saw in Sec. 8.2.4, an autocorrelation or autocovariance function can often be factored into a slowly varying contribution arising from variations in overall intensity and a short-range function describing correlation between neighboring points. As in (8.119), we can write

$$K_{\mathbf{g}}(\mathbf{r}, \mathbf{r}') = a(\Delta\mathbf{r}) b(\bar{\mathbf{r}}). \quad (13.267)$$

For example, this formula holds for Poisson random processes with $a(\Delta\mathbf{r}) = \delta(\Delta\mathbf{r})$ and $b(\bar{\mathbf{r}})$ being the fluence [see (11.94)]. It also has use for describing the field autocovariance in coherent imaging systems [see (18.115)].

From (8.142) we know that the stochastic Wigner distribution function corresponding to (13.267) is

$$W_{\Delta\mathbf{g}}(\bar{\mathbf{r}}, \boldsymbol{\rho}) = A(\boldsymbol{\rho}) b(\bar{\mathbf{r}}). \quad (13.268)$$

If $b(\bar{\mathbf{r}})$ is slowly varying so that it is approximately equal to $b(\mathbf{r}_0)$ over the signal support, then (13.266) becomes

$$\text{SNR}_{Hot}^2(\mathbf{r}_0) = \frac{1}{b(\mathbf{r}_0)} \int d^2\rho \frac{|\Delta\bar{G}(\boldsymbol{\rho})|^2}{A(\boldsymbol{\rho})}. \quad (13.269)$$

The factor $1/b(\mathbf{r}_0)$ may be surprising, but in fact $\Delta\bar{G}(\boldsymbol{\rho})$ will scale as $b(\mathbf{r}_0)$ in most problems, so the overall result will be that $\text{SNR}_{Hot}^2(\mathbf{r}_0) \propto b(\mathbf{r}_0)$. This proportionality can be seen explicitly in the expression for the ideal observer's SNR given in (13.242).

It is interesting to relate these results to prewhitening. Let the output of a linear processing operation on the data be

$$y(\mathbf{r}) = \int d^2r' o(\mathbf{r}, \mathbf{r}') g(\mathbf{r}'). \quad (13.270)$$

This operation can legitimately be referred to as prewhitening if $\langle \Delta y(\mathbf{r}_1) \Delta y(\mathbf{r}_2) \rangle = \delta(\mathbf{r}_1 - \mathbf{r}_2)$. We leave it to the reader to demonstrate that this property is achieved for the covariance model of (13.267) if

$$o(\mathbf{r}, \mathbf{r}') = \frac{1}{\sqrt{b(\mathbf{r}')}} \int d^2\rho \frac{1}{\sqrt{A(\boldsymbol{\rho})}} \exp[2\pi i \boldsymbol{\rho} \cdot (\mathbf{r} - \mathbf{r}')]. \quad (13.271)$$

Note that $y(\mathbf{r})$ is simply $g(\mathbf{r})/\sqrt{b(\mathbf{r})}$ if $a(\Delta\mathbf{r}) = \delta(\Delta\mathbf{r})$ and hence $A(\boldsymbol{\rho}) = 1$.

From (13.129) we know that the SNR after prewhitening is given by

$$\text{SNR}_{pw}^2 = \int d^2r |\Delta\bar{y}(\mathbf{r})|^2, \quad (13.272)$$

and the reader can show that this expression is equivalent to (13.269) under the assumption of (13.267). Thus (13.269) is the SNR^2 for a *locally prewhitening matched filter*. The more general expression for the locally prewhitened SNR^2 when the model of (13.267) is not valid is (13.266).

Observer efficiency We defined DQE as a measure of the efficiency of a detector in providing information to the ideal observer for performing a specified task. The DQE concept can be applied equally well to observer models, as a means of describing the relative performance of two model observers on the same task using the

same data. Specifically, the efficiency of the Hotelling observer relative to the ideal observer is written

$$\eta_{Hot} = \frac{\text{SNR}_{Hot}^2}{d_{A,ideal}^2}. \quad (13.273)$$

The figure of merit for the ideal observer to be used here is d_A , derived from AUC via (13.21), because d_A summarizes the area under the ROC curve, while the SNR of (13.19) might not. We aren't too interested in computing η_{Hot} for SKE/BKE tasks in Gaussian noise, since we know the efficiency must be unity for that circumstance. What is interesting is the quantification of the difference in performance between the observers for more complex tasks, particularly ones where (13.19) would not be a good summary measure of the ideal observer's performance. Hence the use of d_A .

In Chap. 14 we shall make use of similar definitions of observer efficiency in terms of human performance relative to that of various model observers.

13.3 ESTIMATION THEORY

In Sec. 13.1 we presented a joint description of classification and estimation tasks, emphasizing their connections. As described in detail in Sec. 13.2, classification is partitioning of data space, assigning labels to regions. In contrast, estimation is assigning numbers or vectors to points in data space. We now take up the subject of estimation in detail.

As we saw in Sec. 13.1.1, estimation problems can be categorized by the particular quantity being estimated. In *point estimation*, also called *parameter estimation*, we are given a data vector \mathbf{g} and a parametric form for the conditional density $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$. Our job is to form an estimate of all elements of the vector $\boldsymbol{\theta}$. A second class of problems is one in which two complementary vectors $\boldsymbol{\theta}$ and $\boldsymbol{\theta}_n$ determine the data. We seek to estimate the P -dimensional vector $\boldsymbol{\theta}$; the components of $\boldsymbol{\theta}_n$ are termed *nuisance parameters*. This problem is therefore referred to as *estimation with nuisance parameters*. Most texts on estimation deal only with the problem of point estimation, with little mention of nuisance parameters. We shall first consider parameter estimation without regard for nuisance parameters here as well, later turning to the topic of nuisance parameters and means of dealing with them.

We begin in Sec. 13.3.1 with a discussion of the basic concepts of estimation, including the essential ingredients of the estimation process and figures of merit for parameter estimation. Common terms that are defined and discussed in that section are *bias* and *mean-square error* or *MSE*. As we shall see, there is considerable subtlety in defining these terms; indeed, in many practical problems in imaging, no satisfactory definition exists. In Sec. 13.3.2 we digress from our development of estimation methods to detail some of the difficulties that arise in trying to apply MSE to imaging.

In Sec. 13.3.3 we return to our main thread and discuss Bayesian estimation, in which the underlying parameters are assumed random and characterized by a prior probability density. The powerful method of maximum-likelihood (ML) estimation and properties of ML estimators are presented in Secs. 13.3.4–13.3.6. Other classical estimators are discussed briefly in Sec. 13.3.7. In Sec. 13.3.8, we present a definition of nuisance parameters and discuss ways of dealing with them in pure

estimation problems. In Sec. 13.3.9 we treat hybrid classification-estimation tasks, again from the perspective of nuisance parameters.

13.3.1 Basic concepts

The first ingredient in an estimation problem is the *PD* vector of parameters θ we seek to estimate. In an imaging context, θ may be a low-dimensional vector that parameterizes object size, shape, location, amplitude, etc. Alternatively, we may be interested in the estimation of a figure of merit for the objective evaluation of an imaging system. For example, we may be given a limited set of images for use in the estimation of the area under the ROC curve or related measures of imaging system performance, a problem we consider in more detail in Chap. 14. These applications are to be contrasted with the situation in which a large number of parameters are to be estimated, for example, a large set of expansion coefficients used to represent the object. Chap. 15 is devoted to the complex topic of estimation of coefficients of approximate object expansions. With one exception, we limit the presentation in this chapter to estimation problems in which a small number of parameters are to be determined. The exception is the treatment of some issues that arise in the use of mean-square error as a figure of merit in digital imaging; that presentation sets the stage for a related discussion in Chap. 14.

The prior probability density, $\text{pr}(\theta)$, describes the underlying randomness in the parameter(s). This density is analogous to $\text{Pr}(H_j)$ in the classification problem. As described in the Prologue, Bayesian estimation makes use of such a prior in formulating an estimation procedure; a Bayesian considers the underlying parameter vector to be random. This is in contrast to classical estimation, in which the underlying θ is assumed to be fixed for a given data set.

Another essential element, as we emphasized in Sec. 13.1.2, is knowledge of the mapping from parameter space to the measurement (data) space. This mapping is the probability law on the data conditioned on the true parameter θ , written $\text{pr}(\mathbf{g}|\theta)$. In imaging, this density function is determined by the (possibly nonlinear) relationship between θ and the object, the deterministic mapping from object space to data space, as well as the noise characteristics of the imaging system.

Finally, estimation requires a rule, or procedure, for mapping from the data space to the estimate $\hat{\theta}(\mathbf{g})$. We assume that the estimation rule is deterministic, so that the same data vector always yields the same estimate. We made an analogous assumption in Sec. 13.2, stating that the decision function always yields the same decision given the same data as input. We shall often drop the explicit dependence of the estimate on the data, writing simply $\hat{\theta}$.

Many estimation procedures are formulated as the minimization of some cost function $C(\hat{\theta}, \theta)$ that describes the penalty associated with reporting $\hat{\theta}$ when the true parameter is equal to θ . This cost function is analogous to the classification cost C_{ij} of making decision D_i when hypothesis H_j is true.

There are a variety of methods for characterizing the performance of an estimator. We begin here with a discussion of costs and risks, followed by definitions of the bias and variance of a scalar estimate, and then we shall generalize these expressions to vector estimation. Other relevant aspects, such as whether the estimate is consistent, efficient, or sufficient, will be taken up in Sec. 13.3.6.

Costs and risks Table 13.1 gives three definitions of risk using three different kinds of average cost. Let us consider the assumptions required for the computation of the various definitions of risk. The first row gives a frequentist definition of risk, which we shall call $\bar{C}(\boldsymbol{\theta})$ since it is a function of $\boldsymbol{\theta}$. The computation of the average requires knowledge of the prior probability density on the data conditioned on the underlying parameter, $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$. This averaging operation is analogous to the average performed in (13.6) over all decision outcomes given an underlying true hypothesis state.

The second row of Table 13.1 defines average cost as a function of a particular \mathbf{g} . This Bayesian definition requires knowledge of the posterior probability on $\boldsymbol{\theta}$, that is, $\text{pr}(\boldsymbol{\theta}|\mathbf{g})$. The Bayesian regards $\boldsymbol{\theta}$ as random, but has no concept of an ensemble of \mathbf{g} vectors; the data are fixed. We call this cost function $\bar{C}(\mathbf{g})$ since it is a function of \mathbf{g} . This cost is analogous to the cost computed in (13.5), where the average is performed over all underlying classes for a given decision.

The third row of Table 13.1 defines the overall average cost, found by averaging over the ensemble of possible data vectors $\{\mathbf{g}\}$ for a particular $\boldsymbol{\theta}$, followed by an average over the distribution of underlying parameters $\text{pr}_{\boldsymbol{\theta}}(\boldsymbol{\theta})$. The double average results in a scalar cost \bar{C} that is no longer a function of either $\boldsymbol{\theta}$ or \mathbf{g} . This cost is analogous to the overall average cost of a classification decision computed in (13.7).

In summary, estimates are statistical quantities, hence their evaluation requires statistical methods. We conceive the data as being derived from some noisy measurement system, so that the data would be random given repeated trials of the measurement procedure on the same object, with additional randomness in the case of underlying parameter variability. We shall thus treat two problems in parallel, considering the performance of an estimator acting on noisy data when the underlying parameter is fixed, as well as the extension to the case where there is randomness in the underlying parameter.

Bias Given a data vector \mathbf{g} , let $\hat{\theta}$ denote an estimate of some fixed scalar parameter θ underlying the data. Because $\hat{\theta}$ is a function of noisy data, it is a random variable with a distribution (see Fig. 13.12) that depends on the true value of the underlying parameter. If we know $\text{pr}(\mathbf{g}|\theta)$ and the estimation rule $\hat{\theta}(\mathbf{g})$ we can write the mean of $\hat{\theta}$ as

$$\bar{\hat{\theta}} = \langle \hat{\theta}(\mathbf{g}) \rangle_{\mathbf{g}|\theta} = \int d^M g \text{pr}(\mathbf{g}|\theta) \hat{\theta}(\mathbf{g}), \quad (13.274)$$

where the subscript $\mathbf{g}|\theta$ in the middle form indicates that the average is over all sources of randomness in the data when the parameter has fixed value equal to θ . We therefore call $\bar{\hat{\theta}}$ the conditional mean of $\hat{\theta}$. If we know the conditional PDF of $\hat{\theta}$ itself, we can write

$$\bar{\hat{\theta}} = \int d\hat{\theta} \text{pr}(\hat{\theta}|\theta) \hat{\theta}, \quad (13.275)$$

where now we no longer need an explicit form for $\hat{\theta}(\mathbf{g})$. On the other hand, we need to know $\text{pr}(\hat{\theta}|\theta)$ in this formulation. Since $\hat{\theta}$ is often a nonlinear or even an implicit function of \mathbf{g} , it can be challenging to determine $\text{pr}(\hat{\theta}|\theta)$.

Note that the mean of the estimated value, $\bar{\hat{\theta}}$, may not equal the true value θ . In this case a systematic error, or *bias*, exists in the estimation procedure. We

denote the conditional bias by $b(\theta)$, where

$$b(\theta) = \overline{\hat{\theta}} - \theta. \quad (13.276)$$

The overline indicates an average over all realizations of the data, given the true value θ . An *unbiased* estimate is one for which $b(\theta) = 0$ for all θ .

Fig. 13.12 Distribution of $\hat{\theta}$ conditioned on θ .

Estimability It is not always possible to find an unbiased estimate. It often happens that even noise-free data are not sufficient to determine θ unambiguously. As a simple example, suppose that θ is the integral of some object over a region \mathbf{S} but that the data available consist of an image that covers only the smaller region \mathbf{S}' contained in \mathbf{S} . One could still make an estimate of θ , but there would be no satisfactory way of determining the bias $b(\theta)$. The estimate $\hat{\theta}(\mathbf{g})$ is fully determined by \mathbf{g} , which in turn is determined by the part of the object in \mathbf{S}' , so the mean of $\hat{\theta}$ is well defined but insensitive to the part of the object outside \mathbf{S}' . The true value θ , however, depends on the exterior part of the object also, so different objects will give different θ but the same mean estimate, hence different $b(\theta)$. The bias might be zero for some particular object, but that is not of much use; we would like to have an estimator that is unbiased for all values of the parameter. A stopped clock is an unbiased estimator of the time twice a day.

A parameter is said to be *estimable* or *identifiable* with respect to some data set if there exists an unbiased estimator of it for all true values of the underlying parameter. Some books impose the additional restriction that there must be a *linear* unbiased estimator, but we use the broader definition of estimability.

An alternative approach to defining estimability is in terms of the likelihood $\text{pr}(\mathbf{g}|\theta)$. A parameter is estimable if different values of the parameter lead to different likelihoods. Putting it the other way around, if the statement $\text{pr}(\mathbf{g}|\theta_1) = \text{pr}(\mathbf{g}|\theta_2)$ does not imply that $\theta_1 = \theta_2$, then θ is not estimable.

For linear measurement systems, estimability is closely linked to null functions. Consider our familiar imaging equation, $\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}$. The conditional density $\text{pr}(\mathbf{g}|\mathbf{f})$ depends on \mathbf{f} only through $\mathcal{H}\mathbf{f}$, so if there are two objects \mathbf{f}_1 and \mathbf{f}_2 such that $\mathcal{H}\mathbf{f}_1 = \mathcal{H}\mathbf{f}_2$ but $\theta(\mathbf{f}_1) \neq \theta(\mathbf{f}_2)$, then $\theta(\mathbf{f})$ is not estimable. The two objects differ by a null function, since $\mathcal{H}(\mathbf{f}_1 - \mathbf{f}_2) = 0$, and it is fundamentally the existence of null functions that causes some parameters not to be estimable.

Estimability is critical in digital imaging, especially in indirect methods such as computed tomography, since it determines what one can, in principle, determine about the object from a particular data set. Most importantly, it turns out that

the integral of an object over small pixels or voxels is almost never an estimable parameter, so the bias in pixel values is not very useful in saying how well an imaging system performs. We shall be more specific about this point below in Sec. 13.3.2, and we shall discuss it in detail in Chap. 15 when we consider image reconstruction algorithms.

Ensemble-average bias One way of dealing with the issue of estimability is to average the bias over all possible true values of the parameter, defining an average bias by

$$\bar{\hat{\theta}} = \int d^P \theta \text{pr}(\theta) \int d^M g \text{pr}(\mathbf{g}|\theta) \hat{\theta}(\mathbf{g}), \quad (13.277)$$

or equivalently

$$\bar{b} = \langle b(\theta) \rangle_{\theta} = \bar{\hat{\theta}} - \bar{\theta}. \quad (13.278)$$

The average bias \bar{b} can be zero even for a biased estimator if positive and negative biases cancel out.

Actually computing the average bias requires a probability density on θ . For our example above of data limited to a subregion, we would need a probability density function for the integral of the object over the region of \mathbf{S} that is not contained in the measured region \mathbf{S}' . Note that we do not need a density on the object itself, just its integral.

Modeling errors and bias Bias may be the result of the estimation procedure itself, as we shall see below in the discussion of the use of prior information to form an estimate. Bias can also be the result of an incorrect model for the mapping from the parameter space to the data space. When incorrect assumptions are made regarding the likelihood $\text{pr}(\mathbf{g}|\theta)$, a nonzero bias can be expected. Theoretical and simulation studies sometimes skirt this issue by using the same incorrect likelihood in the computation of both $\hat{\theta}$ and in the evaluation of the bias.

Variance Another common measure of estimator performance is the variance, which describes the fluctuations in the estimate of θ that would be obtained over a repeated number of trials:

$$\text{Var}(\theta) = \sigma_{\hat{\theta}}^2 = \langle |\hat{\theta}(\mathbf{g}) - \bar{\hat{\theta}}|^2 \rangle_{\mathbf{g}|\theta} = \int d^M g \text{pr}(\mathbf{g}|\theta) |\hat{\theta} - \bar{\hat{\theta}}|^2. \quad (13.279)$$

The variance describes the fluctuations of the estimate about the mean of the estimate, *not the true mean*.

The bias and variance of an estimator are closely related to the *accuracy* and *precision* of a measurement, since a measurement is essentially an estimate of some physical quantity. The accuracy of a measurement is the closeness of the measured result to the true value, which is specified by the bias. The precision of a measurement is the reproducibility of multiple measurements, which is specified by the variance.

Mean-square error The bias and variance defined in (13.276) and (13.279) are conditioned on a particular value for the parameter θ . The *mean-square error*, or *MSE*, of an estimate is the overall fluctuation in the estimate, conditioned on a

particular value for θ :

$$\text{MSE}(\theta) = \left\langle |\hat{\theta} - \theta|^2 \right\rangle_{\mathbf{g}|\theta}. \quad (13.280)$$

Note that the MSE is a distance from the true θ , while the variance is a measure of the spread relative to the mean estimate $\bar{\theta}$. For an unbiased estimate the variance and the MSE are identical.

If the parameter θ has some randomness associated with it, the *ensemble mean-square error*, or *EMSE*, is found by taking an additional average over the parameter:

$$\text{EMSE} = \left\langle \left\langle |\hat{\theta} - \theta|^2 \right\rangle_{\mathbf{g}|\theta} \right\rangle_{\theta}. \quad (13.281)$$

Thus computation of the EMSE requires knowledge of the probability density function $\text{pr}(\theta)$. The prior probability density function required to compute the average over θ could be an actual sampling density or a subjective Bayesian prior.

Vector generalizations The generalization of the discussion of performance measures to vector estimates is straightforward. A P -dimensional parameter vector $\boldsymbol{\theta}$ has an estimate $\hat{\boldsymbol{\theta}}$ with mean $\langle \hat{\boldsymbol{\theta}} \rangle$ given by

$$\bar{\boldsymbol{\theta}}(\mathbf{g}) = \int d^M g \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \hat{\boldsymbol{\theta}}(\mathbf{g}) = \int d^P \hat{\boldsymbol{\theta}} \text{pr}(\hat{\boldsymbol{\theta}}|\boldsymbol{\theta}) \hat{\boldsymbol{\theta}}. \quad (13.282)$$

The first integral requires knowledge of the data density $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$ and the explicit form of the mapping $\hat{\boldsymbol{\theta}}(\mathbf{g})$, while the second form assumes we know the conditional PDF of $\hat{\boldsymbol{\theta}}$ itself.

The bias $\mathbf{b}(\boldsymbol{\theta})$ is now a vector quantity:

$$\mathbf{b}(\boldsymbol{\theta}) \equiv \bar{\boldsymbol{\theta}} - \boldsymbol{\theta} \equiv \int_{\infty} d^M g [\hat{\boldsymbol{\theta}}(\mathbf{g}) - \boldsymbol{\theta}] \text{pr}(\mathbf{g}|\boldsymbol{\theta}) = \int_{\infty} d^P \hat{\boldsymbol{\theta}} [\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}] \text{pr}(\hat{\boldsymbol{\theta}}|\boldsymbol{\theta}). \quad (13.283)$$

The average bias is now written $\bar{\mathbf{b}} = \langle \mathbf{b}(\boldsymbol{\theta}) \rangle_{\boldsymbol{\theta}}$.

If we denote the mean of the p^{th} element of the random vector $\hat{\boldsymbol{\theta}}$ by $\langle \hat{\theta}_p \rangle = \bar{\theta}_p$, the variance of the p^{th} element is given by

$$\begin{aligned} \text{Var}(\hat{\theta}_p) &\equiv \left\langle \left[\hat{\theta}_p - \langle \hat{\theta}_p \rangle \right] \left[\hat{\theta}_p - \langle \hat{\theta}_p \rangle \right]^* \right\rangle_{\mathbf{g}|\boldsymbol{\theta}} \\ &= \int_{\infty} d^M g |\hat{\theta}_p(\mathbf{g}) - \langle \hat{\theta}_p(\mathbf{g}) \rangle|^2 \text{pr}(\mathbf{g}|\boldsymbol{\theta}) = \int_{\infty} d^P \theta |\hat{\theta}_p - \langle \hat{\theta}_p \rangle|^2 \text{pr}(\hat{\boldsymbol{\theta}}|\boldsymbol{\theta}), \end{aligned} \quad (13.284)$$

and the full covariance matrix is written:

$$\mathbf{K}_{\hat{\boldsymbol{\theta}}} = \left\langle \left(\hat{\boldsymbol{\theta}} - \bar{\boldsymbol{\theta}} \right) \left(\hat{\boldsymbol{\theta}} - \bar{\boldsymbol{\theta}} \right)^{\dagger} \right\rangle = \langle \Delta \hat{\boldsymbol{\theta}} \Delta \hat{\boldsymbol{\theta}}^{\dagger} \rangle. \quad (13.285)$$

The MSE in the vector case is:

$$\text{MSE} = \left\langle \|\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}\|^2 \right\rangle_{\mathbf{g}|\boldsymbol{\theta}} = \int_{\infty} d^M g \|\hat{\boldsymbol{\theta}}(\mathbf{g}) - \boldsymbol{\theta}\|^2 \text{pr}(\mathbf{g}|\boldsymbol{\theta}) = \int_{\infty} d^P \theta \|\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}\|^2 \text{pr}(\hat{\boldsymbol{\theta}}|\boldsymbol{\theta}). \quad (13.286)$$

The reader can show that the MSE can be written equivalently in terms of the covariance matrix and the bias vector as:

$$\text{MSE} = \text{tr} [\mathbf{K}_{\hat{\boldsymbol{\theta}}}] + \text{tr} [\mathbf{b}\mathbf{b}^\dagger] . \quad (13.287)$$

The mean-square error is thus the sum of two contributions: one from the bias and the other resulting from the variance about the mean estimate.

The EMSE is obtained by averaging the MSE over all $\boldsymbol{\theta}$:

$$\text{EMSE} = \left\langle \left\langle \|\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}\|^2 \right\rangle_{\mathbf{g}|\boldsymbol{\theta}} \right\rangle_{\boldsymbol{\theta}} = \text{tr} [\overline{\mathbf{K}}_{\hat{\boldsymbol{\theta}}}] + \text{tr} \langle \mathbf{b}\mathbf{b}^\dagger \rangle . \quad (13.288)$$

As noted below (13.281), the PDF used to perform the average over $\boldsymbol{\theta}$ could be an actual sampling density or a subjective Bayesian prior. As described in the Prologue and Chap. 8, it becomes increasingly difficult to determine $\text{pr}(\boldsymbol{\theta})$ through sampling as the dimensionality P increases. In such cases, it is common to assume some subjective Bayesian prior, examples of which are explored further in Chap. 15.

13.3.2 MSE in digital imaging

In this section we discuss some technical issues in using MSE in digital imaging, and specifically in image reconstruction from indirect data. The reader wanting to learn the basics of estimation without necessarily applying them to imaging may skip ahead to Sec. 13.3.3.

It is common in digital imaging to specify how well an imaging system is functioning by specifying the MSE between object and image. The implicit assumption is that the purpose of the imaging system is to reproduce the object, so the best image must be the one that looks the most like the object. Our goal here is to examine that approach critically; alternative approaches will be offered in Chap. 14.

The commensurability problem An immediate problem in trying to define an MSE for digital images is that the object and image are in different spaces; the object is a function of continuous variables and the image is a discrete set of numbers. To compute a difference between the two, we must either make the object discrete or the image continuous.

As we saw in detail in Chap. 7, a digital data set is described by a continuous-to-discrete (CD) mapping of the form

$$g_m = \int_{S_f} d^q r f(\mathbf{r}) h_m(\mathbf{r}) + n_m \quad (13.289)$$

or, in operator form,

$$\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n} , \quad (13.290)$$

where \mathbf{g} is the $M \times 1$ data vector, \mathbf{n} is the zero-mean $M \times 1$ noise vector, and \mathbf{f} is the infinite-dimensional Hilbert-space vector corresponding to the function $f(\mathbf{r})$. Though we shall use the notations $f(\mathbf{r})$ and \mathbf{f} interchangeably, as we have in previous chapters, we emphasize here that the object is a function; no discretization is implied by the notation \mathbf{f} .

For direct-imaging systems, \mathbf{g} may be the final digital image, but often some additional processing is applied. For indirect imaging systems, a reconstruction step is always required. We can treat these cases together by denoting the final digital image by the $N \times 1$ vector $\hat{\boldsymbol{\theta}}$, where N may be equal to M , but could also in general be different. If the digital processing is linear, we can write

$$\hat{\boldsymbol{\theta}} = \mathbf{A}\mathbf{g} = \mathbf{A}\mathcal{H}\mathbf{f} + \mathbf{A}\mathbf{n}, \quad (13.291)$$

where \mathbf{A} is an $N \times M$ matrix. For direct imaging without additional processing, $N = M$, and \mathbf{A} is the unit matrix. Specific forms for \mathbf{A} for indirect imaging will be discussed in Chap. 15.

Our problem now is to compute an MSE between the $N \times 1$ vector $\hat{\boldsymbol{\theta}}$ and the original object function $f(\mathbf{r})$. Building on the formalism in Chap. 7, we shall present three possible solutions to this problem.

Discrete error norm One way to compare $\hat{\boldsymbol{\theta}}$ to $f(\mathbf{r})$ is to discretize $f(\mathbf{r})$ to a vector of the same dimension as $\hat{\boldsymbol{\theta}}$. If this discretization is a linear mapping, its general form is given by (7.35) as

$$\boldsymbol{\theta} = \mathcal{D}_\chi \mathbf{f}, \quad (13.292)$$

where the discretization operator \mathcal{D}_χ is defined explicitly in (7.36).

We can now define the discrepancy between this discretized version of the object and the output of the digital imaging system as

$$\delta\boldsymbol{\theta} \equiv \hat{\boldsymbol{\theta}} - \boldsymbol{\theta}. \quad (13.293)$$

With (13.291), the norm of this error is given by

$$\|\delta\boldsymbol{\theta}\|^2 = \|(\mathbf{A}\mathcal{H} - \mathcal{D}_\chi)\mathbf{f} + \mathbf{A}\mathbf{n}\|^2, \quad (13.294)$$

where the norm is in the ND Euclidean space \mathbb{E}^N . The numerical value of this norm depends, of course, on the choice of the discretization functions $\{\chi_n(\mathbf{r})\}$ as well as on the system operator \mathcal{H} , the noise \mathbf{n} , and the processing matrix \mathbf{A} .

Continuous error norm The second option is to make a continuous version of the digital image. If this operation is a linear mapping, its general form is given from (7.37) as

$$\hat{f}(\mathbf{r}) = \left[\mathcal{D}_\phi^\dagger \hat{\boldsymbol{\theta}} \right] (\mathbf{r}) = \sum_{n=1}^N \hat{\theta}_n \phi_n(\mathbf{r}). \quad (13.295)$$

The functions $\{\phi_n(\mathbf{r})\}$ thus serve as interpolating functions.

We can define the discrepancy between the two functions $f(\mathbf{r})$ and $\hat{f}(\mathbf{r})$ as

$$\delta f(\mathbf{r}) \equiv \hat{f}(\mathbf{r}) - f(\mathbf{r}). \quad (13.296)$$

The norm of this error, now defined in $\mathbb{L}_2(\mathbb{R}^q)$, is given by

$$\|\delta f\|^2 = \|(\mathcal{D}_\phi^\dagger \mathbf{A}\mathcal{H} - \mathbf{I})\mathbf{f} + \mathcal{D}_\phi^\dagger \mathbf{A}\mathbf{n}\|^2. \quad (13.297)$$

The simulation solution The third solution to the commensurability problem is to ignore it and do a simulation! This approach, favored in most of the imaging literature, starts by discretizing some assumed continuous object $f(\mathbf{r})$, yielding an $N \times 1$ vector $\boldsymbol{\theta}_a$, defined by

$$\boldsymbol{\theta}_a = \mathcal{D}_\psi \mathbf{f} \quad (13.298)$$

for some set of discretization functions $\{\psi_n\}$.

This vector is now regarded as the “true” object. It is imaged through a matrix \mathbf{H} , as described in Sec. 7.4.1, and the resulting approximate data vector is given by [cf. (7.305)]

$$\mathbf{g}_a = \mathbf{H}\boldsymbol{\theta}_a + \mathbf{n}. \quad (13.299)$$

The noise term should really be written as $\boldsymbol{\epsilon}$ instead of \mathbf{n} since we use the former notation to include both true measurement noise and modeling error, but this distinction is virtually always ignored in simulation studies. Customarily, a zero-mean noise vector \mathbf{n} is generated in the computer and added to $\mathbf{H}\boldsymbol{\theta}$ to give \mathbf{g}_a . This \mathbf{g}_a is then processed just as a real data vector would be, yielding a digital image $\hat{\boldsymbol{\theta}}_a$.

Now, however, there is no commensurability problem since the true object is regarded as the discrete vector $\boldsymbol{\theta}_a$. The error norm is given by

$$\|\delta\boldsymbol{\theta}\|_{sim}^2 \equiv \|\hat{\boldsymbol{\theta}}_a - \boldsymbol{\theta}_a\|_{sim}^2 = \|(\mathbf{A}\mathbf{H}\mathcal{D}_\psi - \mathcal{D}_\psi)\mathbf{f} + \mathbf{A}\mathbf{n}\|^2. \quad (13.300)$$

What do we mean by mean? To convert an error norm to a mean-square error, we must specify what kind of averaging is implicit in the word *mean*. There are three options: First, we can do a spatial average over a single image for a single object and a single realization of the noise. In spite of the terminology used, the MSE that results in this case is a random variable. Second, we can choose to average the error norm over all realizations of the noise for a single object. If we regard the object as nonrandom, the resulting MSE is not a random variable, but it does depend on the specific object chosen. Third, we can average over the noise and also over some ensemble of objects. This approach thus requires some knowledge of the object statistics, the topic of Sec. 8.4.

The spatial average is just the norm divided by the number of voxels in the discrete cases or the area of the object support in the continuous case, so the MSE is proportional to the error norm if we choose this kind of averaging. Explicitly, if we do only the spatial averaging, the continuous MSE is defined by

$$\text{MSE}_{cont} \equiv \frac{1}{A} \|\delta\mathbf{f}\|^2 = \frac{1}{A} \int_{S_f} d^q r |\delta f(\mathbf{r})|^2, \quad (13.301)$$

where A is the area of the object support if $q = 2$ (or the volume if $q = 3$).

For the discrete error norm, the corresponding MSE is defined by

$$\text{MSE}_{disc} \equiv \frac{1}{N} \sum_{n=1}^N |\hat{\theta}_n - \theta_n|^2. \quad (13.302)$$

When we include the other kinds of average, we shall append additional subscripts. For example,

$$\text{MSE}_{cont,n,\mathbf{f}} \equiv \frac{1}{A} \left\langle \left\langle \|\delta\mathbf{f}\|^2 \right\rangle_{\mathbf{n}|\mathbf{f}} \right\rangle_{\mathbf{f}}. \quad (13.303)$$

With three ways of defining the error norm and three ways of averaging it, we have nine definitions of MSE. Some of them are common in the literature. For example, MSE_{sim} , with only the spatial average, probably appears in the majority of papers on image processing. The Wiener-Helstrom estimator (Wiener, 1942; Helstrom, 1967) minimizes $\text{MSE}_{cont,n,f}$, though usually under the assumption that $f(\mathbf{r})$ is a sample function of a stationary random process, and also that the imaging system is so finely sampled that the distinction between continuous and discrete MSEs can be ignored. When the Wiener-Helstrom estimator is modified to use discrete models, it minimizes $\text{MSE}_{disc,n,f}$. The best linear unbiased estimator or BLUE, to be discussed in Sec. 13.3.7, minimizes $\text{MSE}_{disc,n}$ in two steps: first it is designed to be unbiased—which implicitly assumes that all components of $\boldsymbol{\theta}$ are estimable—and then it minimizes the MSE, which for an unbiased estimator is just the average variance.

Note that the issue of estimability does not arise if the MSE includes an average over the object class. While it is true that some objects in the class will almost invariably contain null functions, any MSE with an average over \mathbf{f} will tell us how close we come, on average, to reconstructing an object from the class.

This point is largely moot, however, for two reasons: we never have enough information about the object class to do a believable average over \mathbf{f} , and even if we did, MSE has nothing to do with the intended use of the image. At best, $\text{MSE}_{cont,n,f}$ and $\text{MSE}_{disc,n,f}$ say something about how well we can represent a class of objects, but nothing about how well we can distinguish between two different classes. The details that are important to the intended use of the image may make a very small contribution to the quadratic content (energy), yet accurate reproduction of these details may be essential.

Another objection to MSE is that any value computed will depend on an arbitrary choice of the functions used in the discretization or interpolation steps. Sometimes these choices can make large changes in the numerical values and can even change the rank ordering of the systems supposedly being evaluated.

Effect of null functions To understand better the role of null functions when no average over \mathbf{f} is involved, let us look more closely at the mathematical forms of $\text{MSE}_{cont,n}$, $\text{MSE}_{disc,n}$ and $\text{MSE}_{sim,n}$. With some algebra, the expressions we wish to compare can be rewritten as

$$\text{MSE}_{cont,n} = \frac{1}{A} \|(\mathcal{D}_\phi^\dagger \mathbf{A} \mathcal{H} - \mathbf{I}) \mathbf{f}\|^2 + \frac{1}{A} \text{tr}\{\mathbf{A} \mathbf{K} \mathbf{A}^\dagger \mathcal{D}_\phi \mathcal{D}_\phi^\dagger\}; \quad (13.304)$$

$$\text{MSE}_{disc,n} = \frac{1}{N} \|(\mathbf{A} \mathcal{H} - \mathcal{D}_\chi) \mathbf{f}\|^2 + \frac{1}{N} \text{tr}\{\mathbf{A} \mathbf{K} \mathbf{A}^\dagger\}; \quad (13.305)$$

$$\text{MSE}_{sim,n} = \frac{1}{N} \|(\mathbf{A} \mathcal{H} \mathcal{D}_\psi - \mathcal{D}_\psi) \mathbf{f}\|^2 + \frac{1}{N} \text{tr}\{\mathbf{A} \mathbf{K} \mathbf{A}^\dagger\}, \quad (13.306)$$

where \mathbf{K} is the covariance matrix of the noise and $\text{tr}\{\cdot\}$ denotes the trace operation, or sum of the diagonal elements¹³ of the matrix.

¹³Note that the noise contribution to the MSE in (13.304) can also be written as $\text{tr}\{\mathcal{D}_\phi^\dagger \mathbf{A} \mathbf{K} \mathbf{A}^\dagger \mathcal{D}_\phi\}$ by using the cyclic property of the trace, (A.96), but in this form the trace would have to be interpreted as an integral rather than a sum.

To see how null functions influence the continuous MSE, we can decompose the object function as in (1.127):

$$f(\mathbf{r}) = f_{meas}(\mathbf{r}) + f_{null}(\mathbf{r}), \quad (13.307)$$

where $\mathcal{H}\mathbf{f}_{null} = 0$. With this decomposition, we can rewrite (13.304) as

$$\text{MSE}_{cont,n} = \frac{1}{A} \|(\mathcal{D}_\phi^\dagger \mathbf{A} \mathcal{H} - \mathbf{I})\mathbf{f}_{meas} - \mathbf{f}_{null}\|^2 + \frac{1}{A} \text{tr}\{\mathcal{D}_\phi^\dagger \mathbf{A} \mathbf{K} \mathbf{A}^\dagger \mathcal{D}_\phi\}. \quad (13.308)$$

By the triangle inequality, the first term has a minimum value of $A^{-1} \|\mathbf{f}_{null}\|^2$.

We could simply accept this offset and rate systems by how close they came to the minimum if all systems of interest had the same null space (optical systems with the same aperture but different aberrations, for example), but modern imaging ranges over many different systems with different null spaces. Even different processing algorithms on the same data can differ in the way they attempt to recover null functions. Hence $\|\mathbf{f}_{null}\|^2$ is of critical importance if we want to compare systems on the basis of $\text{MSE}_{cont,n}$. Since this MSE uses just a single object, it depends strongly on the null functions of that object. The nefarious (or unwitting) investigator wanting to show that System A was better than system B could, for example, construct an object as a linear superposition of natural pixels (see Sec. 7.4.3) for system A, thereby removing the contribution $\|\mathbf{f}_{null}\|^2$ from the continuous MSE.

The situation is more complicated in $\text{MSE}_{disc,n}$ since both \mathcal{H} and \mathcal{D}_ψ have null spaces. If these null spaces were identical, then null functions would play no role at all in $\text{MSE}_{disc,n}$. Furthermore, if we chose an object such that $\mathcal{D}_\chi \mathbf{f}$ lay entirely in the measurement space of \mathcal{H} , then again null components of the object would play no role. Even for complicated objects with lots of fine detail not resolved by the system, we can still make $\text{MSE}_{disc,n}$ small just by choosing the matrix \mathbf{A} to reconstruct on a coarse grid and choosing $\{\chi_n(\mathbf{r})\}$ to discretize the object on the same grid. In that case, $\mathbf{A}\mathcal{H}\mathbf{f}$ could easily be a good approximation to the coarsely discretized object $\mathcal{D}_\chi \mathbf{f}$.

The main feature of $\text{MSE}_{sim,n}$ is that it can be completely insensitive to null functions for all choices of the object. Since both $\mathbf{A}\mathcal{H}\mathcal{D}_\psi$ and \mathcal{D}_ψ erase the components of $f(\mathbf{r})$ in the null space of \mathcal{D}_ψ , this null space is always irrelevant for any version of MSE_{sim} . Moreover, the entire first term in (13.308) vanishes when $\mathbf{A} = \mathbf{H}^{-1}$ or $\mathbf{A}\mathcal{H}\mathcal{D}_\psi = \mathcal{D}_\psi$; since one or both of these conditions often hold in simulations, all we can ever hope to learn about the system from MSE measures in such studies is how much the noise is amplified by the processing.

13.3.3 Bayesian estimation

Bayesian estimation is the determination of an estimate of a random $\boldsymbol{\theta}$ through minimization of the Bayes risk. Knowledge of $\text{pr}(\boldsymbol{\theta})$ is assumed, and a cost function $C(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta})$ must be specified. Choosing a cost function is equivalent to choosing a particular tradeoff between bias and variance. In the following sections we shall determine the form of the Bayesian estimator for several commonly chosen cost functions. In each case we begin with the scalar estimation problem. Where possible, the generalization to the vector problem is then given.

Quadratic cost functions and the MMSE estimator The EMSE is a common form for the cost measure $C(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta})$ to be minimized in the design of an estimation procedure.

Since the EMSE is quadratic in $(\hat{\theta} - \theta)$, it is referred to as a quadratic cost function. We shall now derive the form of the estimator that minimizes this cost function, starting with the scalar case.

The EMSE in the scalar case, (13.281), can be written as

$$\begin{aligned} \text{EMSE} &= \left\langle (\hat{\theta} - \theta)^2 \right\rangle_{\mathbf{g}, \theta} = \int d^M g \text{pr}(\mathbf{g}) \int d\theta \text{pr}(\theta|\mathbf{g}) (\hat{\theta} - \theta)^2 \\ &= \int d^M g \text{pr}(\mathbf{g}) \int d\theta \text{pr}(\theta|\mathbf{g}) (\hat{\theta}^2 - 2\theta\hat{\theta} + \theta^2) \\ &= \int d^M g \text{pr}(\mathbf{g}) \left[\hat{\theta}^2 - 2\hat{\theta} \int d\theta \theta \text{pr}(\theta|\mathbf{g}) + \int d\theta \theta^2 \text{pr}(\theta|\mathbf{g}) \right]. \end{aligned} \quad (13.309)$$

We know that $\text{pr}(\mathbf{g})$ is always nonnegative, so the EMSE is minimized by setting

$$\frac{\partial}{\partial \hat{\theta}} \left[\hat{\theta}^2 - 2\hat{\theta} \int d\theta \theta \text{pr}(\theta|\mathbf{g}) + \int d\theta \theta^2 \text{pr}(\theta|\mathbf{g}) \right] = 0. \quad (13.310)$$

The solution is given by

$$2\hat{\theta} - 2 \int d\theta \theta \text{pr}(\theta|\mathbf{g}) = 0, \quad (13.311a)$$

or

$$\hat{\theta}_{\text{MMSE}} = \int d\theta \theta \text{pr}(\theta|\mathbf{g}) = \langle \theta \rangle_{\theta|\mathbf{g}}, \quad (13.311b)$$

where the subscript MMSE stands for *minimum mean-squared-error*. A better term might be MEMSE, or *minimum ensemble mean-squared-error* since the average over θ is required. Note, however, that the average over \mathbf{g} is not required; exactly the same estimate would be obtained with a quadratic cost function averaged over the prior alone, so $\hat{\theta}_{\text{MMSE}}$ is a true Bayesian estimate.

The density function in the integrand of (13.311b) is the posterior probability of θ conditioned on the measured data vector. We see that $\hat{\theta}_{\text{MMSE}}$ is the mean of θ with respect to this density, or the *posterior mean*.

We can use Bayes' rule to write (13.311b) as

$$\hat{\theta}_{\text{MMSE}} = \int d\theta \theta \left[\frac{\text{pr}(\mathbf{g}|\theta) \text{pr}(\theta)}{\text{pr}(\mathbf{g})} \right] = \frac{\int d\theta \text{pr}(\mathbf{g}|\theta) \text{pr}(\theta) \theta}{\int d\theta \text{pr}(\mathbf{g}|\theta) \text{pr}(\theta)}. \quad (13.312)$$

Example: MMSE estimation of the rate of a Poisson process Suppose we have a radioactive sample of unknown concentration and we wish to estimate the rate parameter a of the Poisson process. We further assume that a follows an exponential distribution (C.118): $\text{pr}_a(a) = (1/\beta) \exp(-a/\beta)$. We denote the integer number of counts detected in the sampling interval by n . Then $\text{pr}(n|a)$ is given by the well-known Poisson probability law of (C.165):

$$\text{pr}(n|a) = \frac{e^{-a} a^n}{n!}. \quad (13.313)$$

We find the MMSE estimate for a by solving (13.312):

$$\hat{a}_{\text{MMSE}} = \frac{\int_0^\infty da e^{-a[1+(1/\beta)]} a^{(n+1)}}{\int_0^\infty da e^{-a[1+(1/\beta)]} a^n}. \quad (13.314)$$

A tabulated integral (Gradshteyn and Ryzhik 3.351(3.), 1980) can be used to determine the numerator and denominator, giving

$$\hat{a}_{\text{MMSE}} = \frac{n + 1}{1 + \frac{1}{\beta}}. \tag{13.315}$$

We shall return to this example in the next sections, to demonstrate how differences in the choice of prior or cost function alter the form of the resulting estimate.

Posterior mean and symmetric cost functions It can be shown that any symmetric, convex-upward cost function gives the same form for the optimal estimator we have derived using a quadratic cost function, provided the posterior density is symmetric as well. Furthermore, if the cost function is symmetric and nondecreasing, like the one shown in Fig. 13.13, the optimal estimator is again the posterior mean if the posterior density is a symmetric unimodal function that satisfies the following property (Van Trees, 1968):

$$\lim_{\theta \rightarrow \infty} C(\theta) \text{pr}_{\theta|\mathbf{g}}(\theta|\mathbf{g}) = 0. \tag{13.316}$$

There are many cost functions and posterior PDFs that satisfy (13.316), leading to optimal estimators that are equivalent to $\hat{\theta}_{\text{MMSE}}$. We shall have occasion to refer to this property in later sections.

Fig. 13.13 An example of a symmetric, nondecreasing cost function, in particular, a cost function that is uniform outside a region of width 2ϵ .

Vector generalization The vector generalization of the MMSE is a straightforward extension of (13.311). The vector estimate that minimizes (13.288) is given by

$$\hat{\boldsymbol{\theta}}_{\text{MMSE}} = \int d^P \boldsymbol{\theta} \boldsymbol{\theta} \text{pr}(\boldsymbol{\theta}|\mathbf{g}). \tag{13.317}$$

The conditional mean of the MMSE estimate is given by

$$\bar{\boldsymbol{\theta}}_{\text{MMSE}}(\boldsymbol{\theta}) = \langle \hat{\boldsymbol{\theta}}_{\text{MMSE}} \rangle_{\mathbf{g}|\boldsymbol{\theta}} = \int d^P \boldsymbol{\theta}' \boldsymbol{\theta}' \int d^M g \text{pr}(\boldsymbol{\theta}'|\mathbf{g}) \text{pr}(\mathbf{g}|\boldsymbol{\theta}), \tag{13.318}$$

for all values of the underlying parameter $\boldsymbol{\theta}$. The estimator is biased, but the average bias [see the discussion below (13.283)] is zero.

Linear cost functions A linear cost function is one that takes the form $C(\hat{\theta}, \theta) = c|\hat{\theta} - \theta|$. A plot of this cost function is shown in Fig. 13.14. The estimator that minimizes this cost function is found by solving

$$\frac{\partial}{\partial \hat{\theta}} \int d^M g \text{pr}(\mathbf{g}) \int d\theta \text{pr}(\theta|\mathbf{g}) c|\hat{\theta} - \theta| = 0. \quad (13.319)$$

We again solve for the value of $\hat{\theta}$ that minimizes the inner integral. We can rewrite the absolute value to give

$$\begin{aligned} & \frac{\partial}{\partial \hat{\theta}} \int_{-\infty}^{\infty} d\theta \text{pr}(\theta|\mathbf{g}) (|\hat{\theta} - \theta|) \\ &= \frac{\partial}{\partial \hat{\theta}} \left[\int_{-\infty}^{\hat{\theta}} d\theta \text{pr}(\theta|\mathbf{g}) (\hat{\theta} - \theta) + \int_{\hat{\theta}}^{\infty} d\theta \text{pr}(\theta|\mathbf{g}) (\theta - \hat{\theta}) \right] = 0 \end{aligned} \quad (13.320)$$

as the expression to be solved. When we use Leibniz' rule for taking the partial inside the integrals, we find

$$\int_{-\infty}^{\hat{\theta}} d\theta \text{pr}(\theta|\mathbf{g}) - \int_{\hat{\theta}}^{\infty} d\theta \text{pr}(\theta|\mathbf{g}) = 0 \quad (13.321a)$$

or

$$\int_{-\infty}^{\hat{\theta}} d\theta \text{pr}(\theta|\mathbf{g}) = \int_{\hat{\theta}}^{\infty} d\theta \text{pr}(\theta|\mathbf{g}). \quad (13.321b)$$

This equality holds when $\hat{\theta}$ is equal to the median of the posterior density, so we say that $\hat{\theta}_{\text{lin}}$ is equal to the *posterior median*.

Fig. 13.14 Illustration of a linear cost function for a scalar parameter.

The optimal estimator for a linear cost function in the vector case does not lead to such an easily interpretable form. However, given the fact that the linear cost function is a symmetric, nondecreasing function, $\hat{\theta}_{\text{lin}} = \hat{\theta}_{\text{MMSE}}$ for all unimodal posterior PDFs that satisfy (13.316).

Uniform cost functions and MAP estimation Sometimes the cost is considered negligible if smaller than some tolerance ϵ , and all estimator errors beyond that tolerance are regarded as equally costly. In the scalar case, the form of such a cost function is given by

$$C(\hat{\theta}, \theta) = C(\hat{\theta} - \theta) = 1 - \text{rect} \left(\frac{\hat{\theta} - \theta}{2\epsilon} \right). \quad (13.322)$$

Figure 13.13 shows a plot of this cost function, which is referred to as a *uniform* cost function.

We seek the estimator that minimizes the cost function of (13.322), averaged over all θ and \mathbf{g} . This average cost, or risk is written

$$R = 1 - \int d\theta \operatorname{pr}_\theta(\theta) \int d^M g \operatorname{pr}(\mathbf{g}|\theta) \operatorname{rect}\left(\frac{\hat{\theta} - \theta}{2\epsilon}\right). \quad (13.323)$$

We assume that ϵ is sufficiently small that $\operatorname{pr}_\theta(\theta) \approx \operatorname{pr}_\theta(\hat{\theta})$ and $\operatorname{pr}(\mathbf{g}|\theta) \approx \operatorname{pr}(\mathbf{g}|\hat{\theta})$ in the integral. Then

$$\begin{aligned} R &= 1 - \int d^M g \operatorname{pr}(\mathbf{g}|\hat{\theta}) \int d\theta \operatorname{pr}_\theta(\hat{\theta}) \operatorname{rect}\left(\frac{\hat{\theta} - \theta}{2\epsilon}\right) \\ &= 1 - 2\epsilon \int d^M g \operatorname{pr}(\mathbf{g}|\hat{\theta}) \operatorname{pr}_\theta(\hat{\theta}). \end{aligned} \quad (13.324)$$

This expression is minimized if at each \mathbf{g} we choose $\hat{\theta}(\mathbf{g})$ such that $\operatorname{pr}(\mathbf{g}|\hat{\theta}) \operatorname{pr}_\theta(\hat{\theta})$ is maximized with respect to $\hat{\theta}$. That is,

$$\hat{\theta}_{\text{Unif}} = \operatorname{argmax}_\theta \operatorname{pr}(\mathbf{g}|\theta) \operatorname{pr}(\theta). \quad (13.325)$$

Bayes' rule lets us rewrite (13.325) as

$$\hat{\theta}_{\text{Unif}} = \operatorname{argmax}_\theta \operatorname{pr}(\theta|\mathbf{g}) \operatorname{pr}(\mathbf{g}). \quad (13.326)$$

Since $\operatorname{pr}(\mathbf{g})$ is independent of θ , we have

$$\hat{\theta}_{\text{Unif}} = \operatorname{argmax}_\theta \operatorname{pr}(\theta|\mathbf{g}). \quad (13.327)$$

The quantity $\operatorname{pr}(\theta|\mathbf{g})$ describes the posterior probability of θ after the data \mathbf{g} are obtained; thus the estimation rule of (13.327) is known as *maximum a posteriori*, or MAP, estimation. Equivalently, the MAP estimate is the mode of the posterior, or the *posterior mode*. We shall therefore refer to the resulting estimate as $\hat{\theta}_{\text{MAP}}$.

Interestingly, MAP estimation is often what is meant in the literature on Bayesian estimation. However, as we have just seen, MAP estimation is just a special case of Bayesian estimation in which the particular form of the cost function is (13.322).

Some authors present MAP estimation as the procedure to follow in the absence of a cost function (Whalen, 1971). This is really a special case of the uniform cost function of (13.322) in which ϵ is taken to be small, which was the assumption we made below (13.323).

Fig. 13.15 Graph of the prior $\text{pr}(\theta)$ and the conditional density function $\text{pr}(\mathbf{g}|\theta)$; the product of these, referred to as the weighted likelihood function, is the dark curve.

Figure 13.15 shows a graph of the prior $\text{pr}(\theta)$ and the likelihood $\text{pr}(\mathbf{g}|\theta)$ that appear in (13.325). Their product is shown in bold line width in the figure. The prior serves as a scalar weight on the likelihood function, playing an increasing role as the width of $\text{pr}(\theta)$ narrows, as happens when there is less prior uncertainty in the value of θ . For this reason, MAP estimation is also referred to as weighted-likelihood estimation. The MAP estimate is located where the weighted likelihood reaches a maximum, as shown in the figure.

An equivalent expression for the MAP estimation rule of (13.326) is

$$\hat{\theta}_{\text{MAP}} = \underset{\theta}{\text{argmax}} \{ \ln [\text{pr}(\mathbf{g}|\theta)] + \ln [\text{pr}(\theta)] \} . \tag{13.328}$$

The monotonicity of the logarithm function means it does not affect the location of the maximum in the estimation procedure.

Another way of interpreting MAP estimation is that $\text{pr}(\theta)$ characterizes the prior uncertainty in the parameter, which is often subjective in nature. Then $\text{pr}(\theta|\mathbf{g})$ is the (presumably reduced) uncertainty *after* data are collected, hence the term posterior. We now revisit the problem of estimating the rate of a Poisson process to demonstrate this relationship between the estimate, the data, and the prior.

Example: MAP estimation of the rate of a Poisson process We again wish to estimate the rate parameter a of a Poisson process, where a is assumed to follow an exponential distribution as in the previous example. We are given an MD data vector $\mathbf{g} = \{n_m\}$ of independent samples of the Poisson process, so that

$$\text{pr}(\mathbf{g}|a) = \prod_{m=1}^M \frac{e^{-a} a^{n_m}}{n_m!} . \tag{13.329}$$

The MAP estimate is found by solving

$$0 = \frac{\partial}{\partial a} \ln[\text{pr}(\mathbf{g}|a)] + \frac{\partial}{\partial a} \ln[\text{pr}(a)] = \sum_{m=1}^M \left(-1 + \frac{n_m}{a} \right) - \frac{1}{\beta} , \tag{13.330}$$

or

$$\hat{a}_{\text{MAP}} = \left[\frac{1}{M + (1/\beta)} \right] \sum_{m=1}^M n_m. \quad (13.331)$$

We see that the estimate approaches the sample mean when M is large. In the case of a limited number of samples, however, the estimate is influenced by the value of β , especially for low numbers of counts per sample, where $\hat{a}_{\text{MAP}} \propto \beta$. Note that in the case of a single sample (13.331) reduces to $\hat{a}_{\text{MAP}} = n/[1 + (1/\beta)]$. The MAP estimate is not equal to the MMSE estimate [cf. (13.315)] because the posterior is not symmetric, thanks to the exponential prior.

Vector generalization The vector generalization of (13.325) and (13.327) is straightforward:

$$\hat{\boldsymbol{\theta}}_{\text{MAP}} = \underset{\boldsymbol{\theta}}{\operatorname{argmax}} \operatorname{pr}(\boldsymbol{\theta}|\mathbf{g}) = \underset{\boldsymbol{\theta}}{\operatorname{argmax}} \operatorname{pr}(\mathbf{g}|\boldsymbol{\theta}) \operatorname{pr}(\boldsymbol{\theta}). \quad (13.332)$$

Similarly, a vector form for (13.328) is written

$$\hat{\boldsymbol{\theta}}_{\text{MAP}} = \underset{\boldsymbol{\theta}}{\operatorname{argmax}} \{ \ln [\operatorname{pr}(\mathbf{g}|\boldsymbol{\theta})] + \ln [\operatorname{pr}(\boldsymbol{\theta})] \}. \quad (13.333)$$

The uniform cost function is a symmetric, nondecreasing function; hence, $\hat{\boldsymbol{\theta}}_{\text{MAP}} = \hat{\boldsymbol{\theta}}_{\text{MMSE}}$ for all unimodal forms for $\operatorname{pr}(\mathbf{g}|\boldsymbol{\theta})$ that satisfy (13.316). A Gaussian form for $\operatorname{pr}(\boldsymbol{\theta}|\mathbf{g})$ satisfies this property. In a series of examples, we shall derive the form of the MAP estimator for multivariate Gaussian data and Gaussian priors on the underlying parameters, keeping in mind that the same estimator satisfies the MMSE criterion.

Example: Gaussian parameter uncertainty and Gaussian noise Consider a data vector composed of the sum of $\mathbf{s}(\boldsymbol{\theta})$, which denotes a signal parameterized by $\boldsymbol{\theta}$, a known background \mathbf{b} , and Gaussian noise, so that $\mathbf{g} = \mathbf{s}(\boldsymbol{\theta}) + \mathbf{b} + \mathbf{n}$, with $\mathbf{n} \sim \mathcal{N}_M(\mathbf{0}, \mathbf{K}_n)$ [cf. (13.145)].¹⁴ The parameter vector might contain signal location, scale, etc. (See Sec. 8.4 for a review of parametric signal descriptions.) The conditional PDF of the data is given by [cf. (13.174)]

$$\operatorname{pr}(\mathbf{g}|\boldsymbol{\theta}) = (2\pi)^{-M/2} [\det(\mathbf{K}_n)]^{-1/2} \exp \left\{ -\frac{1}{2} [\mathbf{g} - \mathbf{b} - \mathbf{s}(\boldsymbol{\theta})]^t \mathbf{K}_n^{-1} [\mathbf{g} - \mathbf{b} - \mathbf{s}(\boldsymbol{\theta})] \right\}. \quad (13.334)$$

Suppose the parameter vector is normally distributed according to $\mathcal{N}_P(\bar{\boldsymbol{\theta}}, \mathbf{K}_\theta)$, or

$$\operatorname{pr}(\boldsymbol{\theta}) = (2\pi)^{-P/2} [\det(\mathbf{K}_\theta)]^{-1/2} \exp \left[-\frac{1}{2} (\boldsymbol{\theta} - \bar{\boldsymbol{\theta}})^t \mathbf{K}_\theta^{-1} (\boldsymbol{\theta} - \bar{\boldsymbol{\theta}}) \right]. \quad (13.335)$$

By (13.333), the MAP estimate is found by minimizing

$$[\mathbf{g} - \bar{\mathbf{g}}(\boldsymbol{\theta})]^t \mathbf{K}_n^{-1} [\mathbf{g} - \bar{\mathbf{g}}(\boldsymbol{\theta})] + (\boldsymbol{\theta} - \bar{\boldsymbol{\theta}})^t \mathbf{K}_\theta^{-1} (\boldsymbol{\theta} - \bar{\boldsymbol{\theta}}) \quad (13.336)$$

with respect to $\boldsymbol{\theta}$. The first term tells us to minimize the difference between the data in hand and the data we would expect to obtain given the parameter vector; hence it

¹⁴The reader should not confuse the background \mathbf{b} with the bias vector discussed earlier.

is referred to as the data-agreement term. The second term, which comes from the prior, drives the solution toward agreement with the mean parameter vector. The prior serves to control the contribution of the measurement noise to the estimate; hence it is often referred to as a regularizer. The MAP solution strikes a balance between these two terms, giving a solution that matches the data more closely as the prior broadens, and in contrast, giving an estimate that is increasingly biased toward the prior as the noise in the data increases. We shall have much more to say about regularizers in Chap. 15.

To obtain a more explicit form for the MAP estimate of the parameters in (13.336), an explicit form for the expected data is required. In the next examples we find the form of the MAP estimate when we have a signal of random amplitude, random background level, or both.

Example: Amplitude uncertainty Suppose the random parameter is the amplitude A of a known signal \mathbf{s}_0 , whose other characteristics are all nonrandom and known. Furthermore, we assume $A \sim \mathcal{N}(\bar{A}, \sigma_A^2)$ and all $n_m \sim \mathcal{N}(0, \sigma_n^2)$. Then $\mathbf{g}(A) = A\mathbf{s}_0 + \mathbf{b} + \mathbf{n}$ and $\bar{\mathbf{g}} = \bar{A}\mathbf{s}_0 + \mathbf{b}$. An explicit solution to (13.336) is found by solving

$$\frac{\partial}{\partial A} \left\{ \frac{1}{\sigma_n^2} \|\mathbf{g} - A\mathbf{s}_0 - \mathbf{b}\|^2 + \frac{(A - \bar{A})^2}{\sigma_A^2} \right\} = 0, \quad (13.337)$$

leading to

$$\hat{A}_{\text{MAP}} = \left[\|\mathbf{s}_0\|^2 + \frac{\sigma_n^2}{\sigma_A^2} \right]^{-1} \left[(\mathbf{g} - \mathbf{b})^t \mathbf{s}_0 + \left(\frac{\sigma_n^2}{\sigma_A^2} \right) \bar{A} \right] = C_A [(\mathbf{g} - \mathbf{b})^t \mathbf{s}_0 + \bar{A}'], \quad (13.338)$$

where \bar{A}' is the average amplitude scaled by the ratio of the noise to amplitude variances. In this simple Gaussian case the MAP estimate is linear in the data. It is determined by subtracting the known background from the data, matched filtering with the signal, adding in the scaled mean signal amplitude, and rescaling again. We can see from (13.338) how the relative strengths of the noise and parameter variances influence the MAP estimate.

Recall that the SKE classification problem in Gaussian noise leads to an optimal discriminant that is linear in the data [cf. (13.110) and (13.115)]; similarly we find here that a signal of Gaussian amplitude embedded in Gaussian noise is optimally estimated in a MAP sense through linear estimation.

Example: Random background level Now consider the problem in which we have a signal of nonrandom, known amplitude A on a random background \mathbf{b} . The background has uniform level $b_m = b$ for all m , with b distributed according to $\mathcal{N}(\bar{b}, \sigma_b^2)$. The MAP estimate for the background level is found by solving

$$\frac{\partial}{\partial b} \left\{ \frac{1}{\sigma_n^2} \|\mathbf{g} - A\mathbf{s}_0 - \mathbf{b}\|^2 + \frac{(b - \bar{b})^2}{\sigma_b^2} \right\} = 0, \quad (13.339)$$

which gives

$$\hat{b}_{\text{MAP}} = \left(M + \frac{\sigma_n^2}{\sigma_b^2} \right)^{-1} \left[\sum_m (\mathbf{g} - A\mathbf{s}_0)_m + \left(\frac{\sigma_n^2}{\sigma_b^2} \right) \bar{b} \right] \equiv C_b \left[\sum_m (\mathbf{g} - A\mathbf{s}_0)_m + \bar{b}' \right], \quad (13.340)$$

where \bar{b}' is the average background level multiplied by the ratio of noise to background variances. The MAP estimation procedure starts with the expected value for the background level, scales it by the ratio of the noise and background variances, does a correction that depends on the sum of the differences in each detector element between the actual data and what is expected given the signal, and finally rescales. Like the amplitude estimate of (13.338), the background estimate is also linear in the data.

Note that the M in (13.340) is the dimensionality of the data vector, or the number of detector elements. When this number is much greater than σ_n^2/σ_b^2 , (13.340) reduces to

$$\hat{b}_{\text{MAP}} \approx \frac{1}{M} \sum_m (\mathbf{g} - A\mathbf{s})_m. \quad (13.341)$$

In this case the optimal strategy is to first subtract off the known signal and then find the average data value. In most instances we would expect M to be quite large relative to σ_n^2/σ_b^2 ; otherwise the noise variance would have to be very large relative to the fluctuations in the random background level. We would not use (13.341) only when the prior knowledge is very strong, meaning σ_b^2 is so small that even when it is multiplied by M it is still comparable to σ_n^2 . In general, the availability of M independent measurements for use in estimating the single number b renders the prior knowledge useless relative to the quality of the data as M gets large.

Example: Random amplitude and background level Now let us take up the multi-parameter estimation problem in which both the signal amplitude and background level are random. If we make the assumption that A and b are independent, the MAP solution is found by simultaneously solving (13.337) and (13.339) for the two unknown parameters. The solutions are given by the same expressions for \hat{A}_{MAP} and $\hat{\mathbf{b}}_{\text{MAP}}$ we gave in (13.338) and (13.340), only now the parameter fixed in each solution is replaced by a MAP estimate. Thus

$$\hat{A}_{\text{MAP}} = C_A \left[(\mathbf{g} - \hat{\mathbf{b}}_{\text{MAP}})^t \mathbf{s} + \bar{A}' \right] \quad (13.342a)$$

and

$$\hat{b}_{\text{MAP}} = C_b \left[\sum_m (\mathbf{g} - \hat{A}_{\text{MAP}} \mathbf{s})_m + \bar{b}' \right]. \quad (13.342b)$$

The reader can show that the MAP estimates are now given by

$$\hat{A}_{\text{MAP}} = \left[1 - C_A C_b (s_{\text{tot}})^2 \right]^{-1} C_A \left[\mathbf{g}^t \mathbf{s} + \bar{A}' - C_b (g_{\text{tot}} + \bar{b}') s_{\text{tot}} \right] \quad (13.343a)$$

and

$$\hat{b}_{\text{MAP}} = \left[1 - C_A C_b (s_{\text{tot}})^2 \right]^{-1} C_b \left[g_{\text{tot}} + \bar{b}' - C_A (\mathbf{g}^t \mathbf{s} + \bar{A}') s_{\text{tot}} \right], \quad (13.343b)$$

where $g_{\text{tot}} = \sum_m g_m$ and $s_{\text{tot}} = \sum_m s_m$ are the sums of the data and signal components, respectively. Note that, while the data appear twice in each of the estimators given in (13.343), the estimates are still linear in the data. It can be shown that the optimal estimator (in a minimum mean-square error sense) is always linear if the object and the noise obey Gaussian statistics, regardless of the dimensionality

of the problem (Van Trees, 1968). The resulting parameter estimates are Gaussian distributed and therefore easy to characterize in terms of bias, variance, and so on.

In contrast, we found in Sec. 13.2.11 that the detection of a random Gaussian signal on a random Gaussian background gives a discriminant function that is non-linear in the data, owing to the fact that the data covariance matrices cannot be the same under the two hypotheses (with the exception of the low-contrast limit). The decision variable in that problem is not Gaussian distributed, unlike the estimates we just derived.¹⁵

Adding in the imaging operator In the above examples, the signal and background components of \mathbf{g} were expressed in the data domain without concern for how these entities came to be in that space. We now reconsider the MAP estimation problem when the data are derived from a continuous-to-discrete imaging system. Our goal is to see the role the imaging system plays in the form of the estimator in that case.

Consider a linear imaging model, $\mathbf{g} = \mathcal{H}\mathbf{f}(\boldsymbol{\theta}) + \mathbf{n}$, with $\mathbf{n} \sim \mathcal{N}_M(\mathbf{0}, \mathbf{K}_n)$, so that the conditional PDF on the data is given by

$$\begin{aligned} \text{pr}[\mathbf{g}|\mathbf{f}(\boldsymbol{\theta})] &= \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \\ &= (2\pi)^{-M/2} [\det(\mathbf{K}_n)]^{-1/2} \exp \left\{ -\frac{1}{2} [\mathbf{g} - \mathcal{H}\mathbf{f}(\boldsymbol{\theta})]^t \mathbf{K}_n^{-1} [\mathbf{g} - \mathcal{H}\mathbf{f}(\boldsymbol{\theta})] \right\}. \end{aligned} \quad (13.344)$$

The parameter could be signal size, amplitude, location, etc. We again assume that the parameter vector is normally distributed according to (13.335). By (13.333), the MAP estimate is found by minimizing

$$[\mathbf{g} - \mathcal{H}\mathbf{f}(\boldsymbol{\theta})]^t \mathbf{K}_n^{-1} [\mathbf{g} - \mathcal{H}\mathbf{f}(\boldsymbol{\theta})] + (\boldsymbol{\theta} - \bar{\boldsymbol{\theta}})^t \mathbf{K}_\theta^{-1} (\boldsymbol{\theta} - \bar{\boldsymbol{\theta}}) \quad (13.345)$$

with respect to $\boldsymbol{\theta}$.

Let us return to the problem of signal-amplitude uncertainty, so that the object is $f(\mathbf{r}) = Af_s(\mathbf{r}) + f_b(\mathbf{r})$. We shall assume that the imaging operator \mathcal{H} is linear and therefore object-independent. We further assume that \mathcal{H} is a CD operator, with $\bar{g}_m = (\mathcal{H}\mathbf{f})_m$. Not surprisingly, when the noise is again assumed to be i.i.d. Gaussian, the MAP estimate of the signal amplitude is given by [cf. (13.338)]

$$\hat{A}_{\text{MAP}} = \left[\|\mathcal{H}\mathbf{f}_s\|^2 + \frac{\sigma_n^2}{\sigma_A^2} \right]^{-1} \left[(\mathbf{g} - \mathcal{H}\mathbf{f}_b)^t \mathcal{H}\mathbf{f}_s + \left(\frac{\sigma_n^2}{\sigma_A^2} \right) \bar{A} \right]. \quad (13.346)$$

More generally, when the noise is correlated, we find

$$\hat{A}_{\text{MAP}} = \left[(\mathcal{H}\mathbf{f}_s)^t \mathbf{K}_n^{-1} \mathcal{H}\mathbf{f}_s + \frac{1}{\sigma_A^2} \right]^{-1} \left[(\mathbf{g} - \mathcal{H}\mathbf{f}_b)^t \mathbf{K}_n^{-1} \mathcal{H}\mathbf{f}_s + \left(\frac{\bar{A}}{\sigma_A^2} \right) \right]. \quad (13.347)$$

Other MAP problems and priors Problems involving other types of parameter uncertainty, such as location, scale, or frequency, using different forms for the PDFs in (13.333), can be solved to determine the resulting MAP estimators by following the steps outlined in the previous examples. We have considered Gaussian PDFs for the data and parameters in the examples we have presented for their ease of

¹⁵While strictly speaking the decision variable is non-Gaussian, we argued that it is approximately Gaussian in some cases by way of the central-limit theorem.

manipulation in making the concepts more concrete. However, we recognize the artificiality of this assumption in many problems. A Gaussian model for the amplitude of a signal implies that the amplitude can take on negative values. Perhaps we can justify this model by claiming we are interested in objects that have either positive or negative contrast relative to the average background. However, allowing the background to also have the possibility of negative values is less appealing on physical grounds. At best, we need to assume that \bar{b} is large enough, and σ_b^2 sufficiently small that the probability of a negative background is negligible. Alternative prior models for random objects that have been suggested for imaging applications are presented in Chap. 8.

MAP estimation is applicable when the parameters to be estimated are random as well as nonrandom. For random parameters, the prior $\text{pr}(\boldsymbol{\theta})$ describes the distribution of parameter values that would be observed over repeated samples. When the parameters are assumed to be nonrandom, $\text{pr}(\boldsymbol{\theta})$ is a description of our belief that the nonrandom parameters take on any particular value. The prior serves to bias the estimate toward our expectation of the underlying parameter, before collecting data.

In the absence of prior information, or in deference to the quality of the data, one might eschew the use of a prior altogether. This is one avenue leading to the approach referred to as maximum-likelihood estimation, a method we now consider.

13.3.4 Maximum-likelihood estimation

Maximum-likelihood or *ML* estimation uses the following rule to determine the underlying parameters:

$$\hat{\boldsymbol{\theta}}_{\text{ML}} \equiv \underset{\boldsymbol{\theta}}{\text{argmax}} \text{pr}(\mathbf{g}|\boldsymbol{\theta}). \quad (13.348)$$

This procedure can be written equivalently as [*cf.* (13.333)]

$$\hat{\boldsymbol{\theta}}_{\text{ML}} = \underset{\boldsymbol{\theta}}{\text{argmax}} \ln[\text{pr}(\mathbf{g}|\boldsymbol{\theta})]. \quad (13.349)$$

As stated in the previous section, ML estimation can be considered as a limit to MAP estimation when the prior $\text{pr}(\boldsymbol{\theta})$ is sufficiently broad that $\text{pr}(\mathbf{g}|\boldsymbol{\theta})\text{pr}(\boldsymbol{\theta})$ is dominated by $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$. However, ML estimation is much more than a limiting form of MAP estimation. As we shall see, ML estimation is a powerful procedure in its own right, owing to the unique properties of ML estimates.

Example: Poisson data revisited Consider once again the estimation of the rate parameter of a Poisson process. The conditional PDF of the data has the form given in (13.329). The ML estimate of a is obtained by solving

$$0 = \frac{\partial}{\partial a} \ln \text{pr}(\mathbf{g}|a) = \sum_{m=1}^M \frac{\partial}{\partial a} (-a + n_m \ln a + \text{const}), \quad (13.350)$$

which leads to

$$\hat{a}_{\text{ML}} = \frac{1}{M} \sum_{m=1}^M n_m. \quad (13.351)$$

The ML estimate is the sample mean, which can be compared to the MAP and MMSE results found earlier.

Example: Mean of a Gaussian process Suppose we are given a data vector \mathbf{g} that contains M i.i.d. samples of a Gaussian process with mean μ and variance σ^2 . Our goal is to form an ML estimate of the underlying mean μ .

The conditional PDF of the data is given by

$$\text{pr}(\mathbf{g}|\mu) = \prod_{m=1}^M \left(\frac{1}{2\pi\sigma^2} \right)^{\frac{1}{2}} \exp \left[-\frac{1}{2} \frac{(g_m - \mu)^2}{\sigma^2} \right]. \quad (13.352)$$

The estimate is found by solving (13.349), which in this case becomes

$$0 = \frac{\partial}{\partial \mu} \ln \text{pr}(\mathbf{g}|\mu) = \sum_{m=1}^M \frac{\partial}{\partial \mu} \left[C - \frac{1}{2} \frac{(g_m - \mu)^2}{\sigma^2} \right] = \sum_{m=1}^M \frac{(g_m - \mu)}{\sigma^2}, \quad (13.353)$$

leading to

$$\hat{\mu}_{\text{ML}} = \frac{1}{M} \sum_{m=1}^M g_m. \quad (13.354)$$

We see that the ML estimate is the sample mean, which is the most likely approach someone would use without any knowledge of statistics! This is a common finding (it seems to us) in ML estimation.

Since the estimate of (13.354) is a linear function of the Gaussian data, it too is Gaussian distributed. Note also that $\bar{\mu}_{\text{ML}} = \mu$, so the estimate is unbiased. It is left to the reader to show that

$$\sigma_{\hat{\mu}}^2 = \langle (\hat{\mu} - \bar{\mu})^2 \rangle = \frac{\sigma^2}{M}. \quad (13.355)$$

The greater the number of samples used to form the estimate, the smaller the variance in the result. When a single sample is used, the variance in the ML estimate is the variance in the sample.

Multivariate ML estimation in the Gaussian case Suppose we are given data contaminated by Gaussian noise so that the likelihood of the data takes the form given in (13.334). When the noise is correlated, the ML estimate can be determined from (13.349) to be

$$\hat{\boldsymbol{\theta}}_{\text{ML}} = \underset{\boldsymbol{\theta}}{\text{argmin}} [\mathbf{g} - \bar{\mathbf{g}}(\boldsymbol{\theta})]^t \mathbf{K}_{\mathbf{n}}^{-1} [\mathbf{g} - \bar{\mathbf{g}}(\boldsymbol{\theta})], \quad (13.356)$$

which has the form of a weighted least-squares procedure. The presence of the inverse of the noise covariance matrix serves to weight the low-noise components preferentially in the formulation of the ML estimate. When the noise is uncorrelated, the ML estimate simplifies to

$$\hat{\boldsymbol{\theta}}_{\text{ML}} = \underset{\boldsymbol{\theta}}{\text{argmin}} \|\mathbf{g} - \bar{\mathbf{g}}(\boldsymbol{\theta})\|^2. \quad (13.357)$$

This expression is the well-known form of a least-squares estimator [*cf.* (1.191)]. We simply find the parameter vector that results in an expected data vector that most closely matches the data in hand in a mean-squared-error sense.

13.3.5 Likelihood and Fisher information

In all of the cost functions described in Sec. 13.3.1 we found that a central role is played by $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$. In ML estimation it is *the* quantity being maximized, but even in MAP estimation its role has some level importance that depends on the relative weight of the prior. The quantity $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$ means different things to different people. The frequentist interpretation is that it is a function of \mathbf{g} for fixed $\boldsymbol{\theta}$. Repeated observations can be used to determine the nature of this quantity for a given underlying object (parameter vector). Alternatively, $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$ can be viewed as a function of $\boldsymbol{\theta}$ for fixed \mathbf{g} . In this viewpoint $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$ is a measure of the likelihood of any $\boldsymbol{\theta}$ once the data are in hand. In this section we explore the likelihood function and functions of the likelihood in greater depth.

Score The *score* is a random vector that tells us how sensitive the likelihood is to changes in the parameters:

$$\mathbf{s}(\mathbf{g}) = \frac{\partial}{\partial \boldsymbol{\theta}} \text{pr}(\mathbf{g}|\boldsymbol{\theta}) = \frac{\partial}{\partial \boldsymbol{\theta}} \ln[\text{pr}(\mathbf{g}|\boldsymbol{\theta})]. \quad (13.358)$$

In words, the score is the gradient of the log-likelihood. Since the score is a function of the log-likelihood, which is a random variable through its dependence on \mathbf{g} , the score is also random. Note that $\langle \mathbf{s} \rangle_{\mathbf{g}|\boldsymbol{\theta}} = 0$, where $\langle \cdot \rangle_{\mathbf{g}|\boldsymbol{\theta}}$ denotes an average with respect to $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$:

$$\begin{aligned} \langle \mathbf{s} \rangle_{\mathbf{g}|\boldsymbol{\theta}} &= \int_{\infty} d^M g \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \frac{\partial}{\partial \boldsymbol{\theta}} \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \\ &= \frac{\partial}{\partial \boldsymbol{\theta}} \int_{\infty} d^M g \text{pr}(\mathbf{g}|\boldsymbol{\theta}) = \frac{\partial}{\partial \boldsymbol{\theta}} (1) = 0. \end{aligned} \quad (13.359)$$

Thus the score is a zero-mean random vector.

Our interest in the score and its properties stems from its close relationship to maximum-likelihood estimation. As the gradient of the log-likelihood, $\mathbf{s}(\mathbf{g}, \boldsymbol{\theta}) = 0$ when $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}(\mathbf{g})$. The process of finding the ML estimate is thus equivalent to determining the point in parameter space where all components of the score vanish.¹⁶ The score is useful more generally, though, as we shall see next.

Fisher information and performance bounds The covariance matrix of the score is called the *Fisher information matrix*:

$$\mathbf{F} = \langle \mathbf{s} \mathbf{s}^t \rangle_{\mathbf{g}|\boldsymbol{\theta}}. \quad (13.360)$$

The components of \mathbf{F} are given by

$$\begin{aligned} F_{jk} &= \left\langle \left[\frac{\partial}{\partial \theta_j} \ln \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \right] \left[\frac{\partial}{\partial \theta_k} \ln \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \right] \right\rangle_{\mathbf{g}|\boldsymbol{\theta}} \\ &= \int_{\infty} d^M g \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \left[\frac{1}{\text{pr}(\mathbf{g}|\boldsymbol{\theta})} \frac{\partial}{\partial \theta_j} \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \right] \left[\frac{1}{\text{pr}(\mathbf{g}|\boldsymbol{\theta})} \frac{\partial}{\partial \theta_k} \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \right]. \end{aligned} \quad (13.361)$$

¹⁶We are restricting our attention here to unconstrained ML estimation. Constraints such as positivity could lead to solutions away from the $\mathbf{s} = 0$ point.

We can rewrite (13.361) as

$$\begin{aligned}
 F_{jk} &= \int_{\infty} d^M g \frac{1}{\text{pr}(\mathbf{g}|\boldsymbol{\theta})} \left[\frac{\partial}{\partial \theta_j} \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \right] \left[\frac{\partial}{\partial \theta_k} \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \right] \\
 &= - \int_{\infty} d^M g \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \frac{\partial}{\partial \theta_j} \left[\frac{1}{\text{pr}(\mathbf{g}|\boldsymbol{\theta})} \frac{\partial}{\partial \theta_k} \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \right] \\
 &= - \int_{\infty} d^M g \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \frac{\partial^2}{\partial \theta_j \partial \theta_k} \ln \text{pr}(\mathbf{g}|\boldsymbol{\theta}) = - \left\langle \frac{\partial^2}{\partial \theta_j \partial \theta_k} \ln \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \right\rangle_{\mathbf{g}|\boldsymbol{\theta}}. \quad (13.362)
 \end{aligned}$$

Thus F_{jk} is the second derivative of the average log-likelihood, evaluated at $\boldsymbol{\theta}$. One interpretation, then, is that the components of the Fisher information matrix describe the degree of curvature of the average log-likelihood, which in turn gives an indication of the strength of the peak, or maximum, averaged over all data sets given the underlying parameter vector $\boldsymbol{\theta}$.

Consider an arbitrary (not necessarily ML) estimate $\hat{\boldsymbol{\theta}}(\mathbf{g})$. We assume the estimate is unbiased; if we define $\mathbf{a} = \hat{\boldsymbol{\theta}}(\mathbf{g}) - \boldsymbol{\theta}$ to be the estimation error, then $\langle \mathbf{a} \rangle_{\mathbf{g}|\boldsymbol{\theta}} = 0$ and $\langle \mathbf{a}\mathbf{a}^t \rangle = \mathbf{K}_{\hat{\boldsymbol{\theta}}}$. We can build a new random vector \mathbf{x} from the components of \mathbf{a} and \mathbf{s} :

$$\mathbf{x} = \begin{pmatrix} \mathbf{a} \\ \mathbf{s} \end{pmatrix} \quad \langle \mathbf{x}\mathbf{x}^t \rangle = \begin{pmatrix} \langle \mathbf{a}\mathbf{a}^t \rangle & \langle \mathbf{a}\mathbf{s}^t \rangle \\ \langle \mathbf{s}\mathbf{a}^t \rangle & \langle \mathbf{s}\mathbf{s}^t \rangle \end{pmatrix}, \quad (13.363)$$

where all averages are over the data conditioned on the true parameter $\boldsymbol{\theta}$. We already know the diagonal components of the covariance matrix \mathbf{x} ; we now show that $\langle \mathbf{s}\mathbf{a}^t \rangle = \langle \mathbf{a}\mathbf{s}^t \rangle = \mathbf{I}$:

$$\begin{aligned}
 \langle \mathbf{s}\mathbf{a}^t \rangle_{ij} &= \langle s_i(\hat{\theta}_j - \theta_j) \rangle = \langle s_i \hat{\theta}_j \rangle - \langle s_i \rangle \theta_j = \langle s_i \hat{\theta}_j \rangle \\
 &= \int d^M g \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \left[\frac{\partial}{\partial \theta_i} \ln \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \right] \hat{\theta}_j(\mathbf{g}) \\
 &= \int d^M g \hat{\theta}_j(\mathbf{g}) \frac{\partial}{\partial \theta_i} \text{pr}(\mathbf{g}|\boldsymbol{\theta}) = \frac{\partial \langle \hat{\theta}_j \rangle}{\partial \theta_i} = \frac{\partial \theta_j}{\partial \theta_i} = \delta_{ij}. \quad (13.364)
 \end{aligned}$$

Putting this result together with our knowledge of the covariance on \mathbf{a} and \mathbf{s} gives

$$\langle \mathbf{x}\mathbf{x}^t \rangle = \mathbf{K}_{\mathbf{x}} = \begin{pmatrix} \mathbf{K}_{\hat{\boldsymbol{\theta}}} & \mathbf{I} \\ \mathbf{I} & \mathbf{F} \end{pmatrix}. \quad (13.365)$$

We know that the determinant of any covariance matrix must be greater than or equal to zero; therefore $\mathbf{K}_{\mathbf{x}}$, $\mathbf{K}_{\hat{\boldsymbol{\theta}}}$, and \mathbf{F} are all positive-semidefinite. By definition, a positive-semidefinite matrix satisfies $\mathbf{u}^t \mathbf{K}_{\mathbf{x}} \mathbf{u} \geq 0$ for all nonzero vectors \mathbf{u} (see Sec. A.8.1). The same condition holds for quadratic forms involving a nonzero matrix \mathbf{U} in place of the vector \mathbf{u} (Harville, 1997): $\mathbf{U}^t \mathbf{K}_{\mathbf{x}} \mathbf{U} \geq 0$ when $\mathbf{K}_{\mathbf{x}}$ is positive-semidefinite. We now use this property to prove that $\mathbf{K}_{\hat{\boldsymbol{\theta}}} \geq \mathbf{F}^{-1}$.

We shall assume that there are P features to be estimated, so that $\mathbf{K}_{\hat{\boldsymbol{\theta}}}$ and \mathbf{F} are both $P \times P$ matrices. Let \mathbf{U} be a $2P \times 1$ matrix with

$$\mathbf{U} = \begin{pmatrix} c\mathbf{u}_1 \\ \mathbf{u}_2 \end{pmatrix}, \quad (13.366)$$

where the vectors \mathbf{u}_1 and \mathbf{u}_2 are both $P \times 1$ column vectors. The quadratic condition then becomes

$$(\mathbf{u}_1^t \ \mathbf{u}_2^t) \begin{pmatrix} \mathbf{K}_{\hat{\theta}} & \mathbf{I} \\ \mathbf{I} & \mathbf{F} \end{pmatrix} \begin{pmatrix} \mathbf{u}_1 \\ \mathbf{u}_2 \end{pmatrix} = \mathbf{u}_1^t \mathbf{K}_{\hat{\theta}} \mathbf{u}_1 + \mathbf{u}_1^t \mathbf{u}_2 + \mathbf{u}_2^t \mathbf{u}_1 + \mathbf{u}_2^t \mathbf{F} \mathbf{u}_2 \geq 0. \quad (13.367)$$

For any nonzero \mathbf{u}_1 , we can let $\mathbf{u}_2 = -\mathbf{F}^{-1} \mathbf{u}_1$. Then (13.367) becomes¹⁷

$$\mathbf{u}_1^t \mathbf{K}_{\hat{\theta}} \mathbf{u}_1 - \mathbf{u}_1^t \mathbf{F}^{-1} \mathbf{u}_1 - \mathbf{u}_1^t \mathbf{F}^{-1} \mathbf{u}_1 + \mathbf{u}_1^t \mathbf{F}^{-1} \mathbf{u}_1 \geq 0, \quad (13.368)$$

or

$$\mathbf{u}_1^t \mathbf{K}_{\hat{\theta}} \mathbf{u}_1 \geq \mathbf{u}_1^t \mathbf{F}^{-1} \mathbf{u}_1. \quad (13.369)$$

This inequality is proof that $\mathbf{K}_{\hat{\theta}} - \mathbf{F}^{-1}$ is positive-semidefinite (see Sec. A.11.2). The *Loewner convention* can be used to indicate that (13.369) holds by writing simply

$$\mathbf{K}_{\hat{\theta}} \geq \mathbf{F}^{-1}. \quad (13.370)$$

Consider the particular case where we let $\mathbf{u}_1 = \mathbf{e}_n$ be the column vector $\{0, \dots, 1, \dots, 0\}^t$ with n^{th} component equal to 1 and all other components equal to zero. In this case (13.370) reduces to

$$[\mathbf{K}_{\hat{\theta}}]_{nn} = \text{Var}\{\hat{\theta}_n - \theta_n\} \geq [\mathbf{F}^{-1}]_{nn}. \quad (13.371)$$

This inequality is the well-known *Cramér-Rao lower bound* on the variance of an estimator, after H. Cramér (1946) and C. R. Rao (1945). The unbiased estimate of the n^{th} parameter has a variance that must be at least as large as the n^{th} diagonal element of the inverse of the Fisher information matrix.

For a scalar parameter (13.371) reduces to

$$\text{Var}\{\hat{\theta} - \theta\} \geq \frac{1}{\left\langle \left[\frac{\partial}{\partial \theta} \ln \text{pr}(\mathbf{g}|\theta) \right]^2 \right\rangle}. \quad (13.372)$$

We can extend the CR bound to biased estimators by allowing the mean of \mathbf{a} to be nonzero in the preceding derivation. In this case (13.364) generalizes to

$$\langle \mathbf{sa}^t \rangle_{ij} = \frac{\partial \langle \hat{\theta}_j \rangle}{\partial \theta_i} = \frac{\partial}{\partial \theta_i} [(\langle \hat{\theta}_j \rangle - \theta_j) + \theta_j] = \frac{\partial b_j}{\partial \theta_i} + \delta_{ij}, \quad (13.373)$$

where b_j is a component of the bias vector as defined in (13.276), making $\partial b_j / \partial \theta_i$ the bias gradient. In vector form (13.373) becomes

$$\langle \mathbf{sa}^t \rangle = \nabla_{\theta} \mathbf{b} + \mathbf{I}. \quad (13.374)$$

Now (13.365) becomes

$$\langle \mathbf{xx}^t \rangle = \mathbf{K}_{\mathbf{x}} = \begin{pmatrix} \mathbf{K}_{\hat{\theta}} & \nabla_{\theta} \mathbf{b} + \mathbf{I} \\ (\nabla_{\theta} \mathbf{b} + \mathbf{I})^t & \mathbf{F} \end{pmatrix}, \quad (13.375)$$

¹⁷We are assuming here that \mathbf{F}^{-1} exists; Stoica and Marzetta (2001) provide an alternative theory for situations for which the Fisher matrix is singular.

and

$$\det [\mathbf{K}_{\hat{\theta}} \mathbf{F} - (\nabla_{\theta} \mathbf{b} + \mathbf{I})(\nabla_{\theta} \mathbf{b} + \mathbf{I})^t] \geq 0,$$

or

$$\mathbf{K}_{\hat{\theta}} \geq (\nabla_{\theta} \mathbf{b} + \mathbf{I}) \mathbf{F}^{-1} (\nabla_{\theta} \mathbf{b} + \mathbf{I})^t. \quad (13.376)$$

This inequality gives the lower bound on the variance achievable by *any* estimator. To add to our intuition, let us see what form (13.376) takes in the case of a scalar parameter. We find that

$$\text{Var}\{\hat{\theta} - \theta\} \geq \frac{\left(\frac{db(\theta)}{d\theta} + 1\right)^2}{\left\langle \left[\frac{\partial}{\partial \theta} \ln \text{pr}(\mathbf{g}|\theta)\right]^2 \right\rangle}. \quad (13.377)$$

It is interesting to compare this expression to (13.372). The bias of an estimator alters the lower bound on the variance by an amount that depends on the bias gradient. If the bias is independent of the parameter, no impact on the variance is felt. But, if the bias strongly depends on the parameter, the bound can change dramatically. Note that bias can also decrease the variance if the bias gradient is negative. Consider the scalar estimation problem where we choose an estimation strategy of always setting $\hat{\theta}$ to 3. Then $\partial b/\partial \theta = -1$ and the variance is zero. Thus bias does not uniformly increase variance. In all cases, though, the mean-squared error in $\hat{\theta}$ is inversely proportional to the average of the squared gradient of the log-likelihood.

The derivations of (13.371) and (13.376) rely on the assumption that the Fisher information matrix is nonsingular. Stoica and Marzetta (2001) have shown that a singular Fisher information matrix typically leads to estimates with infinite variance.

An estimator that achieves the bound of (13.376) is called *efficient*. As we shall prove below, when an efficient estimator exists, the ML estimator is efficient.

13.3.6 Properties of ML estimators

Maximum likelihood estimators offer multiple advantages for problems that can be categorized as well-posed. These are problems in which the number of parameters to be estimated is low relative to the amount of data available to form the estimate. Furthermore, the data are known to be influenced by the parameters in such a manner that we can unambiguously determine θ from the data in the noise-free case. Such are the problems we shall focus on in this section. We defer until Chap. 15 the contrasting situation we find ourselves in when attempting to reconstruct a continuous object from a discrete set of measurements, where there is a significant null space that confounds the use of ML methods.

In the early 1900s, R.A. Fisher wrote a series of papers in which he considered various criteria for the evaluation of estimator performance (Fisher, 1922, 1925, 1934, 1935). Chief among these criteria were: consistency, efficiency, and sufficiency.¹⁸ In this classical (non-Bayesian) approach, an estimate is assumed to be a

¹⁸While Fisher derived these criteria, and then proceeded to evaluate ML methods based upon them, it is interesting to note that the early history of the maximum-likelihood principle dates back to the late 18th and early 19th centuries, with contributions by Lagrange, Bernoulli, Gauss, and Laplace (Edwards, 1974).

random variable, through its dependence on the random data. The performance of the estimator is assessed using its sampling distribution, that is, the distribution of estimates obtained over repeated trials for the same underlying true parameter. For example, the bias (13.276) and the variance (13.279) are computed using the sampling distribution. Since these measures can be difficult to compute in some cases, an alternative approach is to consider bounds on estimator performance. This is the motivation for the development of the CR bound on variance presented in the previous section. While the CR bound was developed without regard to the form of the estimator, we shall see that it is particularly relevant to ML estimation.

Before we return to the topic of the CR bound on variance and its relationship to Fisher's criteria, we shall establish one of the properties of ML estimators that makes them exceedingly useful. Recall that up to this point we have restricted our attention to the direct estimation of a parameter vector θ . In what follows we shall expand our treatment to include estimation of *any* arbitrary function of the unknown θ . This extension is made eminently doable thanks to a powerful theorem in ML estimation.

ML estimation of a function of a parameter Let the true value of a parameter be θ , and the function we want to estimate be $\tau(\theta)$. If $\Theta = \tau(\theta)$, then (Scharf, 1991)

$$\hat{\Theta}_{\text{ML}} = \tau(\hat{\theta}_{\text{ML}}). \quad (13.378)$$

In words, the maximum-likelihood estimate of a function is the function of the maximum-likelihood estimate. This property of the ML estimator has been termed *invariance* (Tan and Drossos, 1975; Scharf, 1991). By this principle, all the discussion that follows on ML estimators applies to both direct parameter estimation and estimation of the function of an unknown parameter.

Efficiency According to (13.371), the variance of any unbiased estimator must exceed some minimum value greater than zero. If the bound is achieved, so that the equality in (13.371) holds, the estimator is said to be *efficient*. We now show that if the CR bound is attainable, it will be attained by an ML estimator. Without loss of generality, we consider the scalar case.

We can rewrite (13.372) as

$$\text{Var}\{\hat{\theta} - \theta\} \left\langle \left[\frac{\partial}{\partial \theta} \ln \text{pr}(\mathbf{g}|\theta) \right]^2 \right\rangle \geq 1$$

or

$$\left\{ \int_{\infty} d^M g \text{pr}(\mathbf{g}|\theta) [\hat{\theta}(\mathbf{g}) - \theta]^2 \right\} \left\{ \int_{\infty} d^M g \text{pr}(\mathbf{g}|\theta) \left[\frac{\partial}{\partial \theta} \ln \text{pr}(\mathbf{g}|\theta) \right]^2 \right\} \geq 1. \quad (13.379)$$

This expression is a restatement of the Schwarz inequality. The equality holds if and only if

$$\frac{\partial \ln \text{pr}(\mathbf{g}|\theta)}{\partial \theta} = \alpha(\theta) [\hat{\theta}(\mathbf{g}) - \theta], \quad (13.380)$$

where $\alpha(\theta)$ is a constant that depends on θ . Also, (13.380) must hold for all θ and \mathbf{g} .

The ML estimate is defined by the likelihood equation, (13.349), which we can rewrite as

$$\left. \frac{\partial \ln \text{pr}(\mathbf{g}|\theta)}{\partial \theta} \right|_{\theta=\hat{\theta}_{\text{ML}}} = 0. \quad (13.381)$$

Combining (13.380) and (13.381) gives

$$\alpha(\theta)[\hat{\theta}(\mathbf{g}) - \theta] \Big|_{\theta = \hat{\theta}_{\text{ML}}} = 0. \quad (13.382)$$

The data-dependent solution to (13.382) is to require that $\hat{\theta}(\mathbf{g}) = \hat{\theta}_{\text{ML}}$. Thus, if an efficient estimator exists, the ML estimator is efficient.

Sufficiency and uniqueness We found in Sec. 13.2 that the likelihood ratio is a sufficient statistic for hypothesis testing. It contains all the necessary information for performing the classification task. The concept of a sufficient statistic extends quite naturally to estimation tasks. In estimation, a sufficient statistic is one that captures all the essential features in the data necessary for optimal performance of a given estimation task. The maximum-likelihood estimator is a sufficient statistic for estimation; it makes optimal use of the information in the data. No other estimator can yield more information.

A necessary and sufficient condition for $\hat{\theta}$ to be a sufficient estimate is that the likelihood function must be factorable into the product

$$\text{pr}(\mathbf{g}|\theta) = \text{pr}(\hat{\theta}|\theta) f(\mathbf{g}), \quad (13.383)$$

where $f(\mathbf{g})$ is independent of θ . We leave it to the reader to show that this can be done for the case of Gaussian samples of unknown mean.

A sufficient estimator may exist even when an efficient estimator does not; efficiency is a stricter criteria than sufficiency. A sufficient estimator is unique; we can use a function of the sufficient statistic because it will also be sufficient, and we can choose it such that the estimate may be consistent (defined below) and unbiased.

In general there can be many solutions to (13.349) that give equal likelihood. This is especially the case in high-dimensional problems, there the null space can be infinite-dimensional. In Chap. 15 we explore the application of ML estimation to the high-dimensional problem of image reconstruction; as we shall see there, prior information or smoothness conditions can be introduced to address the nonuniqueness of the ML estimate.

Asymptotic properties Asymptotic properties of an estimate describe the behavior of the estimate as the number of observations approaches infinity. Suppose an estimate based on the data vector \mathbf{g} is denoted $\hat{\theta}_M(\mathbf{g})$, where the data are M independent observations or samples. The estimate is *conditionally consistent* if, for any arbitrarily small, positive ϵ and α , there exists an N such that

$$\text{Pr} \left[\|\hat{\theta}_M(\mathbf{g}) - \theta\| < \epsilon \mid \theta \right] > 1 - \alpha \quad (13.384)$$

for all $M > N$. An estimate is *unconditionally consistent* when (13.384) is true for all θ . This property is called *stochastic convergence*, or *convergence in probability*. Cramér proved that, under reasonably general conditions, an ML estimate is consistent. The density function for a consistent estimate becomes increasingly narrow about the value of the underlying parameter as the number of samples increase. For example, we found that the ML estimate of the variance of a Gaussian process [cf. (13.354)] is proportional to $1/M$.

An example of an estimate that is not consistent is the sample power spectrum. For a single record, an increase in the number of samples (an increase in the record length) does not increase the probability that the estimate of the power spectrum is within ϵ of the true power spectrum. For an example, see Fig. 8.1.

While we might know that an estimate is consistent, that knowledge tells us nothing regarding its behavior for a finite set of observations. Consistency is a property that applies to the estimate as $M \rightarrow \infty$.

The relationship between bias and consistency is not as strong as it appears. A consistent estimator is not necessarily unbiased, and an unbiased estimate is not necessarily consistent. However, a consistent estimator whose asymptotic distribution has finite mean must be asymptotically unbiased.

We have established that the ML estimate is efficient, if an efficient estimator exists. ML estimates achieve the equality sign in the bound given by (13.371) as the number of samples goes to infinity; that is, ML estimates are asymptotically efficient.

When estimates satisfy (13.371), they are said to demonstrate *minimum variance*. Moreover, in the limit of a large number of samples, Fisher showed that an efficient estimate is one whose sampling distribution approaches a minimum-variance Gaussian (Fisher, 1922). Thus an ML estimate is asymptotically Gaussian distributed with minimum variance. It can be shown that, for a large class of consistent statistics, the sampling distribution of the ML estimate is approximately Gaussian as the number of observations increases because of the central-limit theorem (Cramér, 1946). The asymptotic Gaussian nature of ML estimates provides tremendous ease in understanding their properties, even for those ML estimates that are not efficient.

In summary, ML estimates are asymptotically unbiased, efficient, normally distributed and consistent.

Other bounds When ML estimates are not normally distributed, the Cramér-Rao bound may not be a good predictor of the variance of the estimates. For example, in problems where the data are nonlinearly related to the parameter and the noise is high, Müller *et al.* (1995) have shown that the CR bound is not a good measure of the variance of the estimates. Abbey *et al.* (1998) demonstrated how a non-Gaussian density on the estimates can be approximated starting with a Taylor series expansion about the true parameter vector. The isocontours of the resulting approximate densities were shown to capture the skewed distributions of the estimates quite well. This approach was subsequently applied to the estimation of parameters from phase-shifting interferometer/ellipsometer data by Rogala (1999).

Alternatives to the Cramér-Rao bound have been explored for the characterization of estimates. The *Bhattacharyya bound* (Bhattacharyya, 1946, 1947, 1948) has received significant attention, but it can be challenging to compute. While the Cramér-Rao bound involves the calculation of second-order partial derivatives of the likelihood, the Bhattacharyya bound involves higher partial derivatives (Van Trees, 1968).

Another alternative is the *Barankin bound* (Barankin, 1949), which has the advantage that it gives a greatest lower bound and it does not require that the underlying PDFs be differentiable. Barankin demonstrated that an unbiased estimator that achieves the Barankin bound must exist if an unbiased estimator exists. McAulay and Hofstetter (1971) evaluated the performance of the Barankin bound

for estimation of vector parameters in additive white Gaussian noise; while the Barankin bound reduced to the Cramér-Rao bound when the SNR was high, large differences between these bounds were exhibited in other regimes. Kijewski *et al.* (1992) compared CR and Barankin bounds on estimates of lesion parameters in simulated nuclear medicine images for the purpose of collimator optimization. This approach is limited since the Barankin bound is infinite if no unbiased estimator exists (Müller, 1995; Abbey and Denny, 1996). The difficulty in practice is thus in knowing whether an unbiased estimator exists.

If no efficient estimate exists, an unbiased estimator with lower variance might exist. The difficulty comes in knowing how to find it. A significant advantage of ML estimation is that it is straightforward.

13.3.7 Other classical estimators

We have described Bayesian estimation in general and determined the resulting estimators for a variety of cost functions. We then explored ML estimation in considerable detail. The full Bayesian approach requires that the cost function as well as the prior probability of the random parameters and their likelihood function be completely specified. The ML approach does not require a prior, but it still requires full knowledge of the likelihood function. In this section we consider some other estimation methods and their properties.

Linear estimators Linear estimation is always much easier mathematically than general, nonlinear estimation. Sometimes it is even optimal. As we shall see, there is a parallel between linear classification strategies and requirements for their optimality and optimality conditions for linear estimators. In this section we shall present basic properties of some well-known linear estimation strategies. We shall limit the discussion here to basic theory, without reference to specific applications. In particular, while image reconstruction is frequently formulated as a linear estimation problem, the high dimensionality of this application requires an understanding of the specific role played by null functions of the imaging system in the assessment of the estimator. In Chap. 15 we discuss linear and nonlinear image reconstruction algorithms in great detail. Thus we shall defer to that chapter further discussion of linear image reconstruction.

A linear estimator is one that takes the general form $\hat{\boldsymbol{\theta}} = \mathbf{W}^t \mathbf{g}$, where \mathbf{g} is an $M \times 1$ data vector and \mathbf{W} is a $M \times P$ estimator matrix. The P columns of \mathbf{W} represent templates that each yield a parameter estimate. For example, a region-of-interest (ROI) estimator is realized by a column vector \mathbf{w} defined on the space of voxels, where the elements corresponding to voxels in the region of interest take on the value 1, and voxels outside this region are taken as 0.

The forms of the bias and variance of $\hat{\boldsymbol{\theta}}$ are straightforward for a linear estimator. Assuming that $\boldsymbol{\theta}$ is zero mean,¹⁹ we can write the ensemble mean-square error as

$$\text{EMSE} = \langle \|\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}\|^2 \rangle_{\mathbf{g}, \boldsymbol{\theta}} = \langle (\mathbf{W}^t \mathbf{g} - \boldsymbol{\theta})^t (\mathbf{W}^t \mathbf{g} - \boldsymbol{\theta}) \rangle_{\mathbf{g}, \boldsymbol{\theta}}. \quad (13.385)$$

¹⁹This assumption does not limit the generality of the treatment in any way; for nonzero-mean parameters we can always define new parameters with zero mean by simply subtracting off the mean.

We can use calculus of variations to find the \mathbf{W} that gives minimum EMSE. Let $\mathbf{W}' = \mathbf{W} + \epsilon \mathbf{V}$. The optimal \mathbf{W} is found by solving

$$\left. \frac{\partial(\text{EMSE})}{\partial \epsilon} \right|_{\epsilon=0} = 0. \quad (13.386)$$

This leads to the requirement that

$$\langle (\mathbf{V}^t \mathbf{g})^t (\mathbf{W}^t \mathbf{g} - \boldsymbol{\theta}) \rangle_{\mathbf{g}, \boldsymbol{\theta}} = 0. \quad (13.387)$$

This expression is a condition on the optimal \mathbf{W} for all possible \mathbf{V} , including the case $\mathbf{V} = \mathbf{W}$. In that case

$$\langle (\mathbf{W}^t \mathbf{g})^t (\mathbf{W}^t \mathbf{g} - \boldsymbol{\theta}) \rangle_{\mathbf{g}, \boldsymbol{\theta}} = 0, \quad (13.388)$$

which says that the error $\mathbf{W}^t \mathbf{g} - \boldsymbol{\theta}$ must be orthogonal to the estimate $\hat{\boldsymbol{\theta}} = \mathbf{W}^t \mathbf{g}$, when averaged over all sources of randomness. When this condition is satisfied, minimum mean-square error is achieved.

We have derived a condition for the EMSE to reach a minimum. Now we shall derive a form of the estimator \mathbf{W} that achieves this performance. First, we rewrite the condition of (13.387) as

$$\begin{aligned} \left\langle \text{tr} [(\mathbf{W}^t \mathbf{g} - \boldsymbol{\theta})(\mathbf{V}^t \mathbf{g})^t] \right\rangle_{\mathbf{g}|\boldsymbol{\theta}} \Big|_{\boldsymbol{\theta}} &= \text{tr} \left[\mathbf{V} \left\langle \langle (\mathbf{W}^t \mathbf{g} - \boldsymbol{\theta}) \mathbf{g}^t \rangle_{\mathbf{g}|\boldsymbol{\theta}} \right\rangle_{\boldsymbol{\theta}} \right] \\ &= \text{tr} \left[\mathbf{V} \langle \mathbf{W}^t \mathbf{K}_{\mathbf{g}|\boldsymbol{\theta}} - \boldsymbol{\theta} \bar{\mathbf{g}}_{\boldsymbol{\theta}}^t \rangle_{\boldsymbol{\theta}} \right] = 0, \end{aligned} \quad (13.389)$$

where $\bar{\mathbf{g}}_{\boldsymbol{\theta}}$ denotes the average data vector conditioned on the underlying parameter $\boldsymbol{\theta}$ and $\mathbf{K}_{\mathbf{g}|\boldsymbol{\theta}}$ is the data covariance matrix when the underlying parameter is $\boldsymbol{\theta}$.

The last step we must take to find the form of the minimum EMSE estimator is to average the conditional quantities in (13.389) over the prior probability density on $\boldsymbol{\theta}$, obtaining

$$\text{tr} \left[\mathbf{V} (\mathbf{W}^t \bar{\mathbf{K}}_{\mathbf{g}} - \mathbf{K}_{\bar{\mathbf{g}}, \boldsymbol{\theta}}) \right] = 0, \quad (13.390)$$

where $\bar{\mathbf{K}}_{\mathbf{g}}$ is the covariance of the data averaged over $\boldsymbol{\theta}$, and $\mathbf{K}_{\bar{\mathbf{g}}, \boldsymbol{\theta}}$ is the cross-covariance of $\boldsymbol{\theta}$ and $\bar{\mathbf{g}}_{\boldsymbol{\theta}}$.

Since (13.390) must hold for all \mathbf{V} , the linear estimator \mathbf{W} that achieves minimum mean-square error is given by

$$\mathbf{W}^t = \mathbf{K}_{\bar{\mathbf{g}}, \boldsymbol{\theta}} \bar{\mathbf{K}}_{\mathbf{g}}^{-1}. \quad (13.391)$$

An estimator of this form is often referred to as a Wiener estimator (Wiener, 1942) or the Wiener-Helstrom estimator (Helstrom, 1967), although it is more commonly encountered as a ratio of power spectra for applications where the data are assumed to be continuous and stationary.

We have shown that the Wiener estimator is the linear estimator that achieves minimum EMSE. In the case of jointly Gaussian data, the Wiener estimator achieves minimum EMSE of all estimators. (In this special case the Wiener estimator is the posterior mean given in (13.312).)

Recall from Sec. 13.2 that for classification problems where knowledge of the full joint probability on the data is not available, we often can compute the first- and second-order statistics of the data. Then we can determine the performance of the Hotelling observer for the task. If the data are truly Gaussian distributed, the

Hotelling observer is the overall optimal observer in an SNR sense. Analogously, when our knowledge is limited to the first and second order statistics of the data, we can determine the optimal linear estimator, that is, the Wiener estimator. If the data are truly Gaussian, this estimator achieves minimum EMSE of all estimators.

Best linear unbiased estimators A *best linear unbiased estimator*, or *BLUE*, achieves the minimum conditional variance among all unbiased estimators constrained to be linear. Unlike the Wiener estimator, a BLUE takes no account of object variability. Rather, it minimizes the conditional variance of $\hat{\theta}$ for a given \mathbf{f} ; it minimizes MSE, not EMSE. This estimator is also referred to as the Gauss-Markov estimator. When the data covariance is large, the Wiener estimator approaches the Gauss-Markov estimator.

Most texts on estimation derive mathematical expressions for Gauss-Markov estimates for problems involving data linearly related to the underlying parameter according to the model $\mathbf{g} = \mathbf{H}\boldsymbol{\theta} + \mathbf{n}$. We have deliberately avoided examples of this form because they are not directly applicable to estimation of object parameters such as tumor size or activity. However, this data model is the basis for many image reconstruction approaches, as we discuss in great detail in Chap. 15.

Uniformly minimum-variance unbiased estimates A minimum-variance estimate is one that achieves a variance less than that of any other estimate. *Uniformly minimum-variance unbiased estimates*, or *UMVU* estimates, are unbiased and have minimum variance among all unbiased estimates, hence the name. UMVU estimates are usually unique. They may or may not be linear. Rade and Westergren (1990) suggest two approaches for the determination of an UMVU estimate. The first is to find an unbiased estimator that is a function of a complete sufficient statistic. Such an estimate is automatically the minimum variance estimator. As Cox and Hinkley (1994) put it, any function of a complete sufficient statistic is the unique minimum-variance estimator of its expectation. The second approach is to find an unbiased estimate $\hat{\theta}$ and solve for its expectation conditioned on the sufficient statistic.

Rade and Westergren provide a table of parameters and their UMVU estimates, along with the variance of the estimate, for a variety of parameter distributions.

13.3.8 Nuisance parameters

Thus far, our treatment of estimation theory has assumed that we are given data \mathbf{g} from some known probability law $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$ and that we want to estimate a parameter $\boldsymbol{\theta}$ that fully determines the PDF. We have ignored the fact that this assumption is often not valid. Here we consider the role of *nuisance parameters*, which we are not interested in estimating but which must be stated in order for the PDF on the data to be fully specified.

Definition of nuisance parameters Suppose that the PDF on \mathbf{g} is fully determined by the PD vector of parameters of interest $\boldsymbol{\theta}$ and some complementary LD vector of parameters $\boldsymbol{\theta}_n$, called a nuisance vector. We define a nuisance parameter as any parameter that does not influence the overall cost, or Bayes risk (see Sec. 13.3.1).

Consider the problem of estimating depth of interaction as well as energy and lateral position of a high-energy photon absorbed in a semiconductor detector. If

the photons arrive normal to the detector surface, as with a collimator, depth of interaction z is a nuisance parameter, carrying no useful information about the photon fluence. This is unfortunate since we have a good objective prior (the exponential absorption law) on z and could do a fairly good job of estimating it (see Sec. 13.3.3). The question is, would an estimate of z be a good thing to have? To answer this question, we must determine the impact of having an estimate of z on the overall cost, relative to other approaches we might take toward z .

There are basically four ways we might deal with nuisance parameters:

- (1) Replace $\boldsymbol{\theta}_n$ with some typical value $\boldsymbol{\theta}_0$, so that $\text{pr}(\mathbf{g}|\boldsymbol{\theta}) \approx \text{pr}(\mathbf{g}|\boldsymbol{\theta}, \boldsymbol{\theta}_{n0})$.
- (2) Ignore the problem and assume a form for $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$.
- (3) Estimate $\boldsymbol{\theta}_n$.
- (4) Assume some prior and marginalize over $\boldsymbol{\theta}_n$.

We shall consider each of these approaches in turn.

The first option, replacing $\boldsymbol{\theta}_n$ with some typical value $\boldsymbol{\theta}_{n0}$, amounts to taking $\text{pr}(\boldsymbol{\theta}_n)$ as a delta function—a very strong prior! This approach sounds extreme but in fact is often used in imaging with little or no justification. For example, in SPECT (single-photon emission computed tomography, treated in detail in Chap. 17), scatter correction is often performed using an assumed scatter coefficient at each location; this is a nuisance parameter when the activity at each location is to be estimated.

The second approach often taken is to ignore the problem altogether and assume some form for $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$. This approach sounds even more extreme, but it describes the approach being taken when image reconstruction is done using a discrete object model and the modeling errors are ignored.

The third approach is to estimate both $\boldsymbol{\theta}$ and $\boldsymbol{\theta}_n$, in hopes that doing so will improve the estimate of $\boldsymbol{\theta}$. Note that many times $\boldsymbol{\theta}_n$ is infinite-dimensional, so that this approach is not realizable. Suppose, however, that it is possible to estimate $\boldsymbol{\theta}_n$. We can show how having to estimate the nuisance parameters affects our ability to estimate the parameters of interest, in terms of the variance of the estimate.

From (13.372) we know that the variance on an estimate of any parameter θ_p is bounded according to $\text{Var}\{\hat{\theta}_p\} \geq [\mathbf{F}^{-1}]_{pp}$, where \mathbf{F} is the $P \times P$ Fisher information matrix for $\boldsymbol{\theta}$. If only 1 of the P parameters is unknown and in need of estimation, then the bound on that estimate is given by (13.373). That is, $\text{Var}\{\hat{\theta}_p\} \geq 1/\mathbf{F}_{pp}$ bounds the estimate on the p^{th} parameter when all the other parameters, presumed for this discussion to be nuisance parameters, are known. We can use the extended Cauchy-Schwarz inequality of (A.192) to write

$$|\mathbf{a}^t \mathbf{b}|^2 \leq (\mathbf{a}^t \mathbf{F} \mathbf{a})(\mathbf{b}^t \mathbf{F}^{-1} \mathbf{b}), \quad (13.392)$$

since \mathbf{F} is positive-definite. If we let $\mathbf{a} = \mathbf{b} = \mathbf{e}_p$, the column vector $\{0, \dots, 1, \dots, 0\}^t$ with the p^{th} component equal to 1 and all other components equal to zero, we obtain

$$|\mathbf{e}_p^t \mathbf{e}_p|^2 \leq (\mathbf{F}_{pp})(\mathbf{F}^{-1})_{pp}. \quad (13.393)$$

The left side is equal to 1, giving

$$\frac{1}{(\mathbf{F}_{pp})} \leq (\mathbf{F}^{-1})_{pp}. \tag{13.394}$$

Thus the bound on the variance for the parameter estimated in the absence of nuisance parameters is lower than the bound that is active in the presence of nuisance parameters.

Now let us consider the fourth option, which is to assume some prior $\text{pr}(\boldsymbol{\theta}_n)$ on the nuisance parameters and form the marginalized likelihood:²⁰

$$\text{pr}(\mathbf{g}|\boldsymbol{\theta}) = \int_{\infty} d\boldsymbol{\theta}_n \text{pr}(\mathbf{g}|\boldsymbol{\theta}, \boldsymbol{\theta}_n) \text{pr}(\boldsymbol{\theta}_n|\boldsymbol{\theta}), \tag{13.395}$$

where now all P elements of $\boldsymbol{\theta}$ are unknown parameters we want to estimate. The risk is a function of only these parameters, and is given by

$$\begin{aligned} \langle C(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}) \rangle &= \int d\boldsymbol{\theta} \int d\boldsymbol{\theta}_n \int d\hat{\boldsymbol{\theta}} \int d\hat{\boldsymbol{\theta}}_n C(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}) \text{pr}(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}, \boldsymbol{\theta}_n, \hat{\boldsymbol{\theta}}_n) \\ &= \int d\boldsymbol{\theta} \int d\boldsymbol{\theta}_n \int d\hat{\boldsymbol{\theta}} \int d\hat{\boldsymbol{\theta}}_n C(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}) \text{pr}(\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\theta}}_n|\boldsymbol{\theta}, \boldsymbol{\theta}_n) \text{pr}(\boldsymbol{\theta}_n|\boldsymbol{\theta}) \text{pr}(\boldsymbol{\theta}) \\ &= \int d\boldsymbol{\theta} \int d\boldsymbol{\theta}_n \int d\hat{\boldsymbol{\theta}} \int d\hat{\boldsymbol{\theta}}_n C(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}) \int d^M g \text{pr}(\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\theta}}_n|\mathbf{g}) \text{pr}(\mathbf{g}|\boldsymbol{\theta}, \boldsymbol{\theta}_n) \text{pr}(\boldsymbol{\theta}_n|\boldsymbol{\theta}) \text{pr}(\boldsymbol{\theta}), \end{aligned} \tag{13.396}$$

where the last line explicitly shows that the cost is averaged over all possible realizations of the data and the parameters.

We can rearrange the order of integration to obtain:

$$\begin{aligned} &\langle C(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}) \rangle \\ &= \int d\boldsymbol{\theta} \text{pr}(\boldsymbol{\theta}) \int d\hat{\boldsymbol{\theta}} C(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}) \int d\hat{\boldsymbol{\theta}}_n \int d^M g \text{pr}(\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\theta}}_n|\mathbf{g}) \int d\boldsymbol{\theta}_n \text{pr}(\mathbf{g}|\boldsymbol{\theta}, \boldsymbol{\theta}_n) \text{pr}(\boldsymbol{\theta}_n|\boldsymbol{\theta}) \\ &= \int d\boldsymbol{\theta} \text{pr}(\boldsymbol{\theta}) \int d\hat{\boldsymbol{\theta}} C(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}) \int d\hat{\boldsymbol{\theta}}_n \int d^M g \text{pr}(\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\theta}}_n|\mathbf{g}) \text{pr}(\mathbf{g}|\boldsymbol{\theta}). \end{aligned} \tag{13.397}$$

We could stop right here since only the marginalized likelihood $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$ appears. The estimation rule cannot depend separately on the original joint likelihood.

Note that the estimators are specific functions of the data:

$$\hat{\boldsymbol{\theta}} = f(\mathbf{g}) \quad \text{and} \quad \hat{\boldsymbol{\theta}}_n = f_n(\mathbf{g}), \tag{13.398}$$

so

$$\text{pr}(\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\theta}}_n|\mathbf{g}) = \delta[\hat{\boldsymbol{\theta}} - f(\mathbf{g})] \delta[\hat{\boldsymbol{\theta}}_n - f_n(\mathbf{g})]. \tag{13.399}$$

Substituting (13.399) into (13.397), we find

$$\langle C(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}) \rangle = \int d^M g \int d\boldsymbol{\theta} C[\boldsymbol{\theta}, f(\mathbf{g})] \text{pr}(\mathbf{g}|\boldsymbol{\theta}) \text{pr}(\boldsymbol{\theta}). \tag{13.400}$$

²⁰We thank Dan Marks for posing the problem and formulating the solution we present here.

Now we will stop, because to go on would be to rederive familiar results from Sec. 13.3.3. Whatever estimation rule we would obtain from that section still holds, dependent only on the forms of the prior $\text{pr}(\boldsymbol{\theta})$ and cost function, as if $\boldsymbol{\theta}_n$ had never existed! The optimal strategy in the presence of nuisance parameters is to marginalize over them rather than estimate them. The key step that led us to this conclusion was assuming a cost function that was independent of $\boldsymbol{\theta}_n$.

13.3.9 Hybrid detection/estimation tasks

In Sec. 13.2.10 we considered the problem of detection of signals with one or more random parameters $\boldsymbol{\theta}$. We derived the optimal classification strategy that minimizes Bayes risk. We found that the optimal decision strategy, given knowledge of the prior probability densities $\text{pr}_{\boldsymbol{\theta}}(\boldsymbol{\theta})$ of the parameters, involved marginalizing over $\boldsymbol{\theta}$ [see (13.147)] to compute the likelihood of the data in the signal-present case. We presented examples where signal scale, frequency, or location were random. These were nuisance parameters; the observer does not report an estimate of their value, and no penalty is associated with errors in their estimate. In the language used here, the cost is just a 2×2 matrix, not a function of the signal parameter. Thus, similar to what we found above in the estimation case, a cost function that is independent of the nuisance parameter results in an optimal strategy involving marginalizing over the nuisance parameters.

Generalized likelihood-ratio detection Suppose under H_2 that a signal with random parameters $\boldsymbol{\theta}_s$ is present, along with a background with random parameters $\boldsymbol{\theta}_b$. Under H_1 only the random background is present. If the prior probability density on these random parameter vectors is unknown, a common approach is to form the generalized likelihood ratio

$$\Lambda(\mathbf{g}) = \frac{\max_{\boldsymbol{\theta}_s, \boldsymbol{\theta}_b} [\text{pr}(\mathbf{g} | \boldsymbol{\theta}_s, \boldsymbol{\theta}_b, H_2)]}{\max_{\boldsymbol{\theta}_b} [\text{pr}(\mathbf{g} | \boldsymbol{\theta}_b, H_1)]}. \quad (13.401)$$

The interpretation of this detection strategy is that the observer forms maximum-likelihood estimates of the unknown parameters $\boldsymbol{\theta}_s$ and $\boldsymbol{\theta}_b$ under H_2 , forms a maximum-likelihood estimate of $\boldsymbol{\theta}_b$ under H_1 , and chooses the hypothesis with greater overall likelihood. This approach is known as generalized likelihood-ratio detection. No estimates of the parameters are reported; a simple binary classification is performed.

The reasonableness of the generalized likelihood-ratio approach does not imply optimality in a minimum-decision-error or minimum-cost sense. In fact, as we shall now show, when the cost function depends on the underlying parameters, the result is a decision strategy that does not involve computation of the maximum-likelihood estimate under each hypothesis.

Parameter-dependent cost functions Suppose the task is again the detection of a random signal on a random background and that the classification cost function depends on the random parameters and their estimates. For example, there is a penalty for a false location in the random-location problem, or the penalty for missing a lesion increases with lesion size. We can construct a cost function that involves both the parameter estimates and the decision and determine the optimal classification strategy given that cost function.

If θ_s is a random parameter vector associated with the signal and θ_b is one associated with the background, the elements of the cost matrix are:

- $C_{22}(\theta_s, \hat{\theta}_s, \theta_b, \hat{\theta}_b)$ = cost of deciding H_2 and giving estimates $\hat{\theta}_s$ and $\hat{\theta}_b$ when H_2 is true and the actual values of the parameters are θ_s and θ_b .
- $C_{21}(\hat{\theta}_s, \theta_b, \hat{\theta}_b)$ = cost of deciding H_2 and giving estimates $\hat{\theta}_s$ and $\hat{\theta}_b$ when H_1 is true and the actual value of the background parameter vector is θ_b . (In this case, θ_s does not exist, so it has no actual value.)
- $C_{12}(\theta_s, \theta_b, \hat{\theta}_b)$ = cost of deciding H_1 and giving estimate $\hat{\theta}_b$ for the background when H_2 is true and the actual values of the parameters are θ_s and θ_b . (Since the decision is signal-absent, no $\hat{\theta}_s$ is reported.)
- $C_{11}(\theta_b, \hat{\theta}_b)$ = cost of deciding H_1 and giving estimate $\hat{\theta}_b$ when H_1 is true and the actual background parameter vector is θ_b . (In this case θ_s does not exist, and no value of $\hat{\theta}_s$ is reported.)

A reasonable step at this point would be to drop the dependence of all costs on θ_b and $\hat{\theta}_b$ since there rarely is a cost associated with an inaccurate background estimate. (The background parameters are nuisance parameters.) With this assumption, the elements of the cost matrix are

- $C_{22}(\theta_s, \hat{\theta}_s)$ = cost of deciding H_2 and obtaining estimate $\hat{\theta}_s$ when H_2 is true.
- $C_{21}(\hat{\theta}_s)$ = cost of deciding H_2 and giving estimate $\hat{\theta}_s$ when H_1 is true.
- $C_{12}(\theta_s)$ = cost of deciding H_1 when H_2 is true.
- C_{11} = constant = cost of deciding H_1 when H_1 is true.

The cost C_{21} is dependent on the estimate $\hat{\theta}_s$, allowing for the possibility that it might be more risky to falsely detect a lesion at some locations, or that the cost of estimating that the pseudo-lesion is large is different from estimating it to be small. Similarly, C_{12} is a function of the underlying signal parameters, recognizing that the cost of missing the lesion might be a function of lesion size or location.

By analogy to (13.396), the risk is given by

$$\begin{aligned}
 \langle C \rangle &= \sum_{i=1}^2 \sum_{j=1}^2 \int d\theta_s \int d\hat{\theta}_s C_{ij}(\theta_s, \hat{\theta}_s) \text{pr}(D_i, H_j, \theta_s, \hat{\theta}_s) \\
 &= \sum_{i=1}^2 \sum_{j=1}^2 \int d\theta_s \int d\hat{\theta}_s C_{ij}(\theta_s, \hat{\theta}_s) \text{pr}(D_i, \hat{\theta}_s | H_j, \theta_s) \text{pr}(H_j, \theta_s) \\
 &= \int d\theta_s \int d\hat{\theta}_s C_{22}(\theta_s, \hat{\theta}_s) \text{pr}(D_2, \hat{\theta}_s | H_2, \theta_s) \text{pr}(\theta_s | H_2) \text{Pr}(H_2) \\
 &\quad + \int d\hat{\theta}_s C_{21}(\hat{\theta}_s) \text{pr}(D_2, \hat{\theta}_s | H_1) \text{Pr}(H_1) \\
 &\quad + \int d\theta_s C_{12}(\theta_s) \int d\hat{\theta}_s \text{pr}(D_1, \hat{\theta}_s | H_2, \theta_s) \text{pr}(\theta_s | H_2) \text{Pr}(H_2) \\
 &\quad + C_{11} \int d\hat{\theta}_s \text{pr}(D_1, \hat{\theta}_s | H_1) \text{Pr}(H_1), \tag{13.402}
 \end{aligned}$$

where D_i is the decision and H_j is the true state.

When we insert the dependence on \mathbf{g} we obtain

$$\begin{aligned} \langle C \rangle &= \int d^M g \int d\boldsymbol{\theta}_s \int d\hat{\boldsymbol{\theta}}_s C_{22}(\boldsymbol{\theta}_s, \hat{\boldsymbol{\theta}}_s) \text{pr}(D_2, \hat{\boldsymbol{\theta}}_s | \mathbf{g}) \text{pr}(\mathbf{g} | H_2, \boldsymbol{\theta}_s) \text{pr}(\boldsymbol{\theta}_s | H_2) \text{Pr}(H_2) \\ &\quad + \int d^M g \int d\hat{\boldsymbol{\theta}}_s C_{21}(\hat{\boldsymbol{\theta}}_s) \text{pr}(D_2, \hat{\boldsymbol{\theta}}_s | \mathbf{g}) \text{pr}(\mathbf{g} | H_1) \text{Pr}(H_1) \\ &\quad + \int d^M g \int d\boldsymbol{\theta}_s C_{12}(\boldsymbol{\theta}_s) \int d\hat{\boldsymbol{\theta}}_s \text{pr}(D_1, \hat{\boldsymbol{\theta}}_s | \mathbf{g}) \text{pr}(\mathbf{g} | H_2, \boldsymbol{\theta}_s) \text{pr}(\boldsymbol{\theta}_s | H_2) \text{Pr}(H_2) \\ &\quad + C_{11} \int d^M g \int d\hat{\boldsymbol{\theta}}_s \text{pr}(D_1, \hat{\boldsymbol{\theta}}_s | \mathbf{g}) \text{pr}(\mathbf{g} | H_1) \text{Pr}(H_1). \end{aligned} \quad (13.403)$$

Using a delta function representation of the estimator, as in (13.399), gives

$$\text{pr}(D_i, \hat{\boldsymbol{\theta}}_s | \mathbf{g}) = \text{pr}(D_i | \hat{\boldsymbol{\theta}}_s, \mathbf{g}) \text{pr}(\hat{\boldsymbol{\theta}}_s | \mathbf{g}) = \text{pr}(D_i | \mathbf{g}) \text{pr}(\hat{\boldsymbol{\theta}}_s | \mathbf{g}) = \text{pr}(D_i | \mathbf{g}) \delta[\hat{\boldsymbol{\theta}}_s - f(\mathbf{g})]. \quad (13.404)$$

Then

$$\begin{aligned} \langle C \rangle &= \int d^M g \int d\boldsymbol{\theta}_s C_{22}(\boldsymbol{\theta}_s, f(\mathbf{g})) \text{pr}(D_2 | \mathbf{g}) \text{pr}(\mathbf{g} | H_2, \boldsymbol{\theta}_s) \text{pr}(\boldsymbol{\theta}_s | H_2) \text{Pr}(H_2) \\ &\quad + \int d^M g C_{21}(f(\mathbf{g})) \text{pr}(D_2 | \mathbf{g}) \text{pr}(\mathbf{g} | H_1) \text{Pr}(H_1) \\ &\quad + \int d^M g \int d\boldsymbol{\theta}_s C_{12}(\boldsymbol{\theta}_s) \text{pr}(D_1 | \mathbf{g}) \text{pr}(\mathbf{g} | H_2, \boldsymbol{\theta}_s) \text{pr}(\boldsymbol{\theta}_s | H_2) \text{Pr}(H_2) \\ &\quad + C_{11} \int d^M g \text{pr}(D_1 | \mathbf{g}) \text{pr}(\mathbf{g} | H_1) \text{Pr}(H_1). \end{aligned} \quad (13.405)$$

When we combine the integrals over \mathbf{g} and $\boldsymbol{\theta}$ we find:

$$\begin{aligned} \langle C \rangle &= \int d^M g \left\{ \int d\boldsymbol{\theta}_s \left[C_{22}(\boldsymbol{\theta}_s, f(\mathbf{g})) \text{pr}(D_2 | \mathbf{g}) \right. \right. \\ &\quad \left. \left. + C_{12}(\boldsymbol{\theta}_s) \text{pr}(D_1 | \mathbf{g}) \right] \text{pr}(\mathbf{g} | H_2, \boldsymbol{\theta}_s) \text{pr}(\boldsymbol{\theta}_s | H_2) \text{Pr}(H_2) \right\} \\ &\quad + \left\{ C_{21}(f(\mathbf{g})) \text{pr}(D_2 | \mathbf{g}) + C_{11} \text{pr}(D_1 | \mathbf{g}) \right\} \text{pr}(\mathbf{g} | H_1) \text{Pr}(H_1). \end{aligned} \quad (13.406)$$

Let Γ_i denote the region of \mathbf{g} -space for which the decision is D_i . Since $\text{pr}(D_i | \mathbf{g}) = 1$ if \mathbf{g} lies in Γ_i and zero otherwise, we have

$$\begin{aligned} \langle C \rangle &= \int_{\Gamma_2} d^M g \left\{ \int d\boldsymbol{\theta}_s \left[C_{22}(\boldsymbol{\theta}_s, f(\mathbf{g})) \text{pr}(\mathbf{g} | H_2, \boldsymbol{\theta}_s) \text{pr}(\boldsymbol{\theta}_s | H_2) \text{Pr}(H_2) \right. \right. \\ &\quad \left. \left. + C_{21}(f(\mathbf{g})) \text{pr}(\mathbf{g} | H_1) \text{Pr}(H_1) \right\} \right. \\ &\quad \left. + \int_{\Gamma_1} d^M g \left\{ \int d\boldsymbol{\theta}_s \left[C_{12}(\boldsymbol{\theta}_s) \text{pr}(\mathbf{g} | H_2, \boldsymbol{\theta}_s) \text{pr}(\boldsymbol{\theta}_s | H_2) \text{Pr}(H_2) \right] \right. \right. \\ &\quad \left. \left. + C_{11} \text{pr}(\mathbf{g} | H_1) \text{Pr}(H_1) \right\}. \end{aligned} \quad (13.407)$$

We now have a double optimization problem: choose Γ_2 and $f(\mathbf{g})$ to minimize $\langle C \rangle$. There is no need to choose Γ_1 separately since Γ_1 and Γ_2 comprise all of \mathbf{g} -space.

To make further headway, we must assume specific forms for the cost functions in (13.407). We shall adopt a MAP cost function for $C_{22}[\boldsymbol{\theta}_s, f(\mathbf{g})]$:

$$C_{22}[\boldsymbol{\theta}_s, f(\mathbf{g})] = C_{22} \times \left\{ 1 - \text{rect} \left[\frac{\boldsymbol{\theta}_s - f(\mathbf{g})}{\epsilon} \right] \right\}, \quad (13.408)$$

where C_{22} without an argument is the cost of a true-positive classification with a tolerance in the error of the signal-parameter estimate specified by ϵ . To simplify the example we shall assume that the cost of rendering a false-negative decision is independent of $\boldsymbol{\theta}_s$, and similarly, the cost associated with the erroneous signal parameter estimates in the absence of a signal does not depend on the estimate:

$$C_{12}(\boldsymbol{\theta}_s) = C_{12} \quad (13.409)$$

and

$$C_{21}[f(\mathbf{g})] = C_{21}. \quad (13.410)$$

With ϵ tending to zero, (13.407) becomes

$$\begin{aligned} \langle C \rangle = & \int_{\Gamma_2} d^M g \left\{ C_{22} [\text{pr}(\mathbf{g}|H_2) \text{Pr}(H_2) - \epsilon \text{pr}(\mathbf{g}|H_2, \hat{\boldsymbol{\theta}}_s) \text{pr}(\hat{\boldsymbol{\theta}}_s|H_2) \text{Pr}(H_2)] \right. \\ & \left. + C_{21} \text{pr}(\mathbf{g}|H_1) \text{Pr}(H_1) \right\} \\ & + \int_{\Gamma_1} d^M g \{ C_{12} \text{pr}(\mathbf{g}|H_2) \text{Pr}(H_2) + C_{11} \text{pr}(\mathbf{g}|H_1) \text{Pr}(H_1) \}, \quad (13.411) \end{aligned}$$

where we have substituted $\hat{\boldsymbol{\theta}}_s$ for $f(\mathbf{g})$.

We can write the integrals over Γ_1 in terms of integrals over Γ_2 to find

$$\begin{aligned} \langle C \rangle = & C_{12} \text{Pr}(H_2) + C_{11} \text{Pr}(H_1) \\ & + \int_{\Gamma_2} d^M g \{ (C_{22} - C_{12}) \text{pr}(\mathbf{g}|H_2) \text{Pr}(H_2) + (C_{21} - C_{11}) \text{pr}(\mathbf{g}|H_1) \text{Pr}(H_1) \\ & - \epsilon C_{22} \text{pr}(\mathbf{g}|H_2, \hat{\boldsymbol{\theta}}_s) \text{pr}(\hat{\boldsymbol{\theta}}_s|H_2) \text{Pr}(H_2) \}. \quad (13.412) \end{aligned}$$

By Bayes rule we can write the last term in (13.412) as

$$\epsilon C_{22} \text{pr}(\mathbf{g}|H_2, \hat{\boldsymbol{\theta}}_s) \text{pr}(\hat{\boldsymbol{\theta}}_s|H_2) \text{Pr}(H_2) = \epsilon C_{22} \text{pr}(\hat{\boldsymbol{\theta}}_s|\mathbf{g}, H_2) \text{pr}(\mathbf{g}|H_2) \text{Pr}(H_2), \quad (13.413)$$

and the average cost becomes, finally,

$$\begin{aligned} \langle C \rangle = & C_{12} \text{Pr}(H_2) + C_{11} \text{Pr}(H_1) \\ & + \int_{\Gamma_2} d^M g \{ (C_{22} - C_{12}) \text{pr}(\mathbf{g}|H_2) \text{Pr}(H_2) + (C_{21} - C_{11}) \text{Pr}(H_1) \text{pr}(\mathbf{g}|H_1) \\ & - \epsilon C_{22} \text{pr}(\hat{\boldsymbol{\theta}}_s|\mathbf{g}, H_2) \text{pr}(\mathbf{g}|H_2) \text{Pr}(H_2) \}. \quad (13.414) \end{aligned}$$

If $\epsilon \rightarrow 0$, we must choose Γ_2 so that

$$(C_{11} - C_{21}) \text{Pr}(H_1) \text{pr}(\mathbf{g}|H_1) > (C_{22} - C_{12}) \text{pr}(\mathbf{g}|H_2) \text{Pr}(H_2). \quad (13.415)$$

That is, we make decision D_2 if

$$\frac{\text{pr}(\mathbf{g}|H_2)}{\text{pr}(\mathbf{g}|H_1)} > \frac{(C_{21} - C_{11}) \text{Pr}(H_1)}{(C_{12} - C_{22}) \text{Pr}(H_2)}, \quad (13.416)$$

which is the usual decision strategy for the ideal observer in the absence of parameter uncertainty. The term proportional to ϵ in (13.414) has the following interpretation: choose $\hat{\theta}_s$ such that $\text{pr}(\hat{\theta}_s|\mathbf{g}, H_2)$ is maximal (*i.e.*, the expected MAP estimator).

In summary, with the stated assumptions about costs, the strategy is to do the hypothesis test with the marginalized likelihood $\text{pr}(\mathbf{g}|H_2)$, followed by MAP estimation of the underlying parameter if D_2 is made. Contrary to popular belief, one should not use the maximum of $\text{pr}(\mathbf{g}|\theta, H_2)$ in the hypothesis test.

Bayesians and frequentists In both pure estimation problems (Sec. 13.3.8) and hybrid detection/estimation problems (this section), we have found that the optimal strategy for handling nuisance parameters is to marginalize rather than to estimate them. This finding begs the question of the appropriate prior to utilize. To a frequentist, the prior should be a sampling prior, verifiable by experiment; an example is the exponential absorption law for photons. To a Bayesian, the prior could incorporate prior beliefs. Indeed, a Bayesian would say that the problem of nuisance parameters is an example of a fundamental dilemma that arises in any inference problem: we *never* have enough empirical information to solve the problem at hand, and we must always bring in prior belief. Our reply, which we shall expound more fully in Chaps. 14 and 15, is that, yes, one can use prior beliefs in estimation problems in imaging, but the final measure of the efficacy of the belief is a long-run, frequentist measure of task performance.

14

Image Quality

In this chapter we consider the many practical issues one must wrestle with in the objective evaluation of imaging systems. Unlike Chap. 13, where knowledge of the relevant population statistics of the image classes is assumed, the emphasis here is on the practical issues that come to the fore when only a finite sample of images is available for determining the image statistics or the observer's performance, or both.

We begin in Sec. 14.1 with a description of various approaches to the assessment of image quality, including methods based on preference assessments, fidelity measures, and information-theoretic approaches. Then, in Sec. 14.1.5, we introduce the key elements that are required for the approach we advocate: the method must be objective, task-based, and account for the statistical properties of the relevant images and observers.

Properties of the human visual system and the determination of classification performance by human observers is the subject of Sec. 14.2, including the conduct of psychophysical experiments and the estimation of summary statistics for human performance. In Sec. 14.3 we turn to the subject of model or algorithmic observers for classification and estimation tasks. The approaches presented in Secs. 14.2 and 14.3 may make use of actual data sets derived from real imaging systems or, more often in research investigations, simulated images. Methods for image simulation are discussed in Sec. 14.4. As emphasized in that section, accurate models of the properties of the object and the physics of the image acquisition system are required if simulated images are to lead to accurate assessments of system performance.

14.1 SURVEY OF APPROACHES

14.1.1 Subjective assessment

The simplest approach to the assessment of image quality is to rely on a viewer's subjective assessment regarding how good an image looks. This approach can be as crass as the presentation of just a single pair of images, one processed by algorithm A and the other processed by contender B, with the developer of algorithm A drawing sweeping conclusions regarding the merits of A over B. A panel of experts might be used to make a stronger case regarding the merits of one algorithm over another, but here again the panel's decision is based on subjective preference rather than objective, task-based performance. There may be a place for beauty contests in the evaluation of imagery, such as when an individual selects a home-entertainment video system. We would argue that even then, most buyers base their subjective preference of one system over others by viewing a range of images; buyers usually take into account technical data across competing systems as well.

In an effort toward putting subjective preference methods on more solid footing, Zetzsche and Hauske (1989) developed a model based on the visual system with the goal of predicting subjective ratings of image quality. If this goal were met, the authors reasoned that they could determine image quality without the need for building physical prototypes of display devices. The predictions of the model were found to have correlations with mean subjective ratings ranging from 0.74 to 0.95 for images in which various artifacts were present.

Methods based on multidimensional scaling (MDS) have been applied to the analysis of subjective image quality ratings (Ahumada and Null, 1993). MDS methods incorporate various approaches for collecting numerical rating from multiple observers given the task of rating the quality of a set of images. Images can be presented in pairs, with the observer given the task of selecting the one with higher quality, or a set of images can be rank-ordered by quality. Normalizations can be done to account for differences in how observers scale the rating values; Thurstone scaling is a procedure that allows observers to use a rating scale nonlinearly (Torgerson, 1958). Once the rating data are in hand, MDS enables the dimensions of image quality to be extracted (Farrell *et al.*, 1991). Standard software packages are available for performing MDS. The difficulty with the MDS approach is that the labeling of the extracted dimensions, in terms of physical characteristics of the images or the image acquisition system, is left to the investigator (Shepard *et al.*, 1972). Moreover, the connection between an observer's rating of the quality of an image and the usefulness of the image for a specified task is never made.

Structured preference assessments formalize the subjective approach through the use of trained observers who perform a prescribed set of analyses. The well-known National Imagery Interpretability Rating Scale (NIIRS) system, which uses an interpretability rating scale for analyzing military reconnaissance images, is an example of a structured-preference approach. The NIIRS system was developed under the leadership of the U.S. Imagery Resolution Assessments and Reporting Standards (IRARS) Committee in the early 1970s. The first NIIRS system evaluated the visibility of military objects in images acquired in the visible spectrum. Later, the NIIRS system was extended to incorporate objects like buildings, roads, railroads and bridges, enabling the evaluation of images without military objects.

The NIIRS system is now able to handle data outside the visible spectrum, including thermal, radar, and multispectral imagery.

Models have been developed for predicting NIIRS ratings just as models have been developed for predicting subjective preference ratings. Given a set of input variables that can include the scene contrast, scene illumination, and imaging system characteristics, the models generate measures of image quality that can be related to the NIIRS scale. Another approach to the estimation of an image quality metric that correlates with the NIIRS scale is based on the power spectrum of the image to be rated, indicating that the measure is heavily influenced by the noise properties of the image.

The NIIRS approach is almost exclusively used for military applications; NIIRS refers to the value of an image for “intelligence purposes,” rather than image quality *per se*. Furthermore, the NIIRS approach is not amenable to the analysis of the variation in true- and false-positive fractions [TPF and FPF, defined in (13.11)] of image interpretations as a function of the reader’s mindset (see Fig. 13.5). Some argue that a preference-based approach is appropriate whenever the task is not well defined. We have not encountered an example where there truly is no specific task. There may be several tasks, in which case the system could be evaluated for each.

We regard preference assessments as useful in go/no-go decisions, giving information on the adequacy of images for further, more rigorous, testing. Indeed, rank-order studies of image quality have been proposed as a formal approach to determining whether the cost of a large-scale objective study is justified (Gur *et al.*, 1997; Rockette *et al.*, 1997; Good *et al.*, 1999; Towers *et al.*, 2000). These studies can make use of highly trained observers and specified tasks; their drawback is that they identify trends without providing an absolute measure of image quality. Statistical methods for planning and analyzing rank-order experiments have been introduced (Rockette *et al.*, 2001).

14.1.2 Fidelity measures

A common approach to image assessment is to assume that the goal in imaging is to reproduce a likeness of the object, leading to the conclusion that the best imaging system is the one that gives the smallest discrepancy between object and image. The most common measure of fidelity is the *mean-square error* (MSE) between object and image; some flavor of MSE is quoted in the majority of papers on image processing or image reconstruction. As we saw in Sec. 13.3.2, however, there are some arbitrary choices to be made in defining MSE, and different choices can lead to quite different conclusions about the quality of an imaging system or processing algorithm.

Problems with fidelity measures MSE and any other fidelity measure will be sensitive to many different properties of an image. If we rotate an image slightly with respect to the object or change the magnification, for example, we can produce a large discrepancy between the object and the image, even if they would otherwise be identical. Similarly, image distortion, such as barrel or pincushion effects, can lead to a large MSE. Finally, gray-scale errors such as nonlinear mapping of the image intensity or even an error in overall brightness can contribute heavily to any fidelity measure.

In many cases, these image modifications are trivial in the sense that they do not degrade the information we want to extract from the images. For example, a radiologist can interpret a chest radiograph just as well if it is rotated by a few degrees on a light box or displayed at a different magnification on a computer monitor.¹ MSE or other measures of fidelity would show that the rotated or scaled image was a poor representation of the object, but the user might not even notice the discrepancy.

Sometimes, however, apparently trivial modifications of an image are important. A cartographer wanting to derive accurate distances from an aerial photograph, for example, would worry a great deal about the magnification, and an astronomer wanting to track the angle between the two members of a binary star would worry about the rotation angle. In designing a lens system for photolithography, distortion might be critical, though for portrait photography it would be imperceptible. Even in these cases, however, a fidelity measure such as MSE is too blunt an instrument to say anything meaningful about the usefulness of an image.

Why not MSE? As delineated in Sec. 13.3.2, there are many arbitrary choices to be made in defining an MSE. For digital images, we must decide whether to discretize the assumed object for comparison with the digital output, to interpolate the digital image in order to get a continuous function to compare to the real object, or just to do a simulation and hope that the results will mean something. For each of these options, we must select a set of functions for discretization or interpolation, and we must select either a single object or a class of objects for comparison in some sense to the images. If the object contains null functions of either the system operator or the discretization operator, as any real object will, then any MSE will be very sensitive to the choice of object.

MSE measures can be very sensitive to relatively trivial image modifications such as magnification, rotation and gray-scale mappings, but they may be completely insensitive to small details that we really want to capture in the image. Furthermore, MSE measures make no distinction between blur and noise. It is easy to construct two very different images, one with high noise but good sharpness and a blurred one with low noise that have the same MSE. The main objection to any MSE metric, however, is that it has nothing to do with the intended use of the image..

14.1.3 JND models

There exists a school of thought in the field of image evaluation that the goal of an image processing or compression algorithm is to create an image that is perceptually equivalent to the original. This school measures image degradation in units of just-noticeable differences, or JNDs, between the original image and its processed counterpart. One JND unit corresponds to a fixed probability, say 50 or 75 percent, that an observer would detect the difference between two images or image regions (Lubin, 1993).

¹There is anecdotal evidence that sometimes such image modifications can even aid the observer by changing the appearance of an image such that a previously-missed signal becomes visible.

The JND approach to image quality is rooted in the threshold theory of vision. Threshold theory states that signal detection occurs when a signal's perceptibility exceeds an observer's threshold; signal detection is a yes or no event. Furthermore, by the Weber-Fechner law, discussed in more detail in Sec. 14.2.1, the threshold for detecting an extended signal increases proportionally with background intensity. In the early days of vision science, much effort was expended on the measurement of the detection thresholds of various signals on different backgrounds. In the JND approach to image quality, the "signal" is a difference in a pair of images; if that difference is below threshold, the images are of equal quality.

All JND models are based on a model of the human visual system with the intent of predicting human performance in the ranking of image quality or the detection of image differences. The simplest approach is to weight image differences using a function that models the sensitivity of the human visual system to spatial frequency, referred to as a contrast sensitivity function (Daly, 1993). The JND model of Carlson and Cohen (1980) decomposes the input images into frequency bands. After the contents of the bands are processed nonlinearly, the outputs are compared to determine where image differences as seen through this simple model of the visual system are greatest. This model has been used to predict the detectability of edges and artifacts. Barten has also presented a model of the visual system that has been used to predict image quality (Barten, 1992, 1993). The Barten JND model utilizes a single integral over spatial frequencies rather than a decomposition into frequency bands, making use of an average contrast sensitivity function of the visual system. The Barten model has been shown to predict subjective image quality for several simple tasks and is the centerpiece of a recent National Electrical Manufacturers Association standard on display quality (NEMA, 2001).

More complex mechanistic models of the visual system have been developed for use in the prediction of visually perceptible differences in gray scale, color, and video imagery (Hultgren, 1990; Lubin, 1993; Daly, 1993). The models can account for such observation factors as viewing distance and light level (pupil diameter). The most comprehensive models include a nonlinearity representing the visual system's nonlinear response to luminance, a contrast sensitivity function, a bank of spatial-frequency and orientation-sensitive filters, and models of the chromatic and temporal properties of the visual system. The output is a JND map of the image differences, quantified per pixel, field, frame, or sequence.

One argument for the use of a JND metric is that the approach implies the matching of the processing algorithm with the visual system, similar to the way in which the information in a color television signal is matched to the human; because color resolution in the visual system is less than gray-scale resolution, the National Television Standards Commission (NTSC) represents color information more sparsely than luminance information.

Advocates of the JND approach argue that it is objective, it correlates with subjective assessments of image quality, and it predicts a large body of human data for both detection and discrimination tasks without the need to fit any free model parameters. The tasks have included disk detection, sine grating detection, checkerboard detection and edge-sharpness discrimination. The task can utilize real objects on real backgrounds; a recent comparison of image quality for the task of microcalcification detection in mammographic images showed a high correlation between JND measures of image quality and human observer performance (Krupinski *et al.*, 2003). Commercial JND-based image evaluation packages are readily available.

JND measures suffer from some of the same problems we have enumerated for fidelity measures, including the lack of distinction between blur and noise and the questionable definition of task. Both fidelity and JND measures quantify some form of image discrepancy: fidelity measures give all image differences equal importance, while JND measures weigh image differences according to their predicted manifestation at the output of the visual system. In order to calculate perceptual image differences, the JND approach requires twinned-noise image pairs, that is, two images in which the noise realization in each is the same. This paradigm is significantly different from the one underlying statistical decision theory, in which each image represents an independent sample from the signal, background, and noise distributions. It is not clear how the JND approach can be extended beyond simulated targets to real images with real signals because it is not possible to acquire real images that are identical except for the presence or absence of some target. An active area of current research is the usefulness of the JND approach for predicting the quality of an imaging system given random signals on random backgrounds in images with unpaired noise realizations.

Nevertheless, the JND community has much to offer the field of objective assessment of image quality. For example, we shall see that model observers play a significant role in the objective assessment of image quality; the sophisticated models of the visual system developed by the JND community may be of use in the development of predictive models of human task performance for more realistic tasks.

14.1.4 Information-theoretic assessment

In 1948, Claude Shannon published his now-famous theory of communication, in which he defined the information content of a message as a measure of the degree to which it is unexpected.² Shannon defined the information content of a single message state n as $I(n) = \log[1/\text{Pr}(n)]$, where $\text{Pr}(n)$ is the prior probability of occurrence of the n^{th} message. Messages with high probability carry little information; high information content is associated with messages that are least expected. By this definition, the mean information content of a message is

$$\bar{I} = \sum_{n=1}^N \text{Pr}(n) I(n) = \sum_{n=1}^N \text{Pr}(n) \log \left[\frac{1}{\text{Pr}(n)} \right] = - \sum_{n=1}^N \text{Pr}(n) \log[\text{Pr}(n)], \quad (14.1)$$

which becomes

$$\bar{I} = \sum_{n=1}^N \frac{1}{n} \log[n] = - \sum_{n=1}^N \frac{1}{n} \log \left[\frac{1}{n} \right] \quad (14.2)$$

when the messages are equally likely.

Shannon's model for a communications system was a nonimaging system comprised of a single source (the message), an encoder, a communications channel that transmitted the message, and a decoder. The purpose of the communications system was to provide the user with a reproduction of the message. Designers of

²In his book on the relationship between information theory and thermodynamic entropy, Brillouin (1956) points out that the theory developed by Shannon came to light earlier in Szilard's discussion of the Maxwell demon (1929). (We thank B. R. Frieden for this historical note.)

encoders, decoders, and transmitters were seeking to ensure that the user received the message that was sent. Not surprisingly, systems whose goal was to reproduce a transmitted message were most often evaluated using fidelity measures.

There is a large literature on the application of information theory to the evaluation of imaging systems. Fellgett and Linfoot (1955) and Linfoot (1955) considered a simplified model of an optical system in which the source is divided into small discrete elements, each capable of a finite number of discrete brightness levels. The information content of the values of the elements can then be defined in terms of their degree of unexpectedness. That is, the information carried by a particular object \mathbf{f} is given by

$$I(\mathbf{f}) = \sum_{n=1}^N \text{pr}(f_n) \log \left[\frac{1}{\text{pr}(f_n)} \right] = - \sum_{n=1}^N \text{pr}(f_n) \log [\text{pr}(f_n)] , \quad (14.3)$$

where f_n is the brightness of the n^{th} object element. In this simple model the object values are assumed to be independent, and we see that the entropy of the set of values becomes the measure of information content [*cf.* (15.158)].

Fellgett and Linfoot generalized this simple model to allow for a continuous distribution of object values and a division of object space into isoplanatic patches. With these additions to the model, Fourier methods can be used to describe the transfer characteristics of the imaging system. Fellgett and Linfoot considered the assessment of an optical system for two tasks: the formation of an image that is similar to the object, and the production of an image that carries the most information about the object without regard to a specific inference or interpretation process. Assessment by similarity leads to fidelity measures; the same issues raised in the previous section on fidelity measures then apply, and Fellgett and Linfoot point out many of these shortcomings as well. Thus Fellgett and Linfoot turn to assessment by information content. Using the object's information measure as a starting point, an imaging system's ability to transfer information is computed and maximized. However, their resulting figure of merit is independent of the statistics of the object set and the measurement noise (film type, in those days). This is seen as a positive result by these authors, because it allows for optimization of optical systems without regard to the statistical properties of the object and the measurements, and no specific task must be considered.

More modern works have followed the approach of Fellgett and Linfoot, emphasizing the information rate of an imaging system (Huck *et al.*, 1997) and its correlation with the visual quality of the resulting images, where visual quality is measured in terms of image sharpness, clarity, and fidelity. Of course, all of these measures encounter the commensurability problem discussed in Sec. 13.3.2. Moreover, these measures are not uniquely related to the performance of a specified observer on a particular task.

Dainty and Shaw (1974) and Shaw (1978) related the information theory of Shannon to their noise-equivalent quanta (NEQ) approach to image assessment. According to these authors, an actual imaging system that degrades the information content of the input is associated with an NEQ relative to the real exposure quanta. As described in Sec. 13.2.13, this theory assumes a linear shift-invariant imaging system and stationary noise, leading to a Fourier-domain framework for describing the detection SNR as a function of spatial frequency. Spatial frequencies correspond to Shannon's channels in this approach (Wagner and Brown, 1985).

A broader view of information-theoretic image formation and assessment exists (O’Sullivan *et al.*, 1998). Object representation is achieved by combinations (not necessarily linear) of basis functions that may or may not be orthogonal; this approach does not automatically assume the object space is decomposed into pixels. The objects may be known exactly or random. The imaging system may be deterministic (low noise, nonrandom) or may be stochastic, and may be direct or indirect. This view of information-theoretic image formation is consistent with the framework shown in Fig. 7.14 for the imaging process. Moreover, in this treatment the task is more generally cast to include measures of optimality for detection, recognition (classification), parameter estimation, and scene estimation (image reconstruction). When the task is detection or classification, the overall performance of a system is measured by the performance of the recognition or detection function; performance measures for detection and recognition tasks include such familiar measures from Chap. 13 as the probability of detection and the probability of a false alarm. Optimal estimation for random objects is achieved using the familiar *maximum a posteriori* (MAP) procedure derived in Chap. 13 when a prior for the object exists; without a prior, maximum-likelihood methods result and are characterized by the Fisher information matrix and the Cramér-Rao bound.

Thus we see that the information-theoretic approach, when presented in this broad manner, is akin to the statistical-decision-theoretic approach presented in Chap. 13. In the information-theoretic approach, all performance metrics quantify the information provided by the measurements and the likelihood function plays a fundamental role in all cases. Similarly, we found in Chap. 13 that the likelihood ratio is central to all measures of task performance that characterize optimal decision/estimation strategies in statistical decision theory. The information-theoretic approach postulates that the user knows “everything except the decision” (O’Sullivan *et al.*, 1998). In other words, an ideal observer is assumed. Information measures are therefore useful for the assessment of raw data, but they are not necessarily good predictors of human performance. This point is particularly relevant to the use of information criteria in deriving optimal reconstruction algorithms. There is no guarantee that the resulting images are optimal when assessed in terms of human performance.

14.1.5 Objective assessment of image quality

For an image-assessment method to be acceptable, it must objectively quantify the usefulness of the images for performing a given task. Task-based measures of image quality have been advocated for many decades, starting with Harris (1964), and including Hanson (1977), Wagner (1978), Judy *et al.* (1981) and Myers *et al.* (1986). The resulting figure of merit must be computable and scalar, so that it can be used unambiguously in the optimization of imaging systems and the assessment of observer performance. Methods based on statistical decision theory satisfy these requirements.

Four key elements are essential in the objective assessment of image quality (Barrett, 1990):

1. Specification of a task;
2. Description of the object class(es) and imaging process, leading to a description of the data;

3. Delineation of the observer;
4. Figure of merit.

Let's consider each of these elements in more detail.

The task In Chap. 13 we considered two kinds of tasks in some detail. One kind of task is the detection of an object in the presence of a background or clutter. The object might have one or more random parameters and the background may or may not be random. A related task is the classification of an image into one of a finite number of alternative classes. A second type of task is the estimation of parameters describing the object or background or both. Chap. 13 gives many examples of detection, classification, and estimation tasks.

We have seen that many of the approaches described in earlier sections define the task as the reproduction of a single object. While object reproduction might be construed as an estimation task, there are several important differences between estimation and object reproduction. First, defining the task as object reproduction leads to the problem of commensurability delineated in Sec. 13.3.2: objects and images live in different spaces. No imaging system can exactly reproduce a continuous object. How then, to choose among systems that all fall short of this impossible goal? In addition, when the stated task is object reproduction, an assumption is being made that all object locations/elements/parameters are equally important; this is not the case in real situations. Finally, no imaging system will be utilized for a single object, so the task definition should encompass the use of the system over the expected range of objects.

Properties of objects and images From the preceding discussion we know that the evaluation of an imaging system should take into account the physical and statistical properties of the set of objects to be imaged. In a classification task, the objects are categorized into a finite set of classes. For example, the evaluation of mammographic imaging systems for the task of breast lesion detection requires the characterization of normal breast tissues and breast lesions in terms of the full probability density function of the objects under each class. While this is an impossible task, tremendous progress is being made toward the characterization of the mean and low-order joint densities of real tissues using ultra-high-resolution projection imaging and autoradiography, among other methods (Hoeschen *et al.*, 2000).

Another method for creating and characterizing a set of objects is through the use of simulations. The use of numerical algorithms to generate random objects gives the investigator the ability to characterize the deterministic and stochastic properties of the objects. Modern simulations are becoming increasingly realistic. Investigators have added simulated targets to real images (creating so-called hybrid images) with sufficient realism that in some cases human observers were unable to discriminate the artificial targets from real ones (Revesz *et al.*, 1974; Eckstein and Whiting, 1996). The future will bring even greater flexibility and realism to simulated images, with the entire anatomy and physiology of a human being modeled on a fine scale as a starting point toward the creation of simulated, highly realistic imagery of normal and abnormal states. Nonmedical imaging applications are following the same trajectory; in astronomy, acoustical imaging, radar, and so on, simulations of objects and imaging systems are vastly improving and leading to

new abilities to generate realistic data sets for image evaluation. Image simulation methods are described in some detail in Sec. 14.4.

The observer Given a task and a set of objects, the next requirement for the assessment of image quality is an observer or strategy for performing the task. The observer might be a human, such as a radiologist or an expert photointerpreter. Models of human observers can be used to predict human performance. Model observers make it possible to optimize imaging systems without the need for lengthy human-observer studies at every design stage. Human observers and their models are relevant to the assessment of images to be displayed for human consumption. For example, the assessment of display devices, reconstruction algorithms, and all manner of image-processing routines are evaluated appropriately using human observers or their surrogates.

The ideal observer is defined in Chap. 13 as the observer that makes optimal use of all available information to perform the specified task. Having no need for image reconstruction, the ideal observer is appropriate for the evaluation of the quality of the raw data for classification tasks.³ Thus the ideal observer is the observer of choice for the assessment of imaging hardware. As detailed in Chap. 13, the ideal observer requires the complete PDF of the data under each hypothesis. In cases where this information is not available, the Hotelling observer can be a useful alternative, requiring only the first- and second-order statistics of the data.

The figure of merit Having specified the task, the objects, and the observer, all that is needed is some way of telling how well the observer performs. For classification tasks, useful figures of merit include the area under the receiver operating characteristic (ROC) curve (AUC), partial ROC areas, sensitivity/specificity pairs, the percent of correct decisions (PC), and the classification signal-to-noise ratio, or SNR. Those readers unfamiliar with the theory of ROC curves are referred to Chap. 13 for background material necessary for understanding the terminology here.

Possible figures of merit for estimation tasks include bias, variance, mean-square error (MSE), and ensemble mean-square error (EMSE). The MSE summarizes the performance of an estimation algorithm in determining the estimable parameters of a single object averaged over multiple data sets. In contrast, EMSE describes estimation performance averaged over both measurement noise and a distribution of objects, allowing for nonestimable parameters. Estimators can also be evaluated using bounds on their performance, the most notable being the Cramér-Rao bound for maximum-likelihood estimators. In Sec. 13.3 the reader can find a lengthier treatment of performance measures for estimation tasks.

Returning to the set of requirements listed at the beginning of this section, we can see that each of the methods described in the previous sections lacks one or more of these key elements. For example, JND methods measure image quality using a distance between two scenes without specification of a task or an object class. Thus, in the remainder of this chapter we shall rely on the approach to the objective assessment of image quality outlined in this section.

³Wagner, Brown, and Pastel suggested the division of imaging systems into detection and display components for assessment purposes as early as 1979.

14.2 HUMAN OBSERVERS AND CLASSIFICATION TASKS

A wide variety of imaging applications make use of a human as the observer or expert reader. The task is almost always classification, because humans are not as adept as machine algorithms at the absolute quantitation of parameters using images as input. The purpose of this section is to chronicle what is known regarding the perception of form by the human visual system, how we measure human performance on classification tasks, and what we have learned regarding human performance for various classification tasks. We shall focus on the perception of pattern and form, with the goal of connecting this to an understanding of human performance on single, static images. The extension to tasks involving temporal information, color, or stereo are beyond our scope, although in many cases the generalizations required to include this kind of information will be suggested.

14.2.1 Methods for investigating the visual system

Centuries ago, the human eye was assumed to work as a simple camera. This view was espoused by the famous astronomer Johannes Kepler as early as 1604. Not long after, René Descartes' famous treatise, *La Dioptrique* (1637), described an experiment in which an eye from an ox was used to "view" the image formed on the retina, which had been scraped away to make the eye translucent. The discovery that the image formed by the eye's lens was inverted was a source of much confusion, since none of us has the experience of seeing the world upside down. Since that time we have come to realize that we do not directly "see" the retinal image; what we perceive is a processed and interpreted version of the image formed at the back of the eye. The retina and the visual components of the eye-brain system are complex entities that have been the subject of amazing discovery since the time of Kepler.

The images formed by the eye's lens onto the retina stimulate the approximately 130 million photoreceptors we know as the rods and cones. These units stimulate bipolar cells that lead to the ganglion cells, whose axons form the optic nerve. The axons of the optic nerve terminate in the lateral geniculate nucleus (LGN) of the thalamus. The cells of the LGN relay signals to a region of the striate cortex called the primary visual cortex. The activity of a cortical cell is thus the result of millions of retinal inputs. Within the visual cortex further signal processing and feature extraction occurs, leading to our visual perception of the world around us.

Early discoveries of the visual system were anatomical, as described so graphically by Descartes. Anatomical studies tell us the spatial sampling of the rods and cones, the number of fibers making up the optic nerve, and the location of their termini. We need other means of determining how these entities function and interrelate.

One means of elucidating the functional properties of the elements of the visual system is through electrophysiological studies in animals. These studies involve the placement of electrodes into single cells in the visual pathway and the subsequent measurement of the cell's response to visual stimuli. In 1940, Hartline became the first to insert electrodes into a single ganglion cell in a vertebrate (a frog) and record axon potentials, following his earlier experiments in the horseshoe crab (1934). Hartline's work was the precursor to the acclaimed work of Hubel and

Wiesel (1962), who shared the Nobel Prize for their pioneering study of the visual system of the cat. Hubel and Wiesel studied the response of single cortical cells to visual patterns of specific orientation and location (bars, edges, and spots) and found that the cells demonstrate orientation selectivity and binocularity. They soon reported similar findings in monkeys (1968).

Many electrophysiological investigations in animal models have followed in the giant footsteps of Hartline, Hubel and Wiesel. For such studies to be relevant to the human visual system, the animal's characteristics must be able to be extrapolated to the human. Since the visual systems of all vertebrates are similar, these measurements provide especially valuable information regarding the behavior of the human visual system.

The functioning of the visual system can also be studied using *psychophysics*, the measurement of the reactions of observers to visual scenes and the development of quantitative relationships between response data and physical characteristics of the input images. The physical characteristics of the images include quantities such as the display luminance, the noise and resolution properties of the images, as well as parameters that specify the target and background. Observer performance is measured in terms of indices such as the area under the ROC curve or the percentage of correct detection or localization responses. Thus psychophysical experiments determine external measures of the visual-system function. Methods for the conduction of psychophysical studies using human observers are presented in Sec. 14.2.3.⁴

Modern imaging methods have brought new tools to the study of the function of the visual system. Using functional imaging methods such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), investigators are determining areas of the brain involved in the performance of visual tasks. Imaging provides a noninvasive alternative to electrophysiological techniques with the ability to map both spatial and temporal response to stimuli.

In what follows we shall describe the more salient features of the visual system that are relevant to understanding human performance on classification tasks using images as inputs. These characteristics play a key role in the development of predictive models of the human observer.

Receptive fields A *receptive field* is an area on the retina that gives excitation or inhibition of a neuron's activity upon changes in illumination. Receptive fields can be defined for ganglion, geniculate, and cortical cells. The receptive field is evidence of a many-to-one relationship between photoreceptors in a region of the retina and the neural cell. In fact, there are about 1000 cortical neurons per retinal cone for visual information processing (Kronauer and Zeevi, 1985).

Receptive fields for the ganglia can be organized into two broad classes: those that have plain receptive fields, and those that have complex receptive fields. Plain receptive fields have a center-surround structure. When a spot of light illuminates their center, an increase in firing rate occurs (excitation); light on the surround region decreases the rate (inhibition). Diffuse light that illuminates both regions gives a cancellation of the signal, resulting in no response. Simple cells are often

⁴While it might be expected that psychophysics is exclusively applied to the study of human observers, psychophysical experiments using trained animals have been performed to elucidate properties of the cat and monkey visual system.

referred to as Kuffler cells, after the early investigator who mapped their behavior in the cat (Kuffler, 1953).

Complex cells, not surprisingly, are tuned to more complex retinal patterns, such as gratings. Enroth-Cugell and Robson (1966) were the first to measure the response of single ganglion cells to cosine gratings in the cat. Both even and odd receptive fields exist, giving the cat visual sensitivity to gratings and edges. At one time it was thought that complex cells were in series with simple cells, but we now know that simple and complex cells act in parallel. For some tasks the response of complex cells occurs earlier than that of simple cells, and for other tasks the opposite is the case (Hoffman and Stone, 1971).

The LGN and cortical neurons are also associated with receptive fields at the retina. Cortical cells have been found that are tuned to edges, lines, movement of lines and gratings at certain orientations, speeds and accelerations, and even angles between lines. While the responses of ganglion, LGN, and cortical neurons to stimuli have significant similarities, there are interesting differences across them as well. Maffei and Fiorentini (1973) compared the responses of these neurons to cosine gratings in the cat and found that the stages respond to different ranges of spatial frequencies. Moreover, the spatial frequency selectivity becomes narrower from the retina to the LGN to the cortex. DeValois *et al.* (1982) also found in the macaque that the sharpest tuning occurs in the cortex.

Lateral inhibition The output of a receptor's ganglion cell is not only impacted by multiple retinal inputs, but also by the behavior of nearby neurons. In studies of the horseshoe crab, Hartline and Ratliff (1957) were the first to show that the output of a ganglion cell can be inhibited when a nearby neuron is excited. This effect is referred to as *lateral inhibition*. The opposite can also occur, in which case the effect is termed *lateral summation*. Lateral inhibition and summation demonstrate one role of the synapse of the bipolar cells that communicate with the ganglion cells, enabling ganglion cells to interact.

Contrast sensitivity function By measuring the electrophysiological response of animals to patterns, the structure and function of multiple receptive fields have been elucidated. In humans, the ability to detect patterns is measured via psychophysics, giving a global response to the pattern rather than a response localized to a single neuron. The *contrast sensitivity function* (CSF) describes the overall sensitivity of the visual system to sinusoidal patterns as a function of pattern frequency. High sensitivity signifies that the pattern can be seen with little contrast; low sensitivity implies that a large contrast is required for the observer to detect the pattern. A great many psychophysical studies have been conducted to determine the sensitivity of human observers to grating patterns, starting with DePalma and Lowry in 1962. Robson (1966) measured both spatial and temporal CSFs in humans in the 1960s. Campbell and Robson (1968) measured the contrast sensitivity to single sinusoidal gratings over a broad range of spatial frequencies at fixed background luminances. By determining the just-visible contrast of sine-wave targets, these authors found that the CSF follows a band-pass shape with a pronounced maximum at 2 to 4 cycles per degree, falling off at both low and high spatial frequency. An idealized CSF is shown in Fig. 14.1.

Fig. 14.1 Idealized example of a contrast sensitivity function.

We now know that the visual system is extraordinarily adaptive; the CSF is dependent on mean luminance level, noise level, color, accommodation, eccentricity, and image size (Kelly, 1977). While color CSFs have a shape similar to that shown in Fig. 14.1, high-frequency color patterns are less detectable than luminance patterns of the same frequency (Cornsweet, 1970). There is also significant variation in contrast sensitivity functions, as well as other parameters of the visual system, across human observers (Ginsburg *et al.*, 1982; Owsley *et al.*, 1983). Ginsburg and Evans (1984) measured the CSFs of a large population of observers and found that the peak value is dependent on the individual.

The CSF is often depicted as the envelope of multiple narrow spatial-frequency-selective responses internal to the visual system. This view stems from evidence that the bandwidth determined via psychophysical study in animals can be much greater than that determined via electrophysiological experimentation. For example, individual neurons in the cat have been found to respond to a narrower range of frequencies (Movshon *et al.*, 1978) than what is found externally via behavioral studies (Blake *et al.*, 1974).

Lateral inhibition reduces sensitivity to signals with large extent. That the CSF is very low at low frequency is consistent with the inhibitory behavior of receptive fields at low frequencies. Several studies have established that the human observer is unable to efficiently integrate information beyond a certain spatial extent (Blackwell, 1946; Burgess *et al.*, 1979; Boff *et al.*, 1986).

Masking Research has shown that the presence of one pattern can make another pattern less visible to an observer. This property is known as *masking*. The opposite of masking is *facilitation*, defined as the improved detection of a pattern in the presence of another. The pattern to be detected is referred to as the *signal*; the additional pattern is referred to as the *mask*. The mask is usually supra-threshold, meaning its contrast is above that required for detection. When the mask contrast becomes sufficiently low, the signal threshold is identical to the the signal threshold in the presence of a uniform background; that is, the signal threshold is what is expected based on the observer's CSF and no masking occurs.

Periodic patterns such as gratings or sinusoids have been shown to mask patterns with similar orientation or spatial frequency (Legge and Foley, 1980; Phillips and Wilson, 1984). This effect is known as *phase-coherent* masking. Another experimental paradigm is to use noise fields of different bandwidths as masks; the

effect is then called *phase-incoherent* masking (Pollehn and Roehrig, 1970; Pelli, 1981; Thomas, 1985). The presence of an aperiodic pattern such as an edge or a gradient can also mask a nearby feature (Fiorentini *et al.*, 1955). Masking demonstrates orientational selectivity as well as frequency-dependent behavior (Campbell and Kulikowski, 1966).

Diffuse light can mask signals. For this reason radiologists are trained to read images in a darkened viewing area after they have adapted to the ambient light level, to better detect low-contrast signals. Scattering in the lens and cornea of the eye can also mask low-contrast signals. This problem is known to worsen with age.

Channels *Channels* are independent processors tuned to different narrow ranges of spatial or temporal frequency. Channels were first hypothesized as visual scientists pondered data from studies using compound-frequency patterns such as sawtooth and rectangular gratings (Campbell and Robson, 1968). These data seemed to indicate that detection of the pattern occurs only when the most detectable component reaches its own threshold, independent of the presence of the other frequency components. Sachs *et al.* (1971) then carried out experiments using compound gratings consisting of just two frequency components. Whenever the second component differed in frequency from the first by more than a certain ratio, the data were consistent with the hypothesis that the two frequency components were being detected independently. Moreover, when two components with frequencies related by an even larger ratio were combined, the grating was no more detectable when the two components were phased so that their peaks added than when their peaks subtracted (Graham and Nachmias, 1971). The investigators concluded that different spatial-frequency components were detected by independent processors tuned to different narrow ranges of spatial frequencies. Detection of a stimulus occurs whenever the activity in one of these processors rises above a threshold. These processors were referred to as channels. Channels can be thought of as mosaics of receptive fields (Sachs *et al.*, 1971).

Many scientists have worked to corroborate the presence of frequency-selective channels in the visual system (Mostafavi and Sakrison, 1976) and to determine their properties in finer detail (Halter, 1976). The electrophysiological recordings of Hubel and Wiesel (1962) are construed by many as the first evidence for channels. Adaptation and masking experiments support the hypothesis that the channels are medium-bandwidth mechanisms (Blakemore and Campbell, 1969; Stromeyer and Julesz, 1972; Stromeyer and Klein, 1975; Legge and Foley, 1980). Narrow-bandwidth channels are suggested by the results of frequency-discrimination tasks (Campbell *et al.*, 1970). The entirety of the data suggests the presence of approximately octave bandwidth spatial-frequency channels over the entire visible range.

There is ample evidence, starting with the work of Hubel and Wiesel (1962), that the visual system also contains orientation-selective channels. DeValois *et al.* (1982) investigated simple cells in the macaque and found them to have an angular resolution of $\pm 20^\circ$. These data are quite similar to the estimates of orientation selectivity in humans obtained using masking experiments (Campbell and Kulikowski, 1966; Phillips and Wilson, 1984). There are also channels tuned to object motion that have direction selectivity (Tolhurst, 1973), with a temporal two-octave bandwidth (Tolhurst, 1975; Watson and Robson, 1981).

Internal noise Human observers are noisy measurement devices. Thus, even if the images presented to a human observer were noise-free, the output of the human would have some variability. While it requires only one optical photon to excite a rod, the number necessary for “seeing” is larger (Hecht *et al.*, 1942). Barlow was the first to suggest that this discrepancy is the result of an internal noise mechanism (1956).

Burgess *et al.* (1981) compared human SKE (signal-known-exactly) detection performance in white noise to an ideal detector with an added internal noise contribution. While this modification to the ideal-observer model improved the model’s agreement with the human data, it was suggested that some form of observer sampling inefficiency was also needed for the model to match the slope of the human data vs. noise spectral density. The authors further suggested that perhaps the observer noise might be a function of image noise. Data from subsequent classification experiments have borne out the suggestion that the visual system has two internal noise components (Burgess and Colborne, 1988). The first component is an additive noise term that is independent of the image luminance. This noise component may be the result of neural noise (Tolhurst *et al.*, 1983), as well as fluctuations in the observer’s decision criterion (Eckstein *et al.*, 1997). The second component is an induced, or image-dependent, component. The induced internal noise has been shown to be proportional to the variance of the image noise (Burgess and Colborne, 1988).

Weber-Fechner law As stated earlier, diffuse light can mask low-contrast signals. As a result, objects on bright backgrounds are harder to detect than objects on dark ones (Cornsweet, 1970). The Weber-Fechner law states that the relative contrast of an object, given by $(L_{max} - L_{min})/L_{mean} = \Delta L/L$, is equal to a constant for a given probability of detection. By this law, the detection of a difference in luminance depends on the baseline, so that relative luminance is important, rather than absolute differences.

Evidence of behavior following the Weber-Fechner Law has been interpreted as a local gain mechanism or a saturating nonlinearity in the visual system, coupled with internal noise (Shapley and Enroth-Cugell, 1985). This law also plays a significant role in the approach used by many investigators in choosing the calibration method for their soft-copy display (Blume and Hemminger, 1997). Many investigators choose to use a *perceptually linearized* display, in which the output luminance at each digital driving level is set so that the step sizes between gray levels is higher at higher absolute luminance levels (Pizer, 1981).

Psychometric functions A *psychometric function* is a plot of the probability of a signal being detected as a function of signal contrast. For a signal of contrast c , the probability of detection is usually fit by a sigmoidal function of the form (Nachmias, 1981)

$$\Pr(D_2|c) = 1 - \exp[-(c/\alpha)^\beta], \quad (14.4)$$

where D_2 indicates that the observer chose in favor of the signal being present, β is a slope parameter, and α shifts the function relative to the signal contrast. Many experiments have been found to indicate approximately equal slope parameters (Mayer and Tyler, 1986).

14.2.2 Modified ideal-observer models

Given the vast array of anatomical, electrophysiological and psychophysical data now available to us, many researchers have worked to develop models for all or portions of the visual system. Some models are highly specialized, with the minimum number of components required to demonstrate the model's ability to predict data obtained in a narrow range of psychophysical experiments. Other models are extraordinarily complex, incorporating foveal sampling, a hierarchy of neural stages, and higher-level signal processing and decision making in an effort to replicate the entire visual system. We shall focus on models that have been developed for the specific purpose of objective evaluation of imaging systems for classification tasks.

In Chap. 13, the ideal observer was introduced as the optimal decision maker for classification tasks as determined by statistical decision theory. The ideal observer sets the upper bar for classification performance. Statistical-decision-theoretic models of the human observer thus use the ideal-observer model as a starting point. We do not need a model with millions of photoreceptors and receptive fields, so long as the model predicts human data on a range of tasks that are useful for image assessment. In fact, a simpler model facilitates imaging system evaluation and optimization over high-dimensional optimization spaces.

The modified-ideal-observer approach to modeling human performance is this: begin with the concept of the ideal observer; compare performance predictions with human performance on actual classification tasks; modify the model to better predict human performance. Modifications to the model should be grounded in the known features of the visual system described in the previous section.

We therefore require a rigorous basis for comparing observer performance. For this, we return to the concept of observer efficiency.

Observer efficiency In Chap. 12 we introduced the concept of detective quantum efficiency as a measure of the SNR transfer characteristics of a detector [*cf.* (12.23)]. In Chap. 13 we extended this concept to describe the efficiency of the Hotelling observer relative to the ideal observer [*cf.* (13.273)]. Analogously, we can define the statistical efficiency of the human observer relative to the ideal observer as

$$\eta_{human} = \frac{\text{SNR}_{human}^2}{\text{SNR}_{ideal}^2}. \quad (14.5)$$

The relative efficiency of any two observers can be similarly defined.⁵

When human and ideal performance are comparable, the efficiency approaches one and we conclude that the human observer is able to make almost complete use of the information in the data to perform the visual task. For efficiencies much less than one, we can conclude that the human observer is inefficient at extracting the relevant information in the image for performing the task. When this occurs, we look for features of the human visual system that might be the basis for the human observer's reduced performance.

⁵Some authors have defined observer efficiency as the ratio of SNRs required by the observers to perform the task. In this school, human efficiency equals the SNR required by the ideal observer divided by the SNR required by the human, where SNR is a physical quantity such as contrast; smaller SNRs denote better performance. We prefer the definition given in (14.5), where SNR quantifies task performance and high SNR is good!

Classification in uncorrelated noise As described in Sec. 13.2.13, the definition of observer efficiency given in (14.5) comes from the basic definition of DQE first given by Albert Rose (1948) as a means of comparing the noise level of an actual radiation detector with that of an ideal one. Rose compared the performance of the eye to an ideal picture pickup device and determined that the minimum contrast c_{min} required for detecting a uniform object on a flat background with quantum noise satisfies

$$c_{min}^2 NA = k, \quad (14.6)$$

where N is the photon density of the uniform background, A is the area of the object and k is a constant dependent on the observer; from experiments on human subjects, Rose determined that k is in the range of 3 to 7. A lower value of k implies a lower c_{min} and hence a more efficient observer.

Recall from Sec. 13.2.8 that the ideal observer takes on a special form when the task is the discrimination of two nonrandom signals in additive Gaussian noise. In this case the ideal observer is equivalent to a prewhitening matched filter (PVMF), which reduces to a simple matched filter when the noise is white. Lawson (1971) demonstrated that the Rose model of (14.6) is a special case of the PVMF for a pillbox signal in Poisson noise of sufficient count rate that the Poisson statistics can be approximated by Gaussian statistics.

The calculation of the ideal observer's SNR is straightforward for SKE/BKE (signal-known-exactly/background-known-exactly) tasks in Gaussian noise and can be done analytically. For this reason the first comparisons of human performance to ideal-observer performance were achieved in SKE/BKE tasks in white, or uncorrelated, Gaussian noise. Burgess *et al.* (1981) found human observers to be highly efficient (η of 0.5 to 0.8) for SKE/BKE detection and discrimination tasks in white noise. Human performance is well predicted by an ideal observer that positions a template over the location of the expected signal and performs a linear summation of the output. The fact that the efficiency is less than one can be explained by internal noise (Burgess and Colborne, 1988).

When the signal extent becomes sufficiently large, human detection efficiency in white noise declines (Burgess *et al.*, 1979). In effect, there is a spatial limit to the human's ability to perform the template-matching operation. We might have expected this from the shape of the CSF of the visual system. Other investigators have found that the human is unable to efficiently process "DC" information (Ratliff, 1965; Van Nes and Bouman, 1967). For this reason some investigators proposed that the PVMF model be modified by adding an "eye filter" (Loo *et al.*, 1984; Burgess, 1994).

Correlated noise Many experiments have been performed to investigate the impact of correlated noise on human discrimination performance (Judy, 1981; Guignard, 1982; Burgess, 1985b; Myers *et al.*, 1985; Blackwell, 1998). Of particular interest in the early 1980s was the character of the noise in computed tomography (CT) images and its impact on human perception. Raw CT data sets have Poisson noise, which is uncorrelated. When CT images are reconstructed from the raw data using the method of filtered backprojection (see Sec. 4.4.3), a filter with a ramp shape in the frequency domain is used, and the resulting images have a ramp-shaped power spectrum at low spatial frequency. Early on, Wagner (1978) hypothesized that human observers would be inefficient when faced with this noise-correlation structure, and suggested that a non-prewhitening matched filter model might be a good predictor

of human performance. Soon after, several studies found that human efficiency relative to the ideal observer is about 20% in CT noise, much less than the efficiencies found in white noise (Judy *et al.*, 1981; Burgess *et al.*, 1985b). Myers *et al.* (1985) investigated human performance for a family of noise power spectra of the form ρ^n , for $n = 1, 2, 3, 4$, where ρ is spatial frequency. Thus $n = 1$ corresponds to the CT case. These studies showed that human efficiency falls rapidly as n increases from 1 to 4.

A natural conclusion to draw from the reduced efficiency of the human observer in tasks limited by correlated noise is that the human observer is indeed unable to perform the prewhitening operation. For this reason the human observer was modeled by some investigators as a matched filter without the prewhitening operation. The efficiency of the human relative to this so-called non-prewhitening matched filter (NPWMF) was shown to be around 50% (Judy and Swensson, 1985), with the difference again explainable by internal noise.

Since the NPWMF equals the PWMF in white noise, the NPWMF model predicts human performance in both correlated and uncorrelated noise. Furthermore, by combining an eye filter and an internal noise mechanism with the NPWMF, an even larger body of human psychophysical data can be explained (Ishida *et al.*, 1984; Loo *et al.*, 1985; Ohara *et al.*, 1986; Giger and Doi, 1987; deBelder *et al.*, 1971; and Wolf, 1980). This observer is often called the NPWE in the literature, to denote the addition of an eye filter to the non-prewhitening matched filter; we shall use this same shorthand below.

The NPWE models the spatial-frequency response of the visual system with a single spatial-frequency filter. Given the experimental evidence that the human visual system has multiple narrow spatial-frequency channels, a preferred approach to modifying the ideal observer is to incorporate this recognized characteristic of the visual system.

Adding channels to the ideal observer The model of the human visual system as a matched filter is effectively a model with an infinite number of channels. Yet there is substantial evidence that the visual system processes images through a finite number of finite-width channels. Myers and Barrett (1987) introduced a handicapped ideal observer, constrained to process scenes through frequency-selective channels, and demonstrated that this modified Bayesian observer ably predicted human performance in correlated noise. They found that this model was robust to the choice of a channel width parameter. By requiring the lowest-frequency channel to have a finite turn-on frequency, this model also predicts the inefficient performance of human observers on tasks that have significant DC content.

Myers and Barrett found the performance predictions of the channelized ideal observer and the NPWMF to be indistinguishable for the problems they studied (stationary Gaussian noise, signal known exactly). They argued in favor of the channelized ideal observer because this model is consistent with a known mechanism of the visual system. Moreover, as we shall see in the following sections, this model has been found to be predictive of human performance over a much broader range of signal detection and discrimination tasks.

Random backgrounds The tasks described in the previous section were ones in which the background was known exactly; the only variation in the data was due to measurement noise. We now consider tasks in which the data are random due to

both background variability as well as measurement noise. The noise in the data is therefore said to have two components.

In Sec. 8.4 we described several approaches for generating random backgrounds, and in Chap. 13 we discussed model observers for tasks in which the background is random and known only in a statistical sense. Several investigators have made use of these methods to study the performance of human observers in random backgrounds and compare the results to model-observer predictions. Rolland and Barrett (1992) generated lumpy backgrounds by randomly superimposing Gaussian blobs on a uniform background according to the procedure described in Sec. 8.4.4. For the task of detecting Gaussian signals of known size and location on the lumpy backgrounds, Rolland and Barrett compared human performance to the performance of the Hotelling or optimal linear observer defined in Sec. 13.2.12 as well as the NPWMF. Rolland and Barrett found that the Hotelling observer was a good predictor of the human performance data. The performance of the NPWMF was not able to predict human performance over the range of system parameters investigated in the study.

Yao and Barrett (1992) combined the background model of Rolland and Barrett with power-law noise of the type investigated by Myers *et al.* (1987) and found that a channelized Hotelling observer was a good predictor of all the human data acquired in these experiments (Barrett *et al.*, 1993). Burgess *et al.* (1994, 1997, 1999) studied human performance in random lumpy backgrounds generated by filtering a Gaussian field. Their results were consistent with the findings of Rolland and Yao: a Hotelling observer constrained to process the frequency-selective channels is able to predict the data over the range of experimental parameters describing the signals and backgrounds. A NPWMF is not predictive, even when modified to include an eye filter. More recent experiments in power-law backgrounds generated by filtering a Gaussian random process were less conclusive; the most predictive model depended on the signal profile in a study by Burgess (2001).

Several studies have been performed to compare human performance to model observers using real images as backgrounds. In a study using backgrounds drawn from real x-ray coronary angiograms, Eckstein *et al.* (1999) found the channelized Hotelling model to be predictive of human performance in detecting simulated abnormalities. Bochud *et al.* (1995, 1999a, 1999b) studied human performance using simulated nodules in mammographic and angiographic backgrounds and compared their results to a non-prewhitening observer with and without an eye filter (a single channel). They found that, owing to the nonstationarity of the images, the models must be allowed to adapt to the statistics of the local background around the signal in order to better predict human performance. Interestingly, the data of Bochud *et al.* (1999b) suggest that the clinical backgrounds have higher-order statistical properties used by the human observer, although not by the Hotelling observer. Similarly, Caelli and Moraglia (1986) showed that a cross-correlator does not predict human performance when the background is a natural scene.

Signals of large spatial extent The inability of human observers to efficiently detect signals of large spatial extent described in Sec. 14.2.1 has direct ramifications on the task-based assessment of the quality of images derived from systems with significant artifact content. For example, the effective point response function (PRF) for images reconstructed from limited-angle tomographic data can be quite noncompact, yielding long-range streak artifacts. The images of compact objects are thus quite

extended and human efficiency for detecting such objects suffers a penalty (Wagner *et al.*, 1992; Myers *et al.*, 1993). These studies found that human performance is modeled quite well by an observer that performs only linear operations on the images. These studies involved signals at random locations, leading to location-dependent artifacts; the ideal observer is nonlinear in this case if the problem is cast as a binary signal-detection problem.

A long-tailed PRF can also arise when veiling glare is present in a display device or gamma rays penetrate the collimator in gamma-ray imaging. Rolland *et al.* (1989) has shown that human classification performance is inefficient for images formed by a system with a long-tailed PRF, consistent with the earlier literature on the inefficient spatial integration properties of the human. Rolland found that human performance is improved by linear filtering designed to narrow the overall system PRF, even though the ideal observer performance is unchanged by image processing (Sec. 13.2.6), as long as it is invertible.

Texture perception In some special circumstances the human can detect signals of large spatial extent quite efficiently. An example is the detection of a known grid of bright lattice points on a noisy background (Wagner *et al.*, 1990a). Another example is the detection of mirror symmetry patterns of dots (Barlow, 1978; Barlow and Reeves, 1979) buried in a background of random dots (Glass patterns). These results can be explained by an observer who uses the strategy of performing a series of local template-matching operations, skirting the need for integration over a large area (Wagner *et al.*, 1989).

A particular form of extended signal is a pattern of a different texture than the texture of the background in which the signal is embedded. In tasks where such an extended signal is to be detected, human efficiency can be extremely low. For example, the detection of a regular grid or lattice of objects, where some randomization of the object locations is involved, results in low human efficiency (Wagner *et al.*, 1990a). Similarly, the detection of random dot patterns (Maloney *et al.*, 1987; Tapiovaara, 1990) and the detection of diffuse liver disease (Garra *et al.*, 1989) can also be low-efficiency tasks. While many investigators have considered human performance in texture discrimination tasks (Julesz, 1981), these studies are rarely placed in the context of ideal-observer performance. Much more work is needed to understand human performance in textured tasks on an absolute scale.

Nonlinear tasks While the channelized Hotelling observer has been found to predict human performance over a wide range of experimental paradigms, that observer is constrained to perform linear operations on the data. In addition, as the previous section describes, there are ample examples of psychophysical studies showing low human efficiency relative to the ideal observer for nonlinear tasks. The question then arises, can the human do nonlinear operations?

There are many examples of tasks for which human efficiency is fairly high even though the optimal strategy is nonlinear. One example is the task of noise variance discrimination, wherein observers are asked to determine which of two scenes has higher pixel variance. The optimal discrimination strategy is quadratic in the data as seen in (13.163). In unpublished studies, we found that humans were able to perform this task quite efficiently. Does this mean the humans are able to do the computations of (13.163)? Maybe not. It can be shown (Wagner *et al.*, 1990b) that

a combination of linear and logic operations can approximate this ideal nonlinear strategy quite efficiently.

Similarly, the detection of 1 of M orthogonal signals in white noise is optimally performed with a nonlinear strategy [see (13.159)]. However, Nolte and Jaarsma (1967) showed that a series of linear operations, followed by the nonlinear operation of selecting the filter with the maximum output, approximates the ideal nonlinear strategy well over much of the signal parameter space of interest (the range of contrasts of use for psychophysical study). Other investigators have also shown that the “maximum-of” detector gives performance predictions very close to those of the optimal observer in the SNR ranges of experimental interest (Pelli, 1985; Wagner, 1990b).

Burgess and colleagues (Burgess and Ghandeharian, 1984a, 1984b; Burgess, 1985a) measured human efficiency in studies with signal uncertainty in white noise. To approximate ideal-observer performance, they computed the performance of an observer that compared the maximum of a series of matched-filter outputs to a threshold, following the theory of Nolte and Jaarsma (1967). Human observer performance was well predicted by this model observer, with an efficiency around 50%. Judy *et al.* (1997) found little degradation in human performance for the detection of sharp-edged disks and Gaussian signals when the disk diameter or Gaussian width was variable, relative to the SKE task.

Since selecting the maximum of a set of outputs from linear filters is a nonlinear or logical operation, we call this model a *linear+logic observer*. The closeness of the optimal observer to the linear+logic model may preclude one model being rejected in favor of the other using psychophysical data.

The field of neural networks sheds some light on the similarity of these models. A fully connected neural network can be shown to approximate ideal-observer performance. The neural network applies a series of filters in the form of weights to each input value, followed by a sigmoidal nonlinearity—a neural network is a linear+logic observer. As described earlier, there is good evidence that neural responses in the human visual system can be represented by a set of linear filtering operations followed by thresholding, and neural networks represent this scheme. Thus, when the human observer performs nonlinear tasks efficiently, we must be cautious before concluding the human can perform the optimal higher-order (in the data) nonlinear operations. It may well be that the human is smartly performing a series of linear operations, followed by a threshold nonlinearity, to obtain near-optimal performance.

Optimal processing of channelized data As demonstrated in Fig. 14.2, the addition of a channel mechanism to a model observer can be visualized by adding a block to the processing steps shown in Fig. 13.1. In the figure we suppose there are P channels, each represented by the column vector \mathbf{u}_p . The output of the channels is given by

$$\mathbf{v} = \mathbf{U}^t \mathbf{g}, \quad (14.7)$$

where \mathbf{U} is the $M \times P$ matrix whose columns are the channel profiles \mathbf{u}_p , and \mathbf{v} is the $P \times 1$ vector of channel outputs. The \mathbf{u}_p represent the channel profiles, which we assume to be real. Processing the images through channels reduces the dimensionality of the data set from M to P . Possible choices for channel profiles are presented below. In some applications, P can be as small as 3.

Each channel output v_p is a random variable, made random by measurement noise and object variability — whatever sources of randomness are in the raw data. The probability density of each channel output is obtained using the methods for transforming random vectors presented in Sec. 8.1.5. Life is usually simpler, though, because in most models each channel output is the sum of multiple data values; the central-limit theorem tells us that the resulting random variable tends to be Gaussian distributed in that case.

Fig. 14.2 Block diagram of a channelized observer.

Given the $\{v_p\}$, a strategy must be defined by which the channel outputs are combined to arrive at a decision that a stimulus either is or is not present. Possible options include adding the responses of the channels or using only the channel with the maximum response (Graham and Nachmias, 1971). Alternatively, the channel outputs may be combined via *probability summation* (Pirenne, 1943). Pirenne conjectured that binocular vision yields lower detection thresholds than monocular vision because the probabilities of detection from the left and right eyes are independent, and signals are detected if they are detected by the right eye, the left eye, or both. Formally, he suggested that the probability of detecting a signal using both eyes is

$$\Pr(D|L + R) = 1 - [1 - \Pr(D|L)][1 - \Pr(D|R)], \tag{14.8}$$

where $\Pr(D|L)$ and $\Pr(D|R)$ are the probabilities of detecting the stimulus with the left and right eyes, respectively. While probability summation has been rejected as an explanation for the relative performance of binocular to monocular vision, it is encountered in some vision-system models as a means of combining the outputs of parallel channels (Daly, 1993). Combinations of differences in channels at each location/pixel have also been suggested (Lubin, 1993; Lloyd and Beaton, 1990; Zetzsche and Hauske, 1989). In some channel models, the sigmoidal form of (14.4) is imposed on the outputs of the frequency- and orientation-selective filters at each location (Legge and Foley, 1980) before the decision-making step.

Optimal methods for combining channel outputs The human observer can also be modeled as a quasi-ideal observer, that is, an observer who is constrained to process visual scenery through channels, but who is otherwise optimal in how the channel outputs are used to perform the task. If the human is modeled as a channelized ideal observer, the model will achieve maximal AUC among all observers constrained to process data through the visual channels. A channelized ideal observer forms the

likelihood ratio of the channel outputs under each hypothesis, giving

$$\Lambda(\mathbf{v}) = \frac{\text{pr}(\mathbf{v}|H_2)}{\text{pr}(\mathbf{v}|H_1)}. \quad (14.9)$$

The model observer's decision strategy is to compare $\Lambda(\mathbf{v})$ to a threshold, choosing H_2 when $\Lambda(\mathbf{v})$ is greater than this value, and H_1 otherwise. As detailed in Chap. 13, the ROC curve and related performance measures for the channelized ideal observer can be determined using (14.9) as a starting point.

Alternatively, a channelized Hotelling observer (CHO) model might be invoked, thereby assuming that the human observer forms an optimal linear combination of the channel outputs. As described in Sec. 13.2.12, there is a well-established theory for determining the optimal linear combination of the channel outputs and the resulting CHO figure of merit using the statistical properties of the channel outputs. For a binary discrimination task, the Hotelling observer's template in the channel space is given by

$$\mathbf{w}_{Hot,\mathbf{v}} = \mathbf{S}_{2\mathbf{v}}^{-1} \Delta \mathbf{v}, \quad (14.10)$$

where $\mathbf{S}_{2\mathbf{v}}$ is the $P \times P$ intraclass scatter matrix of the channel outputs [*cf.* (13.187)] and $\Delta \mathbf{v}$ is the expected difference in the channel outputs under each hypothesis.

The separability of the data in channel space is written in terms of the interclass and intraclass scatter matrices for \mathbf{v} :

$$J_{\mathbf{v}} = \text{tr}[\mathbf{S}_{2\mathbf{v}}^{-1} \mathbf{S}_{1\mathbf{v}}] = \text{tr}[(\mathbf{U}^\dagger \mathbf{S}_{2\mathbf{g}} \mathbf{U})^{-1} (\mathbf{U}^\dagger \mathbf{S}_{1\mathbf{g}} \mathbf{U})], \quad (14.11)$$

where $\mathbf{S}_{1\mathbf{v}}$ is the interclass scatter matrix of the channel outputs [*cf.* (13.186)]. While (14.7) has the form of the linear transformation given in (14.10), including a dimensionality reduction, these expressions differ significantly because transformation using the matrix of visual channel functions \mathbf{U} may result in the separability of the channel outputs being less than the separability of the data, while the operation of (14.10) generates a test statistic that preserves the separability in the channel outputs.

When the channel outputs are Gaussian random variables with equal covariance under the hypotheses, the channelized Hotelling observer and the channelized ideal observer are equivalent. In Sec. 14.3 we shall discuss methods for computing performance measures for channelized model observers.

Channel choices The nature of the signal and the background play a significant role in determining an appropriate choice for the channel profiles $\{\mathbf{u}_p\}$ and the way they are imposed on the data. For example, in an SKE task the channels are centered at the known signal location and the sum represented by (14.7) is done. If, on the other hand, the signal can be located at N multiple orthogonal locations, the channels could be centered at each location to give an $N \times P$ vector of outputs for decision-making purposes. When the signals and background are rotationally symmetric, the channels do not require any angular dependence; orientation-dependent signals and backgrounds require channels with orientation-selective responses.

The channelized ideal-observer model of Myers and Barrett (1987) incorporated radially concentric channels to predict human performance in correlated noise. The model's predictive ability was found to be insensitive to channel width and low-frequency turn-on parameters for the tasks considered in that work. The simplicity of this channel structure was possible because the task was the detection of radially

symmetric signals at known locations. Because the signals were low contrast and the image noise was a filtered Gaussian random process, the model was equivalent to a channelized Hotelling observer.

More complex tasks involving asymmetric signals at varying locations may require more complex channel models. A variety of approaches for representation of channel mechanisms have been pursued by the developers of models of the visual system; these approaches can be incorporated into a CHO framework. Models based on Gabor functions (Daugman, 1988; Lloyd and Beaton, 1990; Watson, 1987) and wavelets (Daugman, 1985; Mallat, 1989; Marcelja, 1980; Watson, 1983) can be made to have both spatial and location specificity. Other options include ratio-of-Gaussian channels (Zetsche and Hauske, 1989) and difference-of-Gaussian (DOG) models (Wilson and Bergen, 1979). Difference-of-mesa (DOM) filters can be used to model radial-frequency filters as well (Daly, 1993). “Mesa” is Spanish for table; a difference of two mesa functions gives a filter with a flat passband, a transition region, and a flat no-pass band. To give radial-frequency filters orientation selectivity, they can be multiplied by a set of functions tuned to orientation. For example, Daly uses what he calls *fan* filters to model the orientation-selective response. The product of the DOM and fan filters are termed cortex filters.

Once a selection has been made of the functions to be used to create a family of channels tuned to an array of orientations and frequencies, the next question is the number of such channels to include in the model. Many studies have indicated that only a fairly small number of channels is required for adequate modeling of human data. Myers and Barrett (1987) found good agreement between human data and CHO predictions with about 6 radial channels. The Daly visual-difference predictor model, designed to predict human performance for JND tasks (Sec. 14.1.3), uses only 6 DOM filters, combined with as few as 6 fan filters (30 degrees each), leading to 31 cortex filters in all $[(\# \text{ of fans}) \times (\# \text{ of DOMs} - 1) + 1]$, since the lowest frequency filter has no orientation specificity). Wilson and Gelb (1984) also suggested the use of 6 spatial-frequency selective DOG filters, each with a range of orientations. There seems to be reasonable consensus that only about 6 channels are needed to cover frequency space; adding about 6 orientation-specific channels to each frequency-selective filter gives a complete model.

Internal noise To achieve even better matching between CHO and human data, the internal noise of the visual system must also be addressed. One way to account for internal noise is to scale the detectability of the human observer to that of the model observer (Burgess *et al.*, 1997; Burgess, 1999), giving $SNR_{human} = \kappa SNR_{model}$, where κ represents the impact of internal noise on detectability. From (14.5) it can be seen that the scaling factor is related to observer efficiency according to $\eta = \kappa^2$.

Another approach is to add noise injectors to the channel model, as shown in Fig. 14.3, giving a modified definition of the channel outputs of (14.7):

$$v_p = \mathbf{u}_p^\dagger \mathbf{g} + \epsilon_p, \tag{14.12}$$

where ϵ_p is an additive Gaussian noise contribution in channel p (Legge and Foley, 1980).

For a channelized linear observer, (14.12) is equivalent to adding noise to the decision variable (Abbey and Bochud, 2000). In particular, the channelized Hotelling observer forms the scalar test statistic t according to

$$t = \mathbf{w}_{Hot}^t \mathbf{v} = \mathbf{w}_{Hot}^t [\mathbf{U}^t \mathbf{g} + \boldsymbol{\epsilon}] = \tilde{v} + \tilde{\epsilon}, \tag{14.13}$$

where the tildes represent the transformation to the decision-variable space. Both \tilde{v} and $\tilde{\epsilon}$ are scalar random variables, and both can usually be assumed to be Gaussian. The point of (14.13) is that a single Gaussian-noise injector at the decision variable level can model additive internal noise.

Observer uncertainty acts as a source of internal noise. It might be expected that observer uncertainty about parameters of the signal would result in a signal-dependent noise contribution, or a channel-dependent noise contribution. For example, one might hypothesize that the magnitude of a matched-filter's template uncertainty would depend on actual signal size, which would result in signal-dependent internal noise. However, Eckstein *et al.* (2000a) note that signal uncertainty is most often modeled as statistically independent of the signal.

Fig. 14.3 Block diagram of a channelized observer including an internal noise mechanism.

Observer efficiency revisited The efficiency of the human observer relative to any model observer can be defined via (14.5). Choices for the denominator include the full ideal observer, the PWMF in SKE/BKE tasks in Gaussian noise, the NPWMF in SKE tasks, and the channelized Hotelling observer. A growing volume of psychophysical data, combined with model-observer calculations, is establishing the channelized Hotelling observer as an excellent predictor of human classification performance over a wide range of experimental paradigms, including ones in which the PWMF and NPWMF models are far less able to predict human performance. For this reason the remainder of this section will emphasize human efficiency relative to the CHO and review some of the many additional studies that have demonstrated the predictive capacity of the CHO model.

CHO success stories Many of the first comparisons of Hotelling and human performance involved the assessment of image quality in nuclear medicine. Fiete *et al.* (1987) investigated human performance in detecting simulated lesions in simulated liver scans and found excellent correlation with the Hotelling observer. Cargill (1989) used a more elaborate simulation for nuclear medicine, involving the detection of abnormalities in simulated images of a computer-generated 3D model of the liver with several possible disease states. She found excellent correlation between human performance and Hotelling predictions of image quality for 9 different collimator designs.

The CHO has also been shown to correlate well with human performance in the assessment of acquisition systems and reconstruction algorithms in tomographic imaging. Abbey and Barrett (1995) found good agreement between the human and

CHO across a range of linear iterative reconstruction algorithm parameters. Gifford *et al.* (1999, 2000a) used human and model observers to evaluate the impact of detector-response compensation on tumor detection in SPECT.

Acceptable levels of lossy image compression have been hotly debated for years. When the compressed images will be used by human observers, the evaluation of the compression algorithms must involve the assessment of the impact of the compression on human performance. Observer models can play a significant role in the evaluation of the large number of potential compression algorithms and the many parameters defined by each, provided the model observer predicts human performance. Eckstein *et al.* (1999) found the CHO and the NPWE to correlate well with human observer performance in the evaluation of image-compression algorithm settings. Based on this fact these investigators used a model observer to optimize the quantization parameters of the JPEG algorithm (Eckstein *et al.*, 2000b); the optimized parameter settings were then validated by psychophysical determination of improved human performance.

Human observers are known to be adaptive to noise level and image content, among other things. The CHO is also adaptive, with a decision strategy that changes when the signal or noise characteristics of the images are altered. Rolland and Barrett (1992) demonstrated that the adaptation of the human observer can be predicted by the CHO. In nuclear medicine, increasing exposure time shifts the dominant source of variability in the data from quantum noise toward the contribution from object variability. Rolland showed that human detection performance improves as exposure time increases, providing evidence of the human's ability to incorporate improved quantum statistics into its decision strategy. Similarly, the Hotelling observer's performance increases with increasing exposure. The correlation between the CHO predictions and the human data was extremely high, over several decades of observer performance. Conversely, the NPWMF strategy is not adaptive; the NPWMF applies a template determined by the difference of the signals under each hypothesis without regard for the character of the background. This observer's performance saturates as exposure time increases, failing to predict the performance of the human observer. No nonadaptive model could possibly predict human performance in this study.

A number of studies have extended the body of knowledge regarding CHO performance in random backgrounds. In addition to the work involving lumpy backgrounds of Rolland, Yao and Burgess discussed previously, it has been shown that the CHO correlates well with human performance in the presence of anatomical backgrounds (Eckstein and Whiting, 1995). Abbey and Barrett (2001) measured human-observer performance in several SKE tasks to investigate the effects of regularization and object variability in tomographic image reconstructions. Across a range of experiments that investigated parameters determining the signal profile, exposure time, and data covariance, the channelized-Hotelling observer was most able to predict the array of human data.

Abbey *et al.* (1999) give an elegant theoretical derivation of an unbiased procedure for determining the template of a linear observer for a detection task. The only inputs to the procedure are the images presented to the observer on each trial and the observer's decision as to which image was deemed "signal-present." The procedure requires the means and covariances of the data under each hypothesis. While the template-estimation procedure is applicable to any linear observer, Abbey *et al.* made use of the procedure for estimating the templates of human

observers and comparing them to the templates of model observers. Edwards *et al.* (2000) extended the template-estimation procedure to the case where the noise is a mixture distribution of Gaussians. Recently, Abbey and Eckstein (2001) suggested the use of Bayesian template-estimation methods; the reduction in variance obtained through these methods may outweigh the small bias that also results. These template-estimation methods are pointing the way toward a better understanding of the human-observer's decision strategy. Perhaps in the future they may even find use in the development of improved methods for computer-aided diagnosis (CAD).

14.2.3 Psychophysical methods for image evaluation

Psychophysical methods are used to measure human-observer performance and assess diagnostic accuracy. In this section we shall review the history of the development of ROC methodology as a tool for understanding the visual system and assessing imaging technologies. We shall then describe methods for the conduct of psychophysical studies.⁶

Early applications of ROC analysis ROC techniques were initially developed during World War II for analyzing the performance of radar systems for detecting aircraft. One of the earliest applications of psychophysical methods to a medical application was the work of Garland (1949), who investigated the diagnostic accuracy of roentgenographic and photofluorographic techniques and presented some of the earliest evidence of reader error and variability. The cross-fertilization that brought ROC methods to visual science was greatly facilitated when W. P. Tanner, a graduate student in psychology at the University of Michigan, was assigned a desk in the office of T. G. Birdsall, one of the early pioneers of ROC methods (Cohn, 1993). In 1954, Tanner and J. A. Swets, also of the University of Michigan, published a seminal paper in which statistical decision theory was first applied to the study of visual performance, even including a section entitled, "A new theory of visual detection." This paper demonstrated that the core principles of statistical decision theory were applicable to observer performance. Most notably, the mathematical model of Fig. 13.4 is applicable to human decision variables, and human observers can control their decision criterion and manipulate it in response to information regarding the prior probability of each hypothesis and the decision costs. The paper presented data collected by yes-no and forced-choice experiments and showed them to be consistent.

It took some time for the perception community to relinquish the theory of an absolute detection threshold for "seeing." In 1963, Nachmias and Steinman published an ROC study meant to determine whether humans have a decision criterion that could be altered by directives from the investigator. The paper concluded that the data supported the variable-criterion hypothesis, but did not rule out the absolute-threshold theory entirely. Finally, in 1969, Kratz published an analysis of the Nachmias and Steinman data that concluded that the absolute-threshold theory could be rejected.

⁶We gratefully acknowledge the presentation materials made available to us by Charles Metz for use in writing this section.

While the variable-threshold theory was being established, Swets and his colleagues were working with great gusto at extending the use of statistical decision theory to the study of decision processes in perception (Swets *et al.*, 1961; Swets, 1964; Green and Swets, 1966). Another mathematical psychologist at the University of Michigan, D. D. Dorfman, and his colleague E. Alf, Jr. published a maximum-likelihood method for estimating ROC curve parameters and determining confidence intervals (1968, 1969). In the same timeframe, L. Lusted became the first investigator to apply ROC methods to medicine in general and medical imaging in particular (1968, 1971). Also, in 1960, the First Freiburg Conference on the Neurophysiology and Psychophysics of the Visual System was held, creating a forum for the movement toward combining and correlating information about the visual system derived from electrophysiological investigation with that derived using ROC methods (Jung and Kornhuber, 1961). This was a time of tremendous growth in methodology and accumulation of data in visual science.

The next decade saw a shift in the center of the ROC universe from the University of Michigan to the University of Chicago, where ROC analysis was applied to a variety of problems in medical imaging. Metz *et al.* demonstrated the relationship between ROC analysis and Shannon's information theory (1973) and published a tutorial on the basic principles of ROC analysis for a medical imaging audience (1978). Goodenough (1975) made use of an *L*-alternative forced-choice paradigm. Starr *et al.* (1975) investigated the detectability of low-contrast disks and spheres on uniform backgrounds in radiography. The early work of Starr *et al.* was one of the first of a set of studies that together demonstrated the limitations of using single measures of imaging system performance like resolution as a measure of image quality. It was also one of the first investigations of the effect of search-region size on ROC curves.

In the 1980s, the advent of relatively inexpensive, fast computers enabled the development and dissemination of free software for curve-fitting of ROC data, making ROC analysis much more widely utilized for image evaluation.⁷ Software for statistical testing also became available. There is now a wide variety of free packages available for the analysis of data acquired under a variety of experimental paradigms and providing an assortment of possible model fits, as well as the statistical comparison of results across imaging systems, observers, and tasks.

The last decade has seen continued development of numerical tools for the analysis of ROC data, the generalization of ROC methods to more complex and clinically relevant tasks, and a significant increase in the utilization of ROC-based methods for studies of image evaluation and observer performance. In the next sections we shall describe in more detail how ROC experiments are designed and performed and the methods for data analysis that are available to investigators today. Our purpose is not to provide a complete "how-to" manual, but rather to give an idea of the many options available to the investigator and the relevant literature where more specific experimental and analytical tools can be found.

The yes-no experiment A single point on an ROC curve can be determined for a given observer on a given binary-classification task using a simple "yes-no" experiment. In each experiment, an observer is presented with a set of images one at a

⁷Some twenty years later, the number of registered users of the free Metz software package is close to 4000!

time, and the observer responds either “yes – the signal is present” or “no – the signal is absent.” (More generally, “yes – class 2 is true” or “no – class 2 is not true.”) By tabulating the fraction of true and false responses at the end of the experiment, a single point on the ROC curve is determined. By instructing the observer to use a different mindset on each of a set of yes-no experiments, a set of points on the ROC curve is found, as depicted in Fig. 13.5. The finer the curve desired, the more yes-no experiments that must be performed.

Rating-scale approach Swets *et al.* (1961) showed that a single rating-scale experiment gives equivalent ROC estimates to that obtained via the inefficient process of repeated yes-no experiments. The rating-scale approach involves the presentation of single images to the observer at a time, with each image presentation referred to as a “trial.” The data collected on each trial is the observer’s certainty that the image belongs to class 2. Table 14.1 gives an example rating scale.

There are many variations on this theme. At one extreme, class 2 can be defined by the presence of an exactly-specified object at an exact location, while at the other extreme it can encompass the presence of any pathology of any kind, with the range of object variability in the middle ground. The number of rating levels can be as few as 5, although 6 or 7 is more commonly encountered, or the experiment can use a continuous rating scale. The use of a continuous rating scale, first advocated by Rockette *et al.* (1992) and validated by King *et al.* (1993), allows for finer distinctions of certainty levels by the observer, and a smaller chance of degenerate data (where the cells of the rating scale are not fairly evenly distributed with responses) in the analysis stage (Wagner *et al.*, 2001). However, some investigators shy away from this method because of a concern that diligent observers will find it difficult to report their rating so finely, and the concern that the intra-observer variability will be increased (the likelihood that the observer will rate the same case at the same level on two independent trials will be infinitely small).

A current controversy is the use of *action scales* like the BI-RADS scale (ACR, 1998) for classification of mammographic images. Action scales incorporate patient management as well as the reader’s level of suspicion. Some investigators have recommended that a pure probability-of-disease rating be acquired in addition to an action rating to avoid the bias that can occur when using an action rating alone for ROC purposes.

Table 14.1 Example rating scale

Rating	Description of certainty level
1	Object is definitely a member of class 1
2	Object is likely to belong to class 1
3	Object is equally likely to belong to class 1 or class 2
4	Object is likely to belong to class 2
5	Object is definitely a member of class 2

Relationship to contrast-detail (CD) diagrams An early paradigm for image assessment was the *contrast-detail* approach. In this method the observer is shown an image containing multiple signals with a range of contrasts and sizes. The observer reports the smallest detectable signal at each contrast. A plot of the detection-contrast versus size (detail) is then generated. When a set of CD diagrams are plotted as a function of exposure or dose, it is termed a CDD diagram (Cohen *et al.*, 1981).

There are several difficulties with the CD-diagram approach. One is that the approach is subjective because it does not control for the observer's variable decision criterion; different observers can be lax or strict in their judgment and even the same observer's criterion for "seeing" the signal can vary. Also, there is no ability to correct for "wishful thinking" on the part of the observer, and without signal-absent locations there is no ability to determine the trade-off with false-positive responses. Thus, while the CD-diagram approach is routinely used as a quality-assurance protocol in many imaging applications, it is not recommended as a quantitative tool in the assessment of imaging systems unless the aforementioned concerns are addressed in the study.

The CD-diagram can be of use when machine observers are used in place of humans. Then the observer's threshold can be set to a fixed level, and the algorithm can be forced to evaluate both signal-present and signal-absent locations. Chakraborty and Eckert (1995) have developed a procedure for the machine evaluation of phantom images for use in the evaluation of image quality.

Forced-choice experiments We first encountered the forced-choice (FC) experimental paradigm in Sec. 13.2.5. In a forced-choice experiment, an observer is forced to make a decision in favor of one of the alternative hypotheses. In the binary-classification task, a pair of images is presented to the observer, either at the same time or sequentially, one from class 1 and the other from class 2. The order/placement of the images is randomized, and usually there is no restriction on viewing time. The observer must decide which alternative belongs to class 2. As derived in Sec. 13.2.5, the percentage of correct responses in a two-alternative forced choice (2AFC) experiment equals the area under the ROC curve. We shall have more to say on this when we discuss the analysis of forced-choice data in Sec. 14.2.4.

The generalization of the FC paradigm to the L -alternative task requires the observer to state which of L -alternative signals is present in a signal-present image, or which of L regions contains a specified signal, for example.

Generalized ROC methods In a classic ROC experiment designed to evaluate an SKE binary classification task, the observer records a single rating on each trial describing his or her certainty that the image belongs to class 1 or class 2 (see Table 14.1). The application of this experimental paradigm to more realistic problems in which the signal is not known exactly is problematic. When there are multiple possible signals, or multiple locations, a single probability score does not capture all the data available from the observer. Most notably, the observer may indicate a high certainty that a signal is present in a signal-present image, but in fact the observer may have missed the true signal and be responding to a noise-only location that is perceived to be signal. Without requiring the observer to provide location data along with the probability rankings, there is no ability to correct for this effect.

An alternative is to require the observer to point to the signal that is detected on an image, and rate the probability that it is there. A *localization ROC* (LROC) curve is a plot of the actually positive images detected with the lesion correctly localized vs. the fraction of actually negative images falsely called positive (Swensson, 1996). The x axis of an LROC curve is thus the same as in a conventional ROC plot. On each image there is either a single signal at an unknown location or there is no lesion. An example LROC curve is shown in Fig. 14.4.

Fig. 14.4 An example LROC curve.

Free-response ROC curves (FROC) were introduced by Bunch *et al.* (1978) to enable the detection-and-localization analysis of images with an arbitrary number of signals. An FROC curve is a plot of the fraction of lesions detected vs. the average number of false-positive detections per image. FROC curves are often used in the assessment of CAD algorithms, where the number of false positives can be high. An example FROC curve is shown in Fig. 14.5

Fig. 14.5 An example FROC curve.

The *alternative free-response ROC* or AFROC curve is a plot of the fraction of lesions detected vs. the fraction of actually negative images falsely called positive (Chakraborty and Winter, 1990). An actually negative image is included in the

fraction of those called positive whenever one or more false-positive locations are identified on it. The x axis of an AFROC curve is similar to the x axis of ROC and LROC curves, only now the ability to mark more than one location on an image is allowed. An example AFROC curve is shown in Fig. 14.6.

Fig. 14.6 An example AFROC curve.

14.2.4 Estimation of figures of merit

Once the experimental procedure has been run and the observer-response data have been collected, the question arises as to how best to analyze the data. In this section we shall describe methods for the analysis of ROC and related data, and the estimation of figures of merit for summarizing image quality for classification tasks.

Analysis of conventional ROC data The foundation for the analysis of ROC-like data is the analysis of conventional rating data. The simplest approach to the generation of an ROC curve from rating data is to determine the number of true- and false-positive responses associated with each rating level. For a rating scale with N levels, this will give a graph with $N - 1$ TPF-FPF pairs, plus the $(0, 0)$ and $(1, 1)$ anchors for the plot. An *empirical* ROC curve is obtained by “connecting the dots” to generate a staircase plot consisting of vertical and horizontal line segments obtained by adding true and positive responses to the curve as a threshold is swept across the response data. For continuous rating data, the AUC estimate obtained by integrating the area under an empirical ROC curve is a Wilcoxon statistic (Bamber, 1975).

When the number of rating levels is small, the empirical ROC curve will be jagged, but a fitting approach can yield a smooth estimate of the curve. However, the assumptions of conventional least-squares curve fitting are invalid, owing to the joint dependence of the ratings on the observer’s mindset (Metz, 1986a). Hence a maximum-likelihood estimation procedure must be used instead. Dorfman and Alf (1968) published the first ML solution to the analysis of rating data.

The most widely used ML method assumes that the data underlying the ratings take on a parametric form with adjustable parameters under each hypothesis. Fig. 13.4 helps to make this concept more concrete: the fitting procedure assumes

the distributions for the decision variable conditioned on each hypothesis take on a particular form, most commonly a Gaussian, and the goal of the estimation procedure is to estimate the parameters of the two distributions given the rating data. The assumption that the two distributions are Gaussians is the so-called *binormal model* (Swets *et al.*, 1961). The binormal model does not limit the decision-variable data to Gaussian distributions; all that is required is that the data obtained under each hypothesis be transformable to Gaussian distributed random variables by the same unknown transformation.

The binormal model yields an estimated ROC curve with a straight-line plot on double-probability paper; the axes are given by the normal deviates z_{TPF} and z_{FPF} [cf. (13.15)]. The conventional ML procedure estimates the slope and intercept of this line, which can be related to the difference in means and the ratio of the variances of the two underlying distributions (Dorfman and Alf, 1969). Methods for obtaining ML binormal fits to ROC curves are also available for continuous rating data (Metz *et al.*, 1998b).

A large number of experiments have demonstrated the validity of the binormal model (Swets, 1986; Metz, 2000). Hanley (1988) has shown that ROC curves obtained from ML parameter fits to a variety of non-Gaussian distribution models, including binomial, Poisson, gamma, χ^2 , rectangular, and triangular forms, are indistinguishable from the Gaussian-based curve, provided the number of data samples is large. Nevertheless, the standard binormal model can result in fitted ROC curves that cross the chance line and have a slope that does not decrease monotonically as the FPF increases (Berbaum *et al.*, 1990). These so-called “improper” ROC curves can be obtained from the standard binormal model when the number of cases is low, the data scale is discrete, or the operating points are not well distributed (degenerate data). To avoid this outcome, the “proper” ROC analysis was introduced by Dorfman *et al.* (1996). Proper ROC curves are constrained from crossing the chance line. Proper models based on bigamma distributions (Dorfman *et al.*, 1996) and binormal distributions (Pan and Metz, 1997; Metz and Pan, 1999) have been investigated. The proper binormal model transforms the data by forming the likelihood ratio associated with the two underlying normal distributions; the result is an ROC curve with a monotonically decreasing slope. An objection to this procedure is that the calculation of the likelihood ratio is not something that the actual observer under test is hypothesized to do. Rather, it is an additional transformation applied to the observer data and thus may not be representative of the observer to which the ROC curve applies.

An alternative fitting approach for ROC rating data is the “contaminated” binormal model (Dorfman *et al.*, 2000a). This model assumes the distribution of decision variables is the bimodal sum of two Gaussians under the signal-present alternative (Dorfman and Berbaum, 2000b). The model has been found to be useful in the analysis of data with small false-positive fractions and to give results very similar to those of the standard binormal fitting procedure for nondegenerate data (Dorfman and Berbaum, 2000c).

Analysis of forced-choice data We described the 2AFC experiment mathematically in Sec. 13.2.5 as one in which the observer is presented with two images \mathbf{g} and \mathbf{g}' , where \mathbf{g} is drawn from $\text{pr}(\mathbf{g}|H_1)$ and \mathbf{g}' is drawn from $\text{pr}(\mathbf{g}'|H_2)$. The images are presented simultaneously in different spatial locations or separately in time at the same location. The assignment of the two underlying sources of images to the two

presentation locations is randomized. The observer's task is to choose the image from class 2. To make the decision, the observer computes two test statistics $T(\mathbf{g})$ and $T(\mathbf{g}')$, and the data vector that gives the higher value is assigned to H_2 . This assignment is correct if $T(\mathbf{g}') > T(\mathbf{g})$. By (13.39), the probability of a correct decision on any trial is AUC. Viewed this way, AUC is a criterion-free parameter-free distribution-independent figure of merit for a classification task (Massof and Emmel, 1987).

To estimate AUC from a forced-choice experiment, the percentage of correct decisions over a large number of trials is determined. To keep score of the number of correct responses, let n_i take on the value 1 for a correct response on trial i and 0 for an incorrect response. Mathematically, $n_i = \text{step}[T(\mathbf{g}'_i) > T(\mathbf{g}_i)]$, where the subscript i denotes the i^{th} trial. Thus n_i is a Bernoulli random variable (see Sec. C.6.1). Over N trials, the AUC estimate is the proportion of correct responses (PC):

$$\widehat{\text{AUC}} = \text{PC} = \frac{1}{N} \sum_{i=1}^N n_i. \quad (14.14)$$

If we assume the response variables are independent from trial to trial, (14.14) is the sum of N i.i.d. Bernoulli random variables. From (C.159) we know that the summand must be a binomial random variable with parameters N and the true AUC. It is well known that (14.14) is an unbiased ML estimate of AUC.

The early work of Tanner and Swets (1954) demonstrated the consistency of data collected in yes-no and forced-choice experiments. While an FC experiment yields an estimate of AUC, it has the disadvantage of not providing any information regarding the shape of the underlying ROC curve. Burgess (1985b) compared ROC and FC experimental methods and concluded that ROC methods make more efficient use of the available images, giving AUC estimates with lower variance, while FC methods make more efficient use of observer time. In an effort to make more efficient use of the available images, some experimenters use a multiple-pass paradigm in which different images from each hypothesis are paired for presentation in each pass. It can be shown that the full ROC curve can be obtained in the limit of every image being paired with every other. Note that the response variables are no longer independent Bernoulli random variables in this case.

Analysis of generalized-ROC experiments The primary advantage of the generalized-ROC approaches described above is their applicability to tasks in which signal uncertainty, usually location uncertainty, plays a key role. Many advances have been made in the last decade toward the development of robust procedures for the analysis of generalized ROC data from LROC, FROC, and AFROC experiments.

Maximum-likelihood methods have been introduced for the fitting of LROC data (Swensson, 1996). An ROC curve can be obtained from LROC data. Swensson (1996) gives the following relationship between the area under the ROC curve and the area under the LROC curve: $A_{\text{LROC}} = 0.5(\text{AUC} + 1)$.

ML analysis tools for FROC data have been introduced by Chakraborty (1989). The procedure assumes that the underlying signal and noise distributions are Gaussians and the number of false-positive responses per image follows a Poisson distribution. The assumptions underlying the analysis of FROC and AFROC are detailed and their validity argued thoroughly in a recent book chapter by Chakraborty (2000), who also suggests that the FROC analysis gives estimates of system perfor-

mance with greater statistical power than those obtained using conventional ROC analysis.

While the use of localization brings a significant degree of reality to the task, compared to the classical ROC experimental design, there is also the added requirement for deciding what region around a signal will be considered a “true-positive” response in the analysis. The choice for this tolerance is arbitrary; yet it has ramifications on the results of the data analysis. There is yet no consensus on the appropriate localization tolerance to use in the analysis of LROC, FROC, and AFROC experiments.

There are few resources for the analysis of more complex experiments involving multiple hypotheses. Kijewski *et al.* (1989) developed an analysis procedure for determining the parameters specifying ROC curves between all pairs of classes in an L -class problem given ratings of the multiple alternatives. Still needed is a practical method for the analysis of multi-alternative tasks using ROC analysis.

Summary measures Once a satisfactory fit to the ROC rating data has been obtained, summary measures of performance can be derived. Global measures of system performance include the AUC, the detectability measure d_A obtained from AUC via (13.21), or the parameters of the binormal model. If it is known that a certain operating point on the ROC curve is more significant for the intended use of the system than others, a local measure of performance might be reported at that operating point; that is, the TPF at a given FPF or the FPF at a given TPF might be reported. Partial area measures giving either the area to the right or below the ROC curve from a specified operating point give a regional measure of performance (McClish, 1989). Jiang *et al.* (1996) provided an extension to partial-area index analyses for systems with high AUC. Finally, if sufficient information is available regarding the cost and benefit of decisions is known, these can be reported at the optimal operating point, or a full cost/benefit curve can be reported and summarized. There are many open questions regarding the best approach to summarizing performance. The AUC is the most widely used figure of merit today.

The ML theorem of (13.378) enables us to say something about the ML estimates of other performance measures based on the ML estimate of $\widehat{\text{AUC}}$. For example, an ML estimate of the observer SNR can be derived from $\widehat{\text{AUC}}_{\text{ML}}$ by inverting (13.20). An ML estimate of the observer’s squared SNR can be obtained by similar reasoning and used in an ML estimation of observer efficiency.

When more than one observer has participated in an ROC study, there are two options for deriving an overall figure of merit. The first is to derive estimates of the binormal model parameters for each observer and average the parameters. The second is to pool the rating data and then perform the ML estimation procedure. Metz (1986b) has discussed the advantages and disadvantages of these alternatives. When multiple observers are used in the evaluation of multiple imaging systems, correlations in the data result. Tools for the analysis of multiple-reader, multiple-case experiments are discussed below.

Error analysis and the comparison of imaging performance When a measure of imaging performance is obtained, it is natural to ask how large the error bars are about that estimate. Moreover, when two imaging systems are being compared, we seek methods for determining the significance of the difference between figures of merit for the competing systems. In Sec. 13.1.1 we discussed a number of drawbacks to

the use of statistical tests of the null hypothesis. These same drawbacks are equally applicable to tests of the null hypothesis using estimated figures of merit for imaging systems.

In his 1920s work on estimation, R. A. Fisher (see Sec. 13.3.6) set the stage for randomized clinical trials by discussing randomized experiments in agricultural research. The analysis of independent imaging modalities was firmly established in the late 1970s, when the National Cancer Institute funded a contract to J. A. Swets and R. A. Pickett of Bolt, Beranek and Newman to develop methods for the assessment of diagnostic technologies. The outcome was a landmark text that presented computer code for the analysis of ROC data, including an analysis of the error in the estimate of AUC for a single modality (1982).

Soon after, Metz and Kronman (1980) and Hanley and McNeil (1982) proposed methods for the comparison of ROC curves for which the data were assumed to be independent. In 1983, Hanley and McNeil extended their work to the situation where the data were obtained from the same set of patients. In 1984, Metz *et al.* provided a method for analyzing differences between ROC curves measured from correlated data. Differences could be given in terms of the difference in AUC, the TPF at a specified FPF, or the parameters of the standard binormal model. Non-parametric methods for comparing the areas under correlated ROC curves based on Wilcoxon statistics have been presented by DeLong *et al.* (1988) and Campbell *et al.* (1988). These early methods for estimating the uncertainty in AUC and comparing ROC curves took into account the variability in the data resulting from the measurement noise and the object variability sampled by the finite set of cases but did not describe or compensate for the contribution from observer variability.

Observer variability is a complex, multivariate phenomenon that was understood in principle as early as the text by Swets and Pickett (1982), which contains two chapters on the subject. Observers respond differently to different cases, and even the same observer's responses are not 100% correlated across repeated readings of the same data set. As we have seen, a reader's response depends on the latent decision criterion, but it also depends on the observer's training, experience, age, fatigue, and other factors. Readers have different skill levels, and some readers are better at some case sets or modalities than others. An excellent example of reader variability due to differences in decision criteria is contained in data published by Elmore *et al.* (1994) and the subsequent commentary by D'Orsi and Swets (1995). Beam *et al.* (1996) have published the largest study to date demonstrating radiologist variability in skill level and decision criterion in the case of mammographic interpretations.

The first practical multivariate method for the analysis of the variance in AUC estimates for correlated tests with the assumption that both observers and images (readers and cases in the medical literature) are random effects was the multi-reader, multi-case (MRMC) method of Dorfman, Berbaum and Metz (Dorfman *et al.*, 1992), now commonly referred to as the DBM MRMC method. The method makes use of a jackknife procedure to generate multiple estimates of AUC, each derived by leaving out one of the observations and analyzing those that remain. The results of each leave-one-out procedure are termed *pseudovalues*. An analysis of the variance in the pseudovalues gives an estimate of the variance in the estimate of AUC. By analyzing the statistics of pseudovalues, the contribution to the variance in the estimate of AUC from the cases or the readers can be obtained.

The DBM MRMC method was first developed for the analysis of discrete rating data. Roe and Metz (1997a, 1997b) further developed and validated the DBM method and made software freely available for either continuous or discrete rating data. An alternative, nonparametric method for analyzing the components of variance in ROC studies based on bootstrapping has been suggested by Beiden *et al.* (2000a). Gifford *et al.* (2001) have recently simulated the application of the DBM method to LROC studies and found it to be useful for studies with low numbers of readers and cases.

In some countries, double reading of certain clinical images is the standard, as a method for reducing the number of incorrect interpretations and reducing reader variability. In the U.S., several commercial CAD systems are now available for use as a second reader to the radiologist. The analysis of adjunctive systems requires careful consideration of the appropriate assumptions regarding the variability of the readers (for example, no threshold variability for a computer) and the means for combining their interpretations. The overall performance of the system will be dependent on these considerations. A method for analyzing the improvements in the accuracy of imaging studies derived by repeated observations was suggested by Metz and Shen (1992). Beiden *et al.* (2001a, 2001b) have presented a nonparametric estimate of the components of variance of AUC for comparing two modalities with different variance structures, for example, where one modality involves a CAD adjunctive device and the other does not.

The original MRMC method required every reader to interpret every image in each modality. Recently, the statistical analysis of “partially paired” data sets has been presented (Zhou and Gatsonis, 1996; Metz *et al.*, 1998a).

Ordinal regression Standard ROC methodology reports the performance of a particular observer on a particular task given a specified imaging system. The dependence of the performance measure on a parameter describing the object (size or amplitude, say) or observer (age or number of years of training) would require a series of studies across the range of the parameter of interest. Given the time and cost required for a single psychophysical study, the notion of performing repeated studies of this sort is daunting.

Tosteson and Begg (1988) proposed the use of ordinal-regression techniques for combining studies of multiple object and observer characteristics in a single study. Toledano and Gatsonis (1995, 1996, 1999) have further developed the method and provided extensions for handling incomplete data. The use of ordinal-regression methods in the optimization of imaging system parameters using realistic models for the imaging process deserves greater attention.

Sources of bias We have described methods for analyzing the uncertainty in estimated measures of system performance without mention of possible sources of error in the estimated mean system performance. There are many sources of bias that can creep into the evaluation of an imaging system (Begg and Greenes, 1983). Probably the most significant is the ground-truth problem, which we shall address again in Sec. 14.4.5. It is difficult in real imaging applications to know the true status of an object, be it an enemy aircraft in a reconnaissance image, a stellar object in astronomy, or an unknown feature in a medical image. Knowledge of ground truth can require expensive verification procedures like long-term follow-up, biopsy, or imaging using an alternative system. Thus, in order to know the truth status

required for scoring observer responses in an ROC study, the investigator might design the study with an absence of subtle objects or confounding cases (Rockette *et al.*, 1995, 1998). Without these cases in the study, the results of the study will not describe the performance of the system on these kinds of cases. Similarly, bias can also result from the skill of the observers involved in the study. In the design of the study, the investigator should carefully consider whether to use experts vs. nonexperts and the extent that they represent the intended use of the system.

In summary, the estimated AUC is a joint description of the performance of the imaging system and the population of images and observers used in the study.

Field tests vs. stress tests A *field test* samples the objects and observers as they are expected to be sampled in routine use. A *stress test* limits the objects or the observers (or both) in order to “challenge” the performance of systems where differences are expected. Studies over subpopulations of observers or objects can potentially enable significant differences in system performance to be demonstrated for those subpopulations. For example, it may be that expert and nonexpert radiologists utilize the output of a CAD algorithm differently, but a study that averages over the two sets of readers would possibly miss this important finding. In another example, the fraction of women with dense/heterogeneous breasts is small; a study comparing film-screen to digital mammography using a broad sample of patients might not uncover a significant advantage of one system over the other for that subpopulation of women.

As described in Sec. 13.1.1, the diligent investigator can always increase the number of cases in a study until a statistically significant result is obtained. However, a judicious selection of the cases used in the study can sometimes reduce the number of images required to show significant differences in system performance, by taking into account known differences in the physical performance characteristics of the imaging systems under comparison.

Summary of process Although there are many open areas of research, methods based on ROC analysis are still the best approach for evaluating classification tasks performed by human and model observers. Before beginning a psychophysical investigation, a few questions should be considered. The first is the nature of the classification task—will standard ROC methods suffice, or is a generalized method that incorporates localization/search needed? Consideration should be given to the need for realism and the adequacy of the information that will be gained, the available methods for data analysis as well as methods for statistical analysis.

Careful consideration should be given to sampling issues for images and readers, recognizing the impact these will have on the conclusions that can be drawn from the study.

The specific viewing conditions should be considered, including the degree of observer adaptation, the display settings, the observation distance, and so on. The human-machine interface is critical; small numbers of observer mistakes due to a poor interface can impact the data appreciably.

It is recommended that a block design be used to avoid image-order effects. Observers can read a subset of the images representing one imaging system, then another, then back to the first, until the entire set under all conditions has been read. Randomize the ordering across readers. Do not expect observation sessions to last more than about an hour, or fatigue can degrade observer performance.

Pilot studies can be used to determine the imaging conditions that will yield the best study power and highest efficiency of observer effort. Staircase methods have been described for determining the object contrast that will give high statistical power (Watson and Pelli, 1983; Watson and Fitzhugh, 1990). These methods adjust the object contrast iteratively over a sequence of 2AFC trials to find the signal contrast that yields a $\text{SNR}_{\text{human}}$ of ~ 0.75 by decreasing the signal amplitude when the observer is correct, and increasing it after decision errors. Once the contrast has been determined that corresponds to that level of performance, the final study can make use of a fixed signal at that contrast — the method of constant stimulus — to give a more precise measure of system performance for that stimulus. Alternatively, the method of ordinal regression allows the evaluation of system performance across a range of stimuli.

Once the data are collected, they can be analyzed by the chosen fitting method. Free software packages are readily available on the worldwide web for this purpose. Then the figure of merit can be estimated along with its confidence interval. Tests for the differences between estimates of figures of merit are also included in several of the freeware packages.

14.3 MODEL OBSERVERS

Model observers serve many purposes. They can be used as tools in the study of the human visual system; by comparing the results of psychophysical studies to model-observer performance measures, researchers gain insights into human perception that can lead to improved models of the human visual system. Such studies give information regarding what tasks the human performs well and what image characteristics impact the human most significantly, potentially leading to improved imaging system designs for generating images for human interpretation. Model observers can also act in place of humans, or in concert with them, in which case we refer to the model as a computer-aided diagnosis (CAD) system.

Above and beyond the use of model observers as tools for understanding the visual system, model observers are an extremely valuable tool in the objective assessment of image quality. Model observers that operate on raw images or detected data enable the objective evaluation and optimization of image acquisition systems. Model observers designed to operate on reconstructed or processed images are useful for the assessment of image-processing algorithms without lengthy human-observer experiments. Because our emphasis in this text is on the design and evaluation of imaging systems, and not on the development of a better understanding of human perception, we shall focus on the use of model observers for the purpose of OAIQ—the objective assessment of image quality—in what follows.

Many of the same statistical methods used to evaluate imaging systems with human observers are applicable to the evaluation and comparison of model observers. The goal of this section is to present methods for determining the performance of a model observer for a given study. As we shall see, the particular model observer chosen and the method of determining its figure of merit will depend on the task as well as the extent to which we know or can characterize the statistics of the data.

We shall begin in Sec. 14.3.1 with a brief review of selected model observers for classification tasks and the requirements for determining each model observer's

performance. We shall then discuss how one chooses a model observer for system evaluation based on classification performance. Sec. 14.3.2 deals with the particular issues involved in the determination of classification performance by linear model observers. The determination of performance measures for ideal observers is the subject of Sec. 14.3.3. Finally, in Sec. 14.3.4, we shall discuss the use of estimation tasks in the objective assessment of image quality.

14.3.1 General considerations

Structure of observer models All model observers used in the objective assessment of imaging systems have a similar structure, illustrated in Fig. 13.1. As described in Sec. 13.2, for classification tasks every model observer computes a scalar test statistic t of the form

$$t = T(\mathbf{g}), \quad (14.15)$$

where \mathbf{g} might be either the raw data or a processed image and $T(\mathbf{g})$ is the observer's discriminant function. A decision is made in favor of hypothesis H_2 if t is greater than some threshold; otherwise H_1 is selected. By determining the number of images classified correctly for all threshold settings, an ROC curve can be generated.

The performance of the model observer can then be summarized using some metric related to the ROC curve. The area under the ROC curve (13.18) and the detectability d_A derived from AUC via (13.21) are common figures of merit. Alternatively, the SNR associated with the test statistic (13.19) can be determined from the first- and second-order statistics of t as a measure of the separability of the data from the two classes. The SNR and the detectability are the same when the test statistic is Gaussian under the two classes.

Categories of observer models for classification Observers can be classified according to whether $T(\mathbf{g})$ is optimal or suboptimal and whether it is a linear or nonlinear function of \mathbf{g} . By definition, optimal observers are the best possible in some sense. The Bayesian or ideal observer makes optimal use of all available information in the data and any additional nonimage information to achieve the highest AUC attainable. The ideal observer's test statistic is the likelihood ratio. In general, the ideal observer's discriminant function is a nonlinear function of the input data.

The Hotelling observer is the ideal linear observer; this observer's discriminant function is optimal in the sense that it achieves maximum SNR amongst all linear observers. The AUC-optimal linear observer is another privileged linear observer; as the name suggests, this observer employs the linear discriminant that achieves the highest possible AUC of all linear discriminants for the task.

Because of the large dimensionality of modern images, it may be necessary to make use of "efficient" features, or channels, that preserve the information in the data while enabling the determination of observer performance. Sec. 13.2.12 describes a method for deriving information-preserving linear features from an analysis of the known first- and second-order statistics of the data. Thus we can design a channelized Hotelling observer (CHO) such that it is still the optimal linear observer in spite of the reduced dimensionality.

The objective assessment of image quality may involve suboptimal model observers, particularly when the goal is to predict human performance. From Sec. 14.2 we know that the human observer has been modelled as an observer that processes images through frequency-selective and orientation-selective channels. The chan-

nelized Hotelling observer has been shown to be a useful predictor of the human observer for a variety of tasks, where the channels in this case are not efficient, but are instead chosen to predict human performance. Alternatively, more mechanistic models of the human visual system might be employed as surrogates for the human. These “anthropomorphic” models can incorporate highly nonlinear building blocks such as adaptive gain and contrast nonlinearity. Such models reduce the dimensionality of the data and incur an information loss as well.

Table 14.2 summarizes the types of model observers that can be employed in the objective assessment of image quality.

Table 14.2 Classification of observer models used in OAIQ

	Optimal	Suboptimal
Nonlinear	Ideal observer	Nonlinear model of human
Linear	Hotelling (max-SNR) CHO (efficient) AUC-optimal linear	CHO (visual channels, internal noise)

Computation vs. estimation As noted in Sec. 14.2, the goal of a psychophysical experiment is the *estimation* of human performance from a finite sample of images. This is in contrast to the methods presented in Chap. 13, which addressed the *computation* of ensemble performance measures for model observers. In this chapter we are concerned with the issues that arise when limited data are available for the estimation of observer performance. As we shall see, we might estimate the model observer’s decision function from finite samples, and use that function to estimate the model’s performance from the same or another set of finite data. Alternatively, a finite data set might be utilized to estimate the statistics of the data under competing hypotheses, with this information then used to estimate a figure of merit for the model observer’s performance directly.

Why OAIQ is easier than pattern recognition While the objective assessment of image quality has striking similarities to classical pattern recognition, the two problems are significantly different. Whenever we evaluate an imaging system we do so in terms of a particular task and a specific observer performing the task; thus we have considerable prior information regarding the objects to be classified and the discriminant function to be utilized. In many circumstances we can make use of a signal-known-exactly task, where the background might be simulated or might be a real clinical background. In contrast to most pattern recognition problems, we also have tremendous knowledge of the physics and statistics of the imaging system under evaluation that we can exploit to simulate noise-free training images. Thus the mean data under each hypothesis is fairly easily determined. Furthermore, the noise PDF $\text{pr}(\mathbf{g}|\mathbf{f})$ is usually known from the physics; hence the noise covariance matrix is also known. With this information we are well positioned for determining a linear observer’s discriminant function. Note also that we can avoid the gold-standard problem to be discussed in Sec. 14.4.5 by using simulated images; then we always know the underlying truth status of each image.

While we might estimate the model observer’s template and evaluate the model observer’s performance from finite data, the feature-extraction step is not ad hoc. It is dictated by the statistics of the data. If the purpose of the study is the prediction

of human performance, the features are further dictated by physiology — a channel model representing the visual system is then used as well.

In OAIQ the amount of prior information we bring to bear on the problem is tremendous relative to various approaches found in pattern recognition and data mining, where the statistics of the data may be completely unknown, the features are unspecified, and even the number of classes is uncertain. Moreover, OAIQ often makes use of simulated images, so there is no limitation to the number of images available, and there is no issue about their true classification.

Basic equations describing the ideal observer As derived in Sec. 13.2.6, the ideal observer achieves maximum AUC, maximum TPF at any FPF, and minimum Bayes risk. The ideal observer's test statistic is the likelihood ratio, given by

$$\Lambda(\mathbf{g}) \equiv \frac{\text{pr}(\mathbf{g}|H_2)}{\text{pr}(\mathbf{g}|H_1)}. \quad (14.16)$$

To classify a data set, the ideal observer compares $\Lambda(\mathbf{g})$ to a threshold.

Alternatively, the ideal observer forms the log-likelihood ratio, given by

$$\lambda(\mathbf{g}) \equiv \ln[\Lambda(\mathbf{g})] = \ln \left[\frac{\text{pr}(\mathbf{g}|H_2)}{\text{pr}(\mathbf{g}|H_1)} \right], \quad (14.17)$$

which is then compared to a threshold to classify an image. Because the log-likelihood ratio is a monotonic function of the likelihood ratio, the AUC of the ideal observer is unchanged by this transformation.

Data needed for ideal-observer studies We see from (14.16) or (14.17) that the computation of the ideal observer's performance requires full knowledge of the probability density function for the data under the competing hypotheses. In general, these are high-dimensional functions, describing the full joint statistical behavior of M data values. There are well-known examples for which the ideal-observer's performance is calculable, most notably the SKE case in Gaussian noise (Sec. 13.2.8) and some non-Gaussian noise models as well (Sec. 13.2.9). However, for random signals and backgrounds, (see Secs. 13.2.10 and 13.2.11), the ideal observer's decision variable takes the form of an integral of huge dimensionality over the posterior density of the data conditioned on known signals and backgrounds. In Sec. 14.3.3 we shall consider various techniques for estimation of the ideal observer's performance.

Basic equations describing linear observers We may not be able to evaluate ideal-observer performance because of the computational complexity or because we simply do not have the statistical information required to use those tools. Or, we may not want to estimate the performance of the ideal observer because the goal of the assessment process is the prediction of human, rather than ideal, performance. For these reasons the assessment effort may focus on the estimation of the performance of linear model observers.

In a binary classification problem, an arbitrary linear discriminant computes a scalar test statistic t from the $M \times 1$ data vector \mathbf{g} using a transformation of the form

$$t = \mathbf{w}^t \mathbf{g}, \quad (14.18)$$

where \mathbf{w} is an $M \times 1$ template. The observer classifies each data set by comparing the value of t to a threshold. The statistics of t determine the performance of the

observer, as measured by AUC or SNR_t . When t is Gaussian-distributed, AUC and SNR_t are related according to (13.20). Given that the linear observer's test statistic is a linear weighted sum of many random variables, the Gaussian assumption for the PDF of t is usually valid as a result of the central-limit theorem.

Optimal linear (Hotelling) observer When the ensemble mean and covariance for \mathbf{g} are known, the observer that maximizes SNR can be derived according to the procedure presented in Sec. 13.2.12. By (13.177) the Hotelling observer's template is known to be

$$\mathbf{w}_{Hot} = \mathbf{K}_{\mathbf{g}}^{-1} \Delta \bar{\mathbf{g}}, \quad (14.19)$$

where $\mathbf{K}_{\mathbf{g}}$ is the ensemble data covariance, assumed to be the same under each hypothesis, and $\Delta \bar{\mathbf{g}}$ is the difference in the mean data vector under the two hypotheses. The assumption of equal data covariance under each hypothesis is a reasonable approximation for weak signals, even though the signals may be random under each hypothesis. The subscript \mathbf{g} on the covariance matrix, which refers to the raw data, is required because we shall later encounter covariance matrices that describe channel outputs, which will be subscripted accordingly. It can be seen that the Hotelling test statistic is the output of a prewhitening matched filter operation that attempts to compensate for all contributions to the correlations in the data.

The performance of the Hotelling observer is given by [cf. (13.178)]

$$\text{SNR}_{Hot}^2 = \Delta \bar{\mathbf{g}}^t \mathbf{K}_{\mathbf{g}}^{-1} \Delta \bar{\mathbf{g}} = \text{tr} [\mathbf{K}_{\mathbf{g}}^{-1} \Delta \bar{\mathbf{g}} \Delta \bar{\mathbf{g}}^t]. \quad (14.20)$$

In the SKE detection problem this expression simplifies to

$$\text{SNR}_{Hot}^2 = \mathbf{s}^t \mathbf{K}_{\mathbf{g}}^{-1} \mathbf{s}, \quad (14.21)$$

where we denote the signal to be detected by \mathbf{s} in the data domain. Note that the data covariance matrix is assumed to be the same under each hypothesis in (14.20) and (14.21) because the contributions from background variations and measurement noise are assumed to dominate contributions from signal variability in the random-signal case.

The Hotelling observer achieves maximum SNR of all linear observers. An alternative approach is to determine the template \mathbf{w} that gives maximum AUC of all linear observers. In Sec. 13.2.12 we presented the problem of classification in Poisson noise as an example for which the ideal observer is linear (without actually imposing a linearity requirement); this is the observer that achieves maximum AUC as discussed in the previous section. However the ideal observer is not the linear observer that achieves maximum SNR for this task. There is a much smaller literature on the AUC-optimal linear observer relative to the large literature on the Hotelling or max-SNR observer. In the case of a normally distributed test statistic, these two observers coincide.

Data needed for Hotelling-observer studies We see from (14.20) and (14.21) that computation of the performance of the Hotelling observer requires knowledge of the ensemble first- and second-order statistics of the data under each hypothesis. When information regarding the mean and covariance of \mathbf{g} is unavailable, we must resort to procedures for estimating the performance of the optimal linear observer from samples.

The difference in the class means under each hypothesis, $\Delta\bar{\mathbf{g}}$, is an $M \times 1$ vector, where each element $\Delta\bar{g}_m = \bar{g}_{2m} - \bar{g}_{1m}$ is the difference in the average value in the m^{th} pixel in the image or data set under the two hypotheses. Its estimate can be obtained by determining the sample mean from sets of images known to be from each class; the behavior of the sample mean as an estimator is well-understood. Moreover, in many studies the signal is simulated and nonrandom, so that (14.21) is relevant and no estimation of the mean is required. Thus the determination of the mean data under each hypothesis is not a major stumbling block in most applications.

The most daunting issue in imaging applications is the determination of an estimate of \mathbf{K}_g , which we shall denote $\hat{\mathbf{K}}_g$. A natural inclination is to assume that $\hat{\mathbf{K}}_g$ is the sample covariance matrix, but the reader is cautioned against acting on this impulse. If the number of image samples, N_s , is less than the number of pixels in each image, M will be singular and noninvertible. This option therefore requires $N_s \geq M$.

Consider the number of elements of a covariance matrix to be estimated in typical imaging scenarios. A flat-panel digital x-ray imager can have 1024×1024 elements. A SPECT system with a 128×128 detector that collects data over 64 projection angles has the same number of elements. Thus these systems have a data vector with $\sim 10^6$ data elements, so \mathbf{K}_g is a $10^6 \times 10^6$ matrix with about a trillion elements. The symmetry of this matrix allows us to reduce the number of elements to be estimated by about a factor of 2, but a half trillion is still a large number.

The linear discriminant based on sample means and covariances for the pixels in the raw data set is the approach commonly referred to as the Fisher discriminant. Because the number of values to be estimated to form the sample covariance matrix is almost always far greater than the number of samples available for the estimation procedure, the Fisher discriminant is rarely a useful estimate of the optimal linear discriminant in imaging applications.

We shall discuss several alternative approaches to the estimation of the Hotelling observer's performance in Sec. 14.3.2.

Basic equations describing channelized linear observers Any linear channel model can be represented by a matrix-vector multiplication like the one given in (14.7):

$$\mathbf{v} = \mathbf{U}^t \mathbf{g}, \tag{14.22}$$

where \mathbf{U} is an $M \times P$ matrix whose columns are the channel profiles \mathbf{u}_p , and \mathbf{v} is the $P \times 1$ vector of channel outputs. The \mathbf{u}_p represent the channel profiles, which we have assumed to be real. Each channel output v_p is a number.

While both (14.7) and (14.22) represent a reduction of the dimensionality of the data set, the critical difference is that we are free to choose the channel profiles in (14.22) to suit our purpose. The channels could be designed to be efficient, giving minimal loss of detectability and thereby providing an estimate of the separability inherent in the data. Alternatively, the channels could be designed to estimate the separability of the data after processing through visual-system channels to predict human performance, which may or may not be efficient depending on the task. A number of possible channel profiles used in the vision literature are described in Sec. 14.2.

The performance of a channelized observer is given by the SNR associated with the channel outputs under each hypothesis:

$$\text{SNR}_{\mathbf{v}}^2 = \Delta \bar{\mathbf{v}}^t \mathbf{K}_{\mathbf{v}}^{-1} \Delta \bar{\mathbf{v}} = \Delta \bar{\mathbf{g}}^t \mathbf{U} [\mathbf{U}^t \mathbf{K}_{\mathbf{g}} \mathbf{U}]^{-1} \mathbf{U}^t \Delta \bar{\mathbf{g}}. \quad (14.23)$$

Data needed for channelized-observer studies The information required to evaluate the performance of a channelized observer is the first- and second-order statistics of the data *as seen through the channels*. We see immediately from (14.23) that the channel covariance matrix to be inverted is much smaller than the data covariance matrix. If the number of channels is P , then $\mathbf{K}_{\mathbf{v}}$ is a $P \times P$ matrix, where P can be as small as 3 to 6. Even if P is 30 to 50, the matrix to be inverted is still a reasonably manageable size.

The second advantage to the use of a channelized model is the flexibility we have in choosing the channel profiles. As we shall see, prior knowledge of the characteristics of the signal and background can suggest particular forms for efficient channels. Alternatively, the channels can be chosen to model human performance. Given the nontrivial time required to perform psychophysical evaluations, the ability to evaluate a set of imaging system parameters using a model that predicts human performance can offer significant advantages.

Which model observer? The question of which model observer to employ is answered by the objective of the evaluation study. If the goal is to evaluate or optimize the hardware of the data acquisition system, then the ideal observer is the model of choice. Optimization with this observer will result in a system with the maximum information in the raw data in the sense of being able to perform the specified task. If it is not possible to compute ideal-observer performance because the calculation of the likelihood of the data under each hypothesis is not tractable, then the ideal linear observer is a useful alternative for use in hardware evaluation and optimization.

When the task is the evaluation of image-processing algorithms, ideal observers are of no use, because they are invariant to invertible image processing (see Sec. 13.2.6). Image processing algorithms, reconstruction methods and display devices exist for presenting images to human observers; thus the appropriate model should be one that predicts human performance. The model might be a highly detailed, mechanistic model of the visual system or a simpler linear channel model like the CHO.

In the next subsections we discuss in more detail each of these model observers and methods for estimating their classification performance.

14.3.2 Linear observers

In this subsection we shall present a number of approaches for determining the performance of linear model observers from finite data sets. We shall first consider the Hotelling observer that makes use of the raw data and describe several methods for estimating the SNR of this observer. As suggested by (14.20) and the discussion that followed, the estimation of this Hotelling observer's SNR must involve some method for dealing with (or circumventing) the need to estimate the inverse of $\mathbf{K}_{\mathbf{g}}$. Once we have exhausted our list of possible approaches to this problem, we shall explore methods that invoke dimensionality-reducing linear channels.

In many instances, image quality can be ascertained through a classification task involving nonrandom signals that are added to real or simulated backgrounds. Thus we shall first assume that the problem is the detection of a known signal, the so-called SKE problem, while allowing for a random background. In this case there is no need to estimate $\Delta\bar{\mathbf{g}}$ in (14.20); it is known, and our goal is to find an estimate of the SNR given in (14.21). This objective is only hampered by the fact that $\mathbf{K}_{\mathbf{g}}$ is unknown. Subsequently, we shall consider methods for estimating linear-observer performance for random signals.

We shall then briefly discuss the characteristics of the estimated figures of merit. Finally, the subsection concludes with a short discussion of methods for determining the AUC-optimal linear observer. Throughout this subsection we make the assumption that the truth status of each image sample is known; methods for dealing with the no-gold-standard problem are presented in Sec. 14.4.5.

Nonrandom signals We consider the object to be the sum of a known signal and a random background according to the decomposition introduced in (8.306):

$$\mathbf{f} = \mathbf{f}_s + \mathbf{f}_b. \tag{14.24}$$

In the detection task, \mathbf{f}_s is zero under H_1 . The backgrounds are assumed to be random and drawn from the same ensemble under each hypothesis.

From (14.24), the mean data for a fixed object and a linear imaging operator \mathcal{H} can be written as a linear superposition of signal and background [*cf.* (8.352)]

$$\bar{\mathbf{g}}(\mathbf{f}) = \mathcal{H}\mathbf{f}_s + \mathcal{H}\mathbf{f}_b \equiv \mathbf{s} + \mathbf{b}, \tag{14.25}$$

where \mathbf{b} is the image of the particular background realization.

Without signal variability, the covariance matrix $\mathbf{K}_{\mathbf{g}}$ describes the randomness in the data due to background variability and measurement noise. It can be written formally in terms of an expectation of the covariance of the data about the mean taken first over the noise for a single background, followed by an average over all backgrounds:

$$\mathbf{K}_{\mathbf{g}} = \langle\langle (\mathbf{g} - \bar{\mathbf{g}})(\mathbf{g} - \bar{\mathbf{g}})^t \rangle_{\mathbf{n}|\mathbf{b}} \rangle_{\mathbf{b}}. \tag{14.26}$$

In the absence of object variability the data covariance matrix reduces to the noise covariance matrix, an entity that is usually known or computable through our knowledge of the image-formation process. Nonrandom backgrounds can be very useful in the validation of software intended to simulate realistic noise properties of an imaging system. However, the objective evaluation of imaging systems in the absence of object variability can yield misleading conclusions; thus image evaluation should employ a random background model if at all possible. Sec. 14.4 describes a number of approaches for simulation of random objects and images.

We have cautioned against the use of sampling methods to directly estimate the sample covariance matrix, and the use of exactly-specified backgrounds in the objective assessment of image quality. How, then, to simplify the calculation of Hotelling SNR in the presence of a random background? One assumption that is often made is that the background is stationary.

Stationarity? A stationarity assumption is attractive because the covariance matrix is then diagonalized by an appropriate Fourier transformation. For example, we

know from Sec. 7.4.4 that a circulant covariance matrix that satisfies $K_{\mathbf{m}\mathbf{m}'} = K_{[\mathbf{m}-\mathbf{m}']_M}$ (where the subscript indicates modulo- M arithmetic in both components of the multi-index) is diagonalized by a discrete Fourier transform. And from Sec. 8.2.8 we know that an infinite covariance matrix that satisfies $K_{\mathbf{m}\mathbf{m}'} = K_{\mathbf{m}-\mathbf{m}'}$ for all \mathbf{m} and \mathbf{m}' is diagonalized by a discrete-space Fourier transform. Following diagonalization by Fourier methods, $\mathbf{K}_{\mathbf{g}}^{-1}$ can be found by taking the reciprocal of each diagonal element.

While Fourier methods based on stationarity assumptions may seem attractive, this approach is fraught with problems. Real covariance matrices are neither infinite nor circulant. The assumption that $\mathbf{K}_{\mathbf{g}}$ is circulant implies digital wrap-around, meaning the statistical correlation of two pixel values representing adjacent detector elements is assumed to be equal to the correlation of two elements on opposite sides of the detector, or even in different projections. In an investigation of image quality in digital radiography, Pineda and Barrett (2001) have shown that stationarity assumptions can give misleading results.

Local stationarity Requiring stationarity of any sort over the whole image field is not only unrealistic, it is also unnecessary if our goal is to compute the SNR of a spatially localized lesion. Since (14.21) is the norm of the vector $\mathbf{K}_{\mathbf{g}}^{-1/2}\mathbf{s}$, we can compute it by summing over only those pixels for which the vector is substantially different from zero. Typically, in direct imaging systems, those pixel elements correspond to a restricted region in data space. If so, we can express the SNR in terms of the Wigner distribution function computed over this region, as discussed in Sec. 13.2.13.

For indirect imaging systems, a spatially localized lesion can contribute to a very nonlocalized set of detector elements. In this situation it is unlikely that an assumption of approximate stationarity would hold over the entire region for which $\mathbf{K}_{\mathbf{g}}^{-1/2}\mathbf{s}$ is significantly greater than zero. Thus for tomographic systems it is necessary to perform a reconstruction first to restore the local nature of the signal to be detected and allow the use of methods that invoke an assumption of approximate stationarity. The argument of the previous paragraph holds if we let \mathbf{g} be the reconstruction and \mathbf{s} be the reconstructed signal.

If $\mathbf{K}_{\mathbf{g}}$ were diagonal (in the multi-indices⁸), the region where approximate stationarity is required would be the same as the subset of pixels for which \mathbf{s} is nonzero, but a nondiagonal covariance means that some elements of $\mathbf{K}_{\mathbf{g}}^{-1/2}\mathbf{s}$ are nonzero even if the corresponding elements of \mathbf{s} are zero. Moreover, the range of the correlations is only a rough guide to selecting the correct subset of pixels; the matrix $\mathbf{K}_{\mathbf{g}}^{-1/2}$ can occupy a substantially larger band around the diagonal than $\mathbf{K}_{\mathbf{g}}$.

We do not know the width of this band if we cannot compute $\mathbf{K}_{\mathbf{g}}^{-1/2}$, but we can proceed experimentally. If we start with a measured covariance matrix, or one computed on a realistic nonstationary model, we can select an $L \times L$ subset of it centered on the signal location. Calling this matrix \mathbf{K}_L , we can compute $\mathbf{s}^t\mathbf{K}_L^{-1}\mathbf{s}$, which would be an estimate of the Hotelling SNR without any stationarity assumption if we were given only this subset of the data. We can then vary L and observe the behavior of this SNR; when it no longer changes, we can assume that we have

⁸See Sec. 8.2.8 for a discussion of discrete random processes and diagonality in multi-index notation.

found the band containing the nonzero elements of $\mathbf{K}_{\mathbf{g}}^{-1/2}$, and we can compare the resulting SNR to that computed with the Wigner distribution function. If agreement is good, we can use the Wigner expression to compute SNR for a variety of signals and all positions in the field and to define local NEQ and DQE as functions of spatial frequency and signal location (see Sec. 13.2.13). This approach may result in a number of nonzero elements in need of estimation that is small enough that the finite number of image samples can support their estimation.

Decomposition of the covariance matrix Another approach is to make use of our knowledge of the physics of the imaging process, which often gives us powerful information regarding the distribution of data for a fixed object. Statistically speaking, we often know $\text{pr}(\mathbf{g}|\mathbf{f})$, from which we can determine the conditional mean $\bar{\mathbf{g}}(\mathbf{f})$ and the conditional covariance $\mathbf{K}_{\mathbf{n}|\mathbf{f}}$.

Key to making use of this prior information is a decomposition of the overall data covariance given in Sec. 8.5.3; we know from (8.347) that $\mathbf{K}_{\mathbf{g}}$ is the sum of two terms, written

$$\begin{aligned}\mathbf{K}_{\mathbf{g}} &= \langle \langle [\mathbf{g} - \bar{\mathbf{g}}(\mathbf{f})][\mathbf{g} - \bar{\mathbf{g}}(\mathbf{f})]^t \rangle_{\mathbf{n}|\mathbf{f}} \rangle_{\mathbf{f}} + \langle [\bar{\mathbf{g}}(\mathbf{f}) - \bar{\bar{\mathbf{g}}}] [\bar{\mathbf{g}}(\mathbf{f}) - \bar{\bar{\mathbf{g}}}]^t \rangle_{\mathbf{f}} \\ &= \langle \mathbf{K}_{\mathbf{n}|\mathbf{f}} \rangle_{\mathbf{f}} + \mathbf{K}_{\bar{\mathbf{g}}} \equiv \bar{\mathbf{K}}_{\mathbf{n}} + \mathbf{K}_{\bar{\mathbf{g}}},\end{aligned}\quad (14.27)$$

where $\bar{\mathbf{K}}_{\mathbf{n}}$ represents the noise covariance averaged over all objects. While both $\bar{\mathbf{K}}_{\mathbf{n}}$ and $\mathbf{K}_{\bar{\mathbf{g}}}$ are influenced by object variability, we emphasize that they are covariances for vectors in data space.

When the signal is random but statistically independent of the background, we can write the covariance matrix for $\bar{\mathbf{g}}$ as [see (8.359)]

$$\begin{aligned}\mathbf{K}_{\bar{\mathbf{g}}} &= \langle [\bar{\mathbf{g}}(\mathbf{f}) - \bar{\bar{\mathbf{g}}}] [\bar{\mathbf{g}}(\mathbf{f}) - \bar{\bar{\mathbf{g}}}]^t \rangle_{\mathbf{f}} = \mathcal{H}\mathcal{K}_{\mathbf{f}}\mathcal{H}^\dagger \\ &= \mathcal{H}\mathcal{K}_{\mathbf{f}_s}\mathcal{H}^\dagger + \mathcal{H}\mathcal{K}_{\mathbf{f}_b}\mathcal{H}^\dagger \equiv \mathbf{K}_{\mathbf{s}} + \mathbf{K}_{\mathbf{b}},\end{aligned}\quad (14.28)$$

where $\mathbf{K}_{\mathbf{s}}$ and $\mathbf{K}_{\mathbf{b}}$ are the covariance of the data about the conditional mean resulting from signal and object variability, respectively. When the signal is nonrandom (14.28) simplifies to $\mathbf{K}_{\bar{\mathbf{g}}} = \mathbf{K}_{\mathbf{b}}$. Even in the random-signal case this simplification can be relevant; if the signal is of sufficiently low contrast, then $\mathbf{K}_{\bar{\mathbf{g}}} \approx \mathbf{K}_{\mathbf{b}}$ because the contribution due to the random background dominates.

Much of what follows on estimation of linear-observer performance is based on the decomposition of (14.27). Though we shall often use the approximation that $\mathbf{K}_{\bar{\mathbf{g}}} \approx \mathbf{K}_{\mathbf{b}}$, we note that (14.27) itself is exact; it requires no Gaussian assumptions regarding either the objects or the noise, and it does not assume that the noise is object-independent. Alternative forms for the object-variability term that make use of alternative ways of expressing the autocovariance of the object in object space are given in Sec. 8.5.3.

Role of the measurement noise To be more explicit about $\bar{\mathbf{K}}_{\mathbf{n}}$, we need to distinguish direct from indirect imaging and object-dependent from object-independent noise.

The simplest case is direct imaging with additive Gaussian measurement noise. As discussed in detail in Chap. 12, electronic noise in different detector elements is usually statistically independent and hence uncorrelated. If every detector element has the same noise variance σ^2 , which is independent of the object \mathbf{f} , then

$$\bar{\mathbf{K}}_{\mathbf{n}} = \mathbf{K}_{\mathbf{n}|\mathbf{f}} = \sigma^2 \mathbf{I}.\quad (14.29)$$

Thus $\bar{\mathbf{K}}_{\mathbf{n}}$ is a multiple of the unit matrix and hence full rank.

The situation is only slightly more complicated with Poisson noise. Since Poisson measurements are conditionally statistically independent with variance equal to the mean, we can write

$$[\mathbf{K}_{\mathbf{n}|\mathbf{f}}]_{mm'} = \bar{g}_m(\mathbf{f}) \delta_{mm'} = [\mathcal{H}\mathbf{f}]_m \delta_{mm'}, \quad (14.30)$$

where the last form is for a linear digital imaging system characterized by the CD operator \mathcal{H} . Averaging over object variability is now straightforward:

$$\bar{\mathbf{K}}_{\mathbf{n}} = \langle \bar{g}_m(\mathbf{f}) \rangle_{\mathbf{f}} \delta_{mm'} = \bar{\bar{g}}_m \delta_{mm'} = [\mathcal{H}\bar{\mathbf{f}}]_m \delta_{mm'}. \quad (14.31)$$

Thus the average noise covariance matrix is diagonal in spite of the object variability, though of course the overall covariance matrix $\mathbf{K}_{\mathbf{g}}$ is not diagonal.

It is not immediately obvious, however, that $\bar{\mathbf{K}}_{\mathbf{n}}$ is full rank. Indeed, the conditional noise covariance $\mathbf{K}_{\mathbf{n}|\mathbf{f}}$ is not full rank if any of the \bar{g}_m is zero. Similarly, $\bar{\mathbf{K}}_{\mathbf{n}}$ is not full rank if any of the $\bar{\bar{g}}_m$ is zero, but this turns out to be of much less concern; the only way a particular $\bar{\bar{g}}_m$ could be zero is if the m^{th} detector element never receives radiation for any object in the ensemble, and in that case we might as well delete that detector element from the data set. Thus we can always assume that $\bar{\mathbf{K}}_{\mathbf{n}}$ is full rank for direct imaging, even with Poisson noise.

For indirect imaging the measurement noise is modified by the reconstruction algorithm. This issue will be discussed at length in the next chapter, but for now we note that analytic expressions for $\mathbf{K}_{\mathbf{n}|\mathbf{f}}$ can be developed, where \mathbf{n} refers to the noise in an image reconstructed by a linear algorithm from either Gaussian or Poisson data (see Sec. 15.4.2). For nonlinear algorithms, analytic covariances are generally not possible, but practical computational methods are available for determining $\mathbf{K}_{\mathbf{n}|\mathbf{f}}$ numerically; for details, see Sec. 15.4.7. These numerical expressions can then be averaged over \mathbf{f} to obtain $\bar{\mathbf{K}}_{\mathbf{n}}$.

Sample averages In Sec. 8.4 we discussed a variety of statistical models for objects and found that there were many circumstances where we could generate samples of \mathbf{f} ; more discussion of methods for simulating random objects is also given in Sec. 14.4. However, it is usually not possible to determine $\text{pr}(\mathbf{f})$ from samples, and we almost always have to resort to the use of sample averages to determine the statistical properties of the data resulting from random objects.

Consider again the case of nonrandom signals (or where the signal is random but of low contrast), so that $\mathbf{K}_{\bar{\mathbf{g}}} = \mathbf{K}_{\mathbf{b}}$, and we want to estimate this covariance matrix. From Sec. 13.2.12 we know that the data covariance resulting from a general random background is given by

$$[\mathbf{K}_{\mathbf{b}}]_{mm'} = \langle (b_m - \bar{b}_m)(b_{m'} - \bar{b}_{m'}) \rangle_{\mathbf{b}}, \quad (14.32)$$

where \bar{b}_m is the mean contribution of the random background to detector element m . This expression describes the fluctuations in the data that would be observed over a large set of simulated or real noise-free images.

One approach to finding an estimate of $\mathbf{K}_{\mathbf{b}}$ is to use a theoretical object model such as a lumpy background (Sec. 8.4) for which the autocovariance function can be specified. This function is then mapped through the blur associated with the imaging system to produce the covariance matrix $\mathbf{K}_{\mathbf{b}}$. If we choose some functional

form (*e.g.*, fractal) for the autocorrelation, we can use sample images to estimate any unknown parameters in the function.

Another approach is to acquire a set of low-noise images and estimate the covariance matrix for the background (in data space) from them. If we do not want to make any assumptions about the form of the autocovariance, we can simply form the sample covariance matrix as a low-rank approximation to the desired ensemble covariance. The samples might be simulated noise-free backgrounds, or they might be experimental background images with low but nonzero noise, obtained with image-averaging or high-dose techniques. Methods for simulating noise-free backgrounds are discussed in Sec. 14.4.

Suppose we have a set of sample background images $\{\mathbf{g}_j, j = 1, \dots, N_s\}$, which are either noise-free (simulated) or for which the noise is negligible compared to the effects of object variability (perhaps because the images were acquired with a long exposure time). We can array each of these images as $M \times 1$ column vectors. We can then subtract the sample mean from each image to form the set $\{\delta\mathbf{g}_j, j = 1, \dots, N_s\}$, and the covariance matrix $\mathbf{K}_{\mathbf{g}}$ can be estimated by

$$\widehat{\mathbf{K}}_{\mathbf{g}} = \mathbf{W}\mathbf{W}^t, \quad (14.33)$$

where \mathbf{W} is the $M \times N_s$ matrix with columns given by sample images:

$$\mathbf{W} = \frac{1}{\sqrt{N_s}} [\delta\mathbf{g}_1, \delta\mathbf{g}_2, \dots, \delta\mathbf{g}_{N_s}]. \quad (14.34)$$

The sample covariance matrix of (14.33) is equally applicable when the set of sample images contains random signals of unknown statistical description as well as random backgrounds.

Once the background covariance matrix is estimated, the noise contribution can be determined (if it is not already known) to yield the full data covariance matrix. For example, we can make use of (14.31) to write the covariance of the data in the weak-signal approximation under Poisson measurement noise as

$$\begin{aligned} [\widehat{\mathbf{K}}_{\mathbf{g}}]_{mm'} &= \langle\langle (g_m - \hat{b}_m)(g_{m'} - \hat{b}_{m'}) \rangle\rangle_{\mathbf{n}|\mathbf{b}} \\ &= \hat{b}_m \delta_{mm'} + [\widehat{\mathbf{K}}_{\mathbf{b}}]_{mm'}. \end{aligned} \quad (14.35)$$

The first term in the last line is $\widehat{\mathbf{K}}_{\mathbf{n}}$, which in this case is a diagonal matrix with elements given by sample averages of the mean background. The second term $\widehat{\mathbf{K}}_{\mathbf{b}}$ is an estimate of the covariance $\mathbf{K}_{\mathbf{g}}$ due to the random backgrounds.

Other non-Poisson forms of object-dependent measurement noise can be simulated to generate noisy images once the simulation of random objects and noise-free data sets is achieved satisfactorily. These images can be used to determine the first- and second-order statistics of the data necessary to determine the SNR of the linear observer, using methods described below.

Matrix-inversion tools Once we are assured that we have a covariance matrix with full rank, the next step is to compute the SNR. Given the size of $\widehat{\mathbf{K}}_{\mathbf{g}}$, direct inversion of the estimated covariance matrix to estimate the detectability via (14.20) or (14.21) is not feasible. We shall consider the following alternative approaches, none of which assumes stationarity in any sense:

1. Iterative computation of the template;
2. Neumann series;
3. Matrix-inversion lemma.

Iterative computation When the observer's template is known, it can be applied to a set of sample images (for which the ground truth is known) to yield a set of test statistics under each class that can be used to compute the observer's AUC or SNR. The optimal linear observer has a template given in (14.19); thus it would appear that the determination of \mathbf{w}_{Hot} also requires the inversion of \mathbf{K}_g . Not so! Fiete *et al.* (1987) suggested that the Hotelling template could be calculated iteratively.

Finding the template amounts to solving the equation $\mathbf{K}_g \mathbf{w} = \mathbf{s}$, where the signal \mathbf{s} is assumed known and \mathbf{K}_g is either known or estimated. This equation is analogous to the imaging equation $\mathbf{Hf} = \mathbf{g}$, where the unknown template takes the place of the unknown object and the covariance matrix plays the role of the imaging system. However, the covariance matrix is square, making it invertible in principle, unlike the system operator in most imaging problems.

The solution can be found by any of the iterative methods enumerated in Chap. 1 or by the regularized methods to be discussed in Chap. 15. One possible solution is given by the Landweber algorithm (1.231), which gives the following template estimates at each iteration:

$$\hat{\mathbf{w}}_{n+1} = \hat{\mathbf{w}}_n + \alpha [\widehat{\mathbf{K}}_n]^{-1} [\mathbf{s} - \widehat{\mathbf{K}}_n \hat{\mathbf{w}}_n], \quad (14.36)$$

where n denotes the iteration number and we have made use of the knowledge that the noise contribution to the covariance matrix is full rank. The beauty of this iterative approach is that no inversion of the full $\widehat{\mathbf{K}}_g$ is required.

Once the template has been estimated, the SNR can be found by applying the template to a set of sample images, determining the mean and variance of the resulting scalar test statistic under each hypothesis, and computing the observer's performance via (13.19). Alternatively, we can directly estimate SNR^2 by (14.21) as $\mathbf{s}^t \hat{\mathbf{w}}$.

Neumann series The covariance matrix may not be diagonal in real situations, but it may be nearly diagonal (at least with the multi-index convention). For example, as we shall see in Chap. 16, for direct imaging applications using x rays the nondiagonal contributions to the data covariance are due to correlations in the object statistics and physical processes like escape of K x rays from the phosphor. When these contributions are not very long-range, the Neumann series approach can be advantageous.

To see why the near-diagonal character of \mathbf{K}_g is useful, suppose initially that

$$\mathbf{K}_g = \sigma^2 \mathbf{I} + \mathbf{A} = \sigma^2 \left[\mathbf{I} + \frac{1}{\sigma^2} \mathbf{A} \right], \quad (14.37)$$

where \mathbf{A} describes the off-diagonal elements. Then we can use the Neumann series (A.59) to write the inverse covariance as

$$\mathbf{K}_g^{-1} = \frac{1}{\sigma^2} \sum_{j=0}^{\infty} \left[-\frac{1}{\sigma^2} \mathbf{A} \right]^j = \frac{1}{\sigma^2} \mathbf{I} - \frac{1}{\sigma^4} \mathbf{A} + \frac{1}{\sigma^6} \mathbf{A}^2 - \dots \quad (14.38)$$

The Hotelling SNR then becomes

$$\text{SNR}_{Hot}^2 = \mathbf{s}^t \mathbf{K}_g^{-1} \mathbf{s} = \frac{\|\mathbf{s}\|^2}{\sigma^2} - \frac{\mathbf{s}^t \mathbf{A} \mathbf{s}}{\sigma^4} + \frac{\mathbf{s}^t \mathbf{A}^2 \mathbf{s}}{\sigma^6} - \dots \quad (14.39)$$

Formally, the Neumann series will converge if $\|\mathbf{A}\|/\sigma^2 < 1$, but that requirement is too stringent for our purposes since it takes no account of the nature of the signal. By the ratio test, the series in (14.39) will converge if

$$\frac{\mathbf{s}^t \mathbf{A}^{n+1} \mathbf{s}}{\sigma^2 \mathbf{s}^t \mathbf{A}^n \mathbf{s}} < 1 \quad (14.40)$$

for all n , and it may still converge (because of the alternating signs) even if (14.40) is violated. In practice, convergence will be rapid if the correlations are weak and short-range and the signal is spatially compact.

More generally, we can always decompose \mathbf{K}_g into a diagonal part \mathbf{D} plus a matrix \mathbf{A} with only off-diagonal terms. Assuming convergence, we then have

$$\mathbf{K}_g = \mathbf{D} + \mathbf{A} = \mathbf{D} [\mathbf{I} + \mathbf{D}^{-1} \mathbf{A}] ; \quad (14.41)$$

$$\mathbf{K}_g^{-1} = \left[\sum_{j=0}^{\infty} [-\mathbf{D}^{-1} \mathbf{A}]^j \right] \mathbf{D}^{-1} ; \quad (14.42)$$

$$\text{SNR}^2 = \mathbf{s}^t \mathbf{K}_g^{-1} \mathbf{s} = \mathbf{s}^t \mathbf{D}^{-1} \mathbf{s} - \mathbf{s}^t \mathbf{D}^{-1} \mathbf{A} \mathbf{D}^{-1} \mathbf{s} + \mathbf{s}^t \mathbf{D}^{-1} \mathbf{A} \mathbf{D}^{-1} \mathbf{A} \mathbf{D}^{-1} \mathbf{s} - \dots \quad (14.43)$$

The first term in this expansion, $\mathbf{s}^t \mathbf{D}^{-1} \mathbf{s}$, is what we computed above when we assumed there were no off-diagonal terms, and the remaining terms are the corrections arising from correlations induced by the detector. If these correlations are sufficiently weak, we may be able to truncate the series after a few terms, making the calculation of SNR easy.

The banded character of the covariance is especially useful if we are trying to detect a spatially compact signal. At the extreme, suppose \mathbf{s} is confined to a single detector element, say $\mathbf{m} = \mathbf{n}$. Then SNR^2 is simply $s_n^2 [\mathbf{K}_g^{-1}]_{nn}$, and the first correction term in (14.43) becomes

$$\mathbf{s}^t \mathbf{D}^{-1} \mathbf{A} \mathbf{D}^{-1} \mathbf{s} = \sum_{\mathbf{j}} \sum_{\mathbf{k}} s_n [\mathbf{D}^{-1}]_{nj} [\mathbf{A}]_{jk} [\mathbf{D}^{-1}]_{kn} s_n = \frac{s_n^2}{D_{nn}^2} A_{nn} = 0 \quad (14.44)$$

since the diagonal elements of \mathbf{A} are zero by definition.

The next term in the series is also simplified if we consider a signal confined to a single pixel:

$$\mathbf{s}^t \mathbf{D}^{-1} \mathbf{A} \mathbf{D}^{-1} \mathbf{A} \mathbf{D}^{-1} \mathbf{s} = \frac{s_n^2}{D_{nn}^2} [\mathbf{A} \mathbf{D}^{-1} \mathbf{A}]_{nn} = \frac{s_n^2}{D_{nn}^2} \sum_{\mathbf{k}} \frac{[A_{nk}]^2}{D_{kk}} \quad (14.45)$$

If we say that $A_{nk} \simeq 0$ when $|\mathbf{n} - \mathbf{k}| \epsilon > \delta$, then the number of terms we have to sum is of order $[\delta/\epsilon]^2$, which could be quite small. Moreover, if the elements of \mathbf{A} are small compared to \mathbf{D}_{nn} , then the correction terms are small and the series converges rapidly.

If the signal covers P pixels, the number of computations required is increased by a factor of P^2 , and a convergence condition analogous to (14.40) must be satisfied.

Matrix-inversion lemma Suppose we want to invert an overall covariance matrix of the form

$$\mathbf{K}_g = \overline{\mathbf{K}}_n + \widehat{\mathbf{K}}_{\overline{\mathbf{g}}} = \overline{\mathbf{K}}_n + \mathbf{W}\mathbf{W}^t, \quad (14.46)$$

where we have assumed that $\widehat{\mathbf{K}}_{\overline{\mathbf{g}}}$ is given by (14.33). For electronic or Poisson noise $\overline{\mathbf{K}}_n$ will be diagonal, but in some applications correlations will be introduced by the detector and $\overline{\mathbf{K}}_n$ will be a nearly diagonal, banded matrix (see, for example, the discussion of x-ray detectors in Sec. 12.3.8).

By the matrix-inversion lemma (A.56a), we see that

$$[\overline{\mathbf{K}}_n + \mathbf{W}\mathbf{W}^t]^{-1} = \overline{\mathbf{K}}_n^{-1} - \overline{\mathbf{K}}_n^{-1}\mathbf{W}[\mathbf{I} + \mathbf{W}^t\overline{\mathbf{K}}_n^{-1}\mathbf{W}]^{-1}\mathbf{W}^t\overline{\mathbf{K}}_n^{-1}. \quad (14.47)$$

The advantage of this form is that $[\mathbf{I} + \mathbf{W}^t\overline{\mathbf{K}}_n^{-1}\mathbf{W}]$ is an $N_s \times N_s$ matrix, where N_s is a few hundred in practice, rather than an $M \times M$ matrix, where M may be 10^6 . Moreover, since $\mathbf{W}^t\overline{\mathbf{K}}_n^{-1}\mathbf{W}$ is positive-semidefinite, the inverse of the $N_s \times N_s$ matrix will always exist. Thus, if $\overline{\mathbf{K}}_n$ can be inverted, either trivially because it is diagonal or by use of a rapidly convergent Neumann series, then it becomes feasible to add the sample covariance representing object variability.⁹

The matrix-inversion lemma reduces the size of the required inverse from $M \times M$ to $N_s \times N_s$ but it is not a dimensionality-reduction method in the sense that it does not entail potential information loss.

Dimensionality reduction using efficient channels The previous approaches depend upon writing the data covariance matrix as the sum of a full-rank, near-diagonal component representing the measurement noise and a low-rank contribution obtained from samples. When we do not have access to low-noise or noise-free samples from which to estimate the second term, an alternative approach is to make use of efficient channels that allow us to estimate the Hotelling observer's SNR in a lower-dimensional space.

In Sec. 13.2.12 we showed that a limited set of features, when properly chosen, preserves the information in the data in terms of yielding the same SNR for a linear observer. We found that an eigenanalysis of the inter- and intra-class scatter matrices results in full preservation of the separability using only $(L - 1)$ features for optimal linear discrimination between L classes. In the binary classification problem, a single feature is all that is needed — quite a dimensionality reduction.

The requirement for finding that single privileged feature is that complete knowledge of the scatter matrices is available in order to do the eigenanalysis. Without such complete knowledge, we must judiciously apply whatever prior information we have regarding the signals to be discriminated and the background statistics to find channels that reduce the dimensionality of the problem with limited loss of detectability.

For a particular set of channel profiles, the Hotelling formalism can be applied in the channel space to determine the \mathbf{w}_v , which is the vector of optimal channel weights. By analogy with (14.19), we write the template in the channel space as

$$\mathbf{w}_v = \mathbf{K}_v^{-1}\Delta\overline{\mathbf{v}}, \quad (14.48)$$

⁹This idea was suggested to us by Brandon D. Gallas (see Barrett *et al.*, 2001).

where $\Delta\bar{\mathbf{v}}$ is the difference in channel outputs under the two hypotheses,

$$\Delta\bar{\mathbf{v}} = \mathbf{U}^t \Delta\bar{\mathbf{g}}, \quad (14.49)$$

and $\mathbf{K}_{\mathbf{v}}$ is the $P \times P$ covariance matrix of the channel outputs:

$$\mathbf{K}_{\mathbf{v}} = \mathbf{U}^t \mathbf{K}_{\mathbf{g}} \mathbf{U}. \quad (14.50)$$

The SNR on the channel outputs is given by

$$\text{SNR}_{\mathbf{v}}^2 = \Delta\bar{\mathbf{v}}^t \mathbf{K}_{\mathbf{v}}^{-1} \Delta\bar{\mathbf{v}}. \quad (14.51)$$

From Sec. 13.2.12 we know that efficient features are ones that preserve the separability of the data in a space of reduced dimensionality, achieving $\text{SNR}_{\mathbf{v}}^2 = \text{SNR}_{\mathbf{g}}^2$.

Laguerre-Gauss channels Consider the example of a detection task in which the detected signal is approximately radially symmetric, centrally peaked and smooth, and situated at a known location on a stationary background with a correlation that has no preferred orientation. With these assumptions it can be expected that the ideal linear template will be centered at the known position of the signal, rotationally symmetric and smooth before discretization to match the CD nature of the imaging system.¹⁰ Laguerre-Gauss channel profiles have been proposed by Barrett *et al.* (1998c) for this task because they form a basis on the space of rotationally-symmetric square-integrable functions in \mathbb{R}^2 .

The Laguerre polynomials are defined in (4.57) as

$$L_p(x) = \sum_{k=0}^p (-1)^k \binom{p}{k} \frac{x^k}{k!}. \quad (14.52)$$

The orthogonality relation for these polynomials is given by (4.58):

$$\int_0^{\infty} dx e^{-x} L_p(x) L_{p'}(x) = \delta_{pp'}. \quad (14.53)$$

We can transform this relationship to a two-dimensional form with the change of variables $x = 2\pi r^2/a_u^2$, where r is the radial distance and a_u plays the role of a scaling factor, giving

$$\frac{1}{2\pi} \int_0^{2\pi} d\theta \int_0^{\infty} \frac{4\pi r dr}{a_u^2} \exp\left(\frac{-2\pi r^2}{a_u^2}\right) L_p\left(\frac{2\pi r^2}{a_u^2}\right) L_{p'}\left(\frac{2\pi r^2}{a_u^2}\right) = \delta_{pp'}. \quad (14.54)$$

We see that the exponential factor of (14.53) has been transformed to a Gaussian factor in (14.54). From this equation we can define the Laguerre-Gauss (LG) functions as

$$u_p(r|a_u) = \frac{\sqrt{2}}{a_u} \exp\left(\frac{-\pi r^2}{a_u^2}\right) L_p\left(\frac{2\pi r^2}{a_u^2}\right), \quad (14.55)$$

where the $\{u_p\}$ are orthogonal (without weighting factors) over \mathbb{R}^2 by (14.54).

Figure 14.7 shows radial dependencies of the first, third, and ninth LG functions, as well as their 2D forms. In order to apply these continuous functions to a

¹⁰Of course, a signal defined on a square pixel grid cannot be exactly rotationally symmetric, but we can ignore this problem if the template covers many pixels.

discrete data set, the functions must be sampled on the same grid used to discretize the data.

Fig. 14.7 The first, third and ninth Laguerre-Gauss functions: *Left*: 2D functions; *Right*: Radial forms. (Courtesy of Brandon Gallas.)

Because the LG functions form a basis for radially-symmetric functions in 2D, they can be used to exactly represent any rotationally symmetric function $f(r)$ by

$$f(r) = \exp\left(\frac{-\pi r^2}{a_u^2}\right) \sum_{p=0}^{\infty} \alpha_j L_p\left(\frac{2\pi r^2}{a_u^2}\right), \quad (14.56)$$

where

$$\alpha_p = \int d^2r u_p(r) f(r). \quad (14.57)$$

Knowledge of the signal and background can be used to choose a_u and estimate the coefficients α_p for a finite set of channels. Alternatively, a range of values for a_u can be investigated, with the number of channels increased until the detectability reaches a maximum over a_u and P . This approach has been investigated extensively by Gallas and Barrett (2003) for an SKE task on a lumpy background with widely varying statistical parameters. These authors found excellent agreement between the channelized linear observer's performance and the ideal linear observer's performance with a small number of channels (5–30). The number of channels needed was found to depend on the complexity of the background statistics.

Channel models for predicting human performance While the previous paragraphs specifically address the considerations that come to the fore when using channels to estimate the performance of the optimal linear observer, the advantages offered by the dimensionality reduction of the channelized-Hotelling approach are common to all linear channel models. As described in Sec. 14.2.2, a variety of linear channel models have been proposed for use in the prediction of human performance. All such models have the similar characteristic that they result in a calculable figure of merit for model-observer performance based on dimensionality reduction.

All channels designed to model the human have another similarity: because the human visual system is insensitive to broad, structureless regions, channel models designed to predict human performance have zero response at zero spatial frequency. As stated in Sec. 4.1.4, Laguerre-Gauss functions are eigenfunctions of the 2D rotationally symmetric Fourier operator. Thus the LG channel profiles in the Fourier domain have the same form as the space-domain channels shown in Fig. 14.7. The LG channels are peaked at $\rho = 0$ in the Fourier domain, just as they are peaked at $r = 0$ in the space domain. The LG channels are therefore not recommended for use in modeling human performance.

The body of literature providing the range of applicability of the various candidate channel models for predicting human performance continues to grow. Whenever a given model is utilized, it is important to validate the performance predictions with psychophysical studies involving human observers if the task or the statistics of the data sets are outside the range of experimental conditions for which the model has previously been shown to be predictive of human performance.

Random signals We have described a variety of methods for estimating the Hotelling observer's performance for SKE tasks. Random signals present an additional level of complexity (and realism). Even so, the generalization of the Hotelling approach to random signals is often straightforward. In particular, when the signals are low contrast, we have already stressed that the data covariance is approximately equal to its composition in the SKE case. In that case the only new question that arises is the estimation of the mean data vector that appears in (14.20).

Estimation of the mean data vector If the task is the detection of a random signal, and there is no prior information regarding the signal distribution, it is straightforward to estimate the sample means for the two classes and subtract them to determine $\Delta\hat{\mathbf{g}}$. The sample mean is the maximum-likelihood estimate of the true mean. The number of values to be estimated is the number of nonzero elements in the difference $(\hat{\mathbf{g}}_2 - \hat{\mathbf{g}}_1)$, which is determined by the extent of the signal as seen through the imaging system.

Prior information can be brought to bear on the estimation of the mean difference vector in a number of ways. If the signal is compact and there is prior information regarding its location, this information can be used to limit the number of values to be estimated to those within a certain region of the image. In the case of random signals of a specified shape, prior information regarding the signal's form can be used to reduce the number of parameters to be estimated to a small set, for example, signal amplitude, width, or location. Furthermore, prior information regarding the underlying distributions of the random parameters can be used to form Bayesian estimation procedures according to the theory presented in Chap. 13.

It should be noted that Hotelling SNR may be a poor indicator of system performance with large signal variability, as discussed in Sec. 13.2.12. If a signal can be located anywhere within a wide field of view, the signal averaged over location is a broad, structureless function and the detectability of the Hotelling observer, or any linear observer, becomes very small. One way around this problem is to replace the original two-alternative detection problem with an $(L + 1)$ -alternative problem where the signal can be at one of L nonoverlapping locations. The simple detection decision can then be made by choosing the location for which the response of the Hotelling observer is maximum, but we also get information on lesion location this way. Another possibility is to allow signal location to be a parameter in the SNR and compute a detectability map as described next.

Signal known exactly, but variable Let us assume that the signal varies randomly but is known to the observer on each trial (the only uncertainty being whether it is present). This task is sometimes referred to as the signal-known-exactly-but-variable, or SKEV, task (Eckstein and Abbey, 2001; Eckstein *et al.*, 2002). Let the randomness in the signal be captured by a random parameter vector $\boldsymbol{\theta}$. For each value of $\boldsymbol{\theta}$, the optimum linear test statistic is given by [cf. (13.208)]

$$\hat{\mathbf{w}}(\boldsymbol{\theta}) = [\hat{\mathbf{K}}_{\mathbf{g}}(\boldsymbol{\theta})]^{-1} \mathbf{s}(\boldsymbol{\theta}), \quad (14.58)$$

where the estimate of $\mathbf{K}_{\mathbf{g}}$ and its inverse must be determined using the methods described above. In particular, the method of template estimation given above may be used to estimate (14.58) without the need for finding an inverse of $\mathbf{K}_{\mathbf{g}}$ in some cases.

The Hotelling SNR can be estimated for each value of the random parameter, following (13.209):

$$\widehat{\text{SNR}}_{\text{Hot}}^2(\boldsymbol{\theta}) = \frac{\{[\hat{\mathbf{w}}(\boldsymbol{\theta})]^t \mathbf{s}(\boldsymbol{\theta})\}^2}{[\hat{\mathbf{w}}(\boldsymbol{\theta})]^t \hat{\mathbf{K}}_{\mathbf{g}}(\boldsymbol{\theta}) \hat{\mathbf{w}}(\boldsymbol{\theta})} = [\hat{\mathbf{w}}(\boldsymbol{\theta})]^t \mathbf{s}(\boldsymbol{\theta}), \quad (14.59)$$

where the second form follows from (14.58).

A summary measure of observer performance can be obtained by averaging (14.59) over $\boldsymbol{\theta}$ if $\text{pr}(\boldsymbol{\theta})$ is known. Alternatively, a detectability map, which plots the SNR^2 as a function of $\boldsymbol{\theta}$, can be presented. Eckstein *et al.* (2002) have found that the optimal parameters for image compression are the same when evaluated using either an SKE or an SKEV paradigm.

AUC and the linear discriminant Thus far we have concentrated on the estimation of the SNR for the Hotelling observer. As discussed in Chap. 13, the Hotelling observer gives maximal SNR and maximal AUC when the data are Gaussian distributed. For non-Gaussian data, the Hotelling observer may not give the best AUC that can be achieved by a linear observer. It is therefore of interest to consider the behavior of AUC for an arbitrary linear discriminant and investigate methods for maximizing this alternative, and arguably superior, figure of merit.

It was shown in (13.44) that

$$\text{AUC}_{\text{lin}} = \frac{1}{2} + \frac{1}{2\pi i} \mathcal{P} \int_{-\infty}^{\infty} \frac{d\xi}{\xi} \psi_{\mathbf{g}1}(\mathbf{w}\xi) \psi_{\mathbf{g}2}^*(\mathbf{w}\xi), \quad (14.60)$$

where \mathbf{w} is the arbitrary $M \times 1$ template of (14.18) that generates the test statistic t from each data vector \mathbf{g} , and $\psi_{\mathbf{g}j}(\cdot)$ is the characteristic function for the data under

hypothesis j . Limiting forms of (14.60) for nonrandom signals and for weak signals are given in Sec. 13.2.5. Note that (14.60) is just a 1D integral—only one line through the multivariate characteristic function under each hypothesis is needed once \mathbf{w} is specified.

This formula for AUC is useful when we have analytic forms for the characteristic functions of the data under the two hypotheses. In background-known-exactly (BKE) problems, we might know the characteristic functions directly from the data statistics, but if the background is random we have to first characterize the object statistics and then propagate them into the data domain as discussed in Sec. 8.5.3. If the object is regarded as a continuous function, we need first to obtain an analytic expression for its characteristic functional, then apply (8.335) or (8.339) to obtain the characteristic functions for the data. For example, lumpy and clustered lumpy backgrounds were introduced in Sec. 8.4.4, and their characteristic functionals were derived in Sec. 11.3.10. Additional examples of analytic characteristic functions will be given in Chap. 18.

When the needed characteristic functions are available, an iterative search can be used to maximize the AUC given by (14.60); useful search algorithms are discussed in Sec. 15.4.3. Since the integral is one-dimensional, this search is not particularly computationally expensive.

A major advantage of the approach suggested by (14.60) is that no matrix inversion is required, unlike the determination of the full Hotelling SNR. While an iterative approach can be used to determine the Hotelling SNR when the noise contribution to the covariance matrix is known, it works by searching for the optimum linear template and indirectly obtaining the SNR. An iterative solution for (14.60) directly yields AUC.

The linear discriminant obtained by searching for the \mathbf{w} that maximizes AUC may differ from the Hotelling observer, as discussed in Sec. 13.2.12. When this occurs, the linear discriminant that gives higher AUC is to be preferred whenever our goal is the linear approximation to the ideal observer.

Errors in estimates of SNR for linear observers It is natural to ask how close the estimated SNR is to the true SNR that would have been obtained with full knowledge of the ensemble statistics of the data. That is, we would like to know the bias and variance of the estimate. In this context, bias and variance refer to the first- and second-order statistics of the estimate when different finite sets of images are used. There are several methods, briefly surveyed below, to estimate the magnitude of the bias and variance from this source.

As with any real-world estimation problem, however, there can also be a systematic bias arising from invalid assumptions or modeling errors, and this kind of bias is much more difficult to assess. With computer-generated images, a major source of systematic bias is unrealistic or oversimplified simulation; with real images, a major problem is uncertainty in the true diagnosis. Both of these issues are discussed in Sec. 14.4; here we focus on statistical errors.

It is straightforward to estimate the variance of estimates of SNR or AUC when simulated images are used; all that is needed is to repeat the simulation several times with independent sets of images and compute the sample variance of the values obtained. More sophisticated resampling methods (see below) can also be used, but their only advantage is a saving in computer time, seldom a primary concern these days. In fact, with simulated images the variance and the statistical

bias can be made arbitrarily small simply by running the computer long enough. If real images are used, however, the number of images might be quite limited, and it becomes more critical to estimate the error associated with an estimate of SNR^2 .

Errors in direct estimation of SNR in channel space One situation in which we can give not only the bias and variance but indeed the full probability density function of the estimated SNR^2 is when dimensionality reduction is performed with efficient or anthropomorphic channels and the resulting channel outputs are normally distributed. In that case we can estimate SNR^2 by

$$\widehat{\text{SNR}}^2 \equiv [\widehat{\Delta\bar{\mathbf{v}}}]^t \widehat{\mathbf{K}}_{\bar{\mathbf{v}}}^{-1} [\widehat{\Delta\bar{\mathbf{v}}}], \tag{14.61}$$

where the hats here denote estimates obtained by sample averages; it is assumed that the number of sample images is larger than the number of channels so that the sample covariance matrix is invertible.

The estimator defined in (14.61) is precisely the one studied by Hotelling in his classic 1931 paper, and it is often referred to as *Hotelling's T^2 statistic*. The PDF of T^2 is closely related to the F distribution; for details see Hotelling (1931) or Anderson (1971). The general behavior of the estimate is illustrated in Fig. 14.8, where it is seen that the estimate is highly biased unless the number of sample images is much larger than the number of channels (and of course it is not even defined if the number of sample images is less than the number of channels).

Fig. 14.8 Schematic behavior of the Hotelling T^2 estimate of SNR^2 as defined in (14.61). The dashed horizontal line indicates the true value of SNR^2 on the channel outputs, and the solid curve shows the mean of the estimate. The error bars are indicative of the variance. We thank Andy Alexander for suggesting this kind of plot.

The basic problem with the Hotelling T^2 estimate is that it makes no use of prior information about the quantity being estimated, namely the SNR^2 on the channel outputs. One key piece of prior information in many cases is knowledge of the mean difference signal in data space, $\bar{\mathbf{g}}$, from which we can determine the mean difference signal in channel space, $\Delta\bar{\mathbf{v}}$, by (14.49). If we regard $\Delta\bar{\mathbf{v}}$ as known and nonrandom, we can define a better estimate of SNR^2 by

$$\widehat{\text{SNR}}^2 \equiv [\Delta\bar{\mathbf{v}}]^t \widehat{\mathbf{K}}_{\bar{\mathbf{v}}}^{-1} [\Delta\bar{\mathbf{v}}]. \tag{14.62}$$

Another key piece of prior information is the covariance decomposition (14.27). If we regard $\bar{\mathbf{K}}_n$ as known and nonrandom and use (14.51), the estimate in (14.62) is modified to

$$\widehat{\text{SNR}}^2 \equiv [\Delta\bar{\mathbf{v}}]^t \left[\mathbf{U}^t \left(\bar{\mathbf{K}}_n + \hat{\mathbf{K}}_{\bar{\mathbf{g}}} \right) \mathbf{U} \right]^{-1} [\Delta\bar{\mathbf{v}}]. \quad (14.63)$$

Note that the hat, denoting sample estimates, now appears over only $\hat{\mathbf{K}}_{\bar{\mathbf{g}}}$, so only that term contributes to the bias and variance of the estimate of SNR^2 .

The statistical properties of (14.62) and (14.63) have not yet been derived, but they should offer substantially smaller bias and variance than the T^2 estimate of (14.61) simply because they use more prior information. All of these estimates, however, assume that the channel outputs are normally distributed; it is advisable to plot experimental histograms to check this assumption.

Training and testing An alternative to direct estimation of SNR^2 is first to estimate the template \mathbf{w} and then to apply it to a set of sample images. When only a single, finite set of images is available, the experimenter must use the set of images for two purposes: training the observer (choosing the number of channels, their weights, and any parameters that characterize the channel profiles); and testing the observer (estimating its performance). This is the so-called “training-testing” paradigm. The training-testing label applies even without dimensionality-reducing feature extraction. When we estimate the template from samples by any method, we are training the observer.

There are two common ways to train and test an observer with a single set of sample images. The first option is to split the data into two independent sets, one set to be used to train the observer and the other to be used for testing the observer. The split does not need to be into subsets of equal size. This approach is sometimes referred to as the holdout method. A related method is the use of $N_s - 1$ images to train the observer, with the final sample used to test the observer. This method is known as the round-robin approach; by repeating the training/testing sequence N_s times, keeping score of the observer’s decision variable each time, an estimate of the observer’s performance is obtained over the entire data set. However, the round-robin method does not yield a single observer, but rather, each held-out image is tested on a different observer.

Gallas (2003) investigated various resampling approaches for determining the bias and variance of the performance estimate for the channelized linear observer trained and tested using variations on the hold-out method. Using a very large set of independent estimates of observer performance (the beauty of Monte Carlo image simulation), Gallas was able to determine the true performance of the channelized observer and thus calculate the bias as well as the variance of the finite-sample methods.

The second training-testing option is the resubstitution method, where the observer is trained and tested on the same set of images. The use of a single set of images to estimate the observer’s template, followed by an estimation procedure that applies that template to the data to determine the first- and second-order statistics of t under each hypothesis to derive an SNR, will give an optimistic result (Wagner *et al.*, 1997). The resulting estimates of observer performance correspond to the results obtained via (14.61) and illustrated in Fig. 14.8.

14.3.3 Ideal observers

We learned in Chap. 13 that the ideal observer for binary classification tasks is one that bases its decision on the likelihood ratio. Many properties of the likelihood ratio and its logarithm, and of performance metrics derived from them, were given in Sec. 13.2. In this section we review a variety of approaches to using these often abstract mathematical concepts in the practical assessment of image quality.

Analogies with the Hotelling problem The basic challenge in computing the test statistic for both the Hotelling and the ideal observer is dimensionality. For the Hotelling observer, we need to construct and invert a huge covariance matrix; for the ideal observer, we need to form huge-dimensional multivariate probability density functions and take ratios of them. In neither case are brute-force methods likely to be fruitful; in both cases we must make use of prior information about the task and imaging system in order to make progress.

An important piece of prior information for the Hotelling problem is the conditional covariance $\mathbf{K}_{\mathbf{n}|\mathbf{f}}$, which is known from the physics of the measurement process. For example, $\mathbf{K}_{\mathbf{n}|\mathbf{f}}$ for raw, unprocessed data and Gaussian noise is given in (14.29), and for Poisson noise it is given by (14.30). The analogous prior information for the ideal observer is the conditional PDF $\text{pr}(\mathbf{g}|\mathbf{f})$, which is again known from the physics. Before processing, $\text{pr}(\mathbf{g}|\mathbf{f})$ is often multivariate Gaussian or multivariate Poisson, and in both cases the multivariate PDF can often be written as a product of univariate PDFs. The effect of processing is discussed in Secs. 15.2.6, 15.4.2 and 15.4.7.

In both Hotelling and ideal-observer studies, it is necessary to choose the object model carefully, allowing enough complexity and variability to capture the essence of real objects, yet retaining adequate mathematical tractability. In both cases, object models such as the lumpy and clustered lumpy backgrounds introduced in Sec. 8.4 are very useful.

The signal model, too, can be chosen to facilitate the computation. In particular, nonrandom signals are very attractive, though it remains an open question how well conclusions from SKE studies can be applied to more realistic tasks.

Decomposition of the PDFs The likelihood ratio is the ratio of two PDFs, each of which can be written somewhat abstractly as

$$\text{pr}(\mathbf{g}|H_j) = \int d\mathbf{f} \text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}|H_j), \quad (j = 1, 2). \quad (14.64)$$

The notation $\text{pr}(\mathbf{f})$ is explained in Sec. 8.2.2 [see especially (8.78) and (8.81)]. In brief, it denotes the density on the full (potentially infinite) set of parameters needed to specify the object as a random process $f(\mathbf{r})$.

The density on the data can also be written as

$$\text{pr}(\mathbf{g}|H_j) = \langle \text{pr}(\mathbf{g}|\mathbf{f}) \rangle_{\mathbf{f}|H_j}. \quad (14.65)$$

Numerous alternative forms of $\text{pr}(\mathbf{g}|H_j)$, with various assumptions about the object and the noise, are given in Sec. 8.5.4.

Thus, in order to determine the densities needed in the likelihood ratio, we need both the conditional density on the data for a given object, $\text{pr}(\mathbf{g}|\mathbf{f})$, and the densities $\text{pr}(\mathbf{f}|H_j)$ on the object under the two hypotheses. Note that $\text{pr}(\mathbf{g}|\mathbf{f})$ does

not depend directly on the hypothesis H_j ; specifying the object specifies the mean of \mathbf{g} , and that in turn specifies the full density in most cases.¹¹ Note also that we do not refer to $\text{pr}(\mathbf{g}|\mathbf{f})$ as a likelihood since it is never our goal to estimate \mathbf{f} ; it is not the goal in this section since we are discussing a classification problem, and it is not even the goal in image reconstruction (see Chap. 15).

Conditional PDFs To be more specific about $\text{pr}(\mathbf{g}|\mathbf{f})$, we need to distinguish direct from indirect imaging and object-dependent from object-independent noise, just as we did in Sec. 14.3.2 when we discussed $\mathbf{K}_{\mathbf{n}|\mathbf{f}}$ [see (14.29) and (14.30)].

Consider first the case of direct imaging with a detector array limited by Gaussian electronic noise. If we assume that all elements in the array are identical and that each generates its own noise independently of the other elements, then the probability density function of \mathbf{n} is

$$\text{pr}_{\mathbf{n}}(\mathbf{n}) = (2\pi\sigma^2)^{-M/2} \prod_{m=1}^M \exp\left(-\frac{n_m^2}{2\sigma^2}\right). \quad (14.66)$$

Since the electronic noise is independent of the mean detector output, the conditional density on the data is just a shifted version of the noise density:

$$\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}_{\mathbf{n}}[\mathbf{g} - \bar{\mathbf{g}}(\mathbf{f})] = (2\pi\sigma^2)^{-M/2} \prod_{m=1}^M \exp\left\{-\frac{[g_m - \bar{g}_m(\mathbf{f})]^2}{2\sigma^2}\right\}. \quad (14.67)$$

For linear systems we can go a step further and write $\bar{g}_m(\mathbf{f}) = [\mathcal{H}\mathbf{f}]_m$.

Similarly, with raw Poisson measurements we have

$$\text{pr}(\mathbf{g}|\mathbf{f}) = \prod_{m=1}^M \exp[-\bar{g}_m(\mathbf{f})] \frac{[\bar{g}_m(\mathbf{f})]^{g_m}}{g_m!}. \quad (14.68)$$

Thus in both of these cases the multivariate density is a product of univariate densities.

The situation is more complicated if we regard \mathbf{g} as the output of some data-processing or image-reconstruction step. Linear processing leaves Gaussian data Gaussian but introduces correlations. Nevertheless, it is straightforward to write down a multivariate expression for $\text{pr}(\mathbf{g}|\mathbf{f})$ since we know how to compute mean vectors and covariance matrices after linear operations, and a multivariate normal is fully specified by its mean and covariance. There is no simple way of expressing $\text{pr}(\mathbf{g}|\mathbf{f})$ after linear processing of Poisson data, but it may be valid to approximate it with a suitably correlated multivariate normal (see Sec. 15.2.6).

Noise on the output of iterative reconstruction algorithms is discussed in Secs. 15.4.2 and 15.4.7. If the algorithm is nonlinear and enforces a positivity constraint, then the noise cannot be Gaussian since negative values cannot occur. Specifically, with multiplicative algorithms such as MLEM (maximum-likelihood expectation-maximization), it often happens that the PDF on the reconstructed image is approximately a correlated log-normal (Wilson *et al.*, 1994; Barrett *et al.*, 1994).

¹¹An exception to this statement will be given in Sec. 18.6.4 where we discuss speckle. As we shall see there, in some speckle problems the variance of the data is different for the signal-present and signal-absent hypotheses.

To summarize, with raw, unprocessed data, $\text{pr}(\mathbf{g}|\mathbf{f})$ usually has a simple analytic form (independent Gaussian or Poisson). With processing, the elements of \mathbf{g} are no longer statistically independent, but it is usually possible to give at least an approximate form for the conditional density. In what follows we shall assume throughout that $\text{pr}(\mathbf{g}|\mathbf{f})$ is known analytically.

As a notational point, we see from (14.66) and (14.67) that the conditional density on unprocessed data \mathbf{g} is completely determined by its mean with both the Gaussian and Poisson noise models, so $\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}[\mathbf{g}|\bar{\mathbf{g}}(\mathbf{f})]$. The same is true after processing; if we know $\bar{\mathbf{g}}$, we can specify the density on \mathbf{g} , and we know $\bar{\mathbf{g}}$ if we know \mathbf{f} . We shall therefore write $\text{pr}(\mathbf{g}|\mathbf{f})$ and $\text{pr}(\mathbf{g}|\bar{\mathbf{g}})$ interchangeably, depending on which conditional variable we wish to emphasize.

Object statistics Statistical properties of objects were the subject of Sec. 8.4. The viewpoint adopted there regards the object as a random process for which each sample function is a vector in a Hilbert space. Since we are concerned only with the measurement component of the object, the Hilbert space of interest has a finite but huge dimensionality. We saw a few cases where the object statistics could be specified analytically, for example as a Gaussian random process or a Gaussian mixture, but in most cases analytic models are either unavailable or unrealistic. The two main options in those cases are to reduce the dimensionality of the statistical description of the object or to use a constructive model that allows us to simulate sample objects even if we cannot specify their statistics.

Dimensionality reduction rests on the assumption that somehow the essential features of a complicated random process can be captured with a relatively small number of parameters. As discussed in Sec. 8.4.1, approaches to finding this low-dimensional representation include principal components analysis (PCA) and independent components analysis (ICA). When ICA is applied to images, it is found that the independent components are the outputs of bandpass filters similar to wavelets or the channels in the human visual system; indeed, some have speculated that our visual system has evolved to extract approximately statistically independent components of natural scenes, thereby permitting efficient transformation of information to the brain.

We postulate that there exist similar low-dimensional representations of objects, as opposed to images, and that they again involve bandpass filters or channels. We know from the discussion in Sec. 8.4.3 that the univariate PDFs on the channel outputs have a long-tailed, kurtotic form. Sometimes they are described empirically in terms of the Lévy family, defined not by the density but by the characteristic function, which has the form $\psi(\xi) = \exp(-b|\xi|^q)$. If the channels are chosen so that the outputs are approximately statistically independent, the multivariate object statistics are described by a finite product of characteristic functions of this form.

The constructive models that have received the most attention in image-quality studies are lumpy and clustered lumpy backgrounds. As defined in (8.303), a sample function of a lumpy background is specified exactly by stating the lump positions $\{\mathbf{r}_n\}$ as well as the number of lumps N . The statistical properties are fully specified by giving the probability laws for \mathbf{r}_n and N .

Alternatively, for many constructive models, the object statistics can be specified by giving an analytic form for the characteristic functional associated with the random field. This concept was introduced in Sec. 8.2.3, and the specific forms

for lumpy and clustered lumpy backgrounds were calculated in Sec. 11.3.9. Other constructive models that can be used to synthesize texture fields, and for which analytic characteristic functionals are available, will be introduced in Chap. 18.

To summarize, random objects may be specified by huge-dimensional PDFs, by lower-dimensional PDFs on channel outputs, by rules that let us construct sample functions, and/or by characteristic functionals. In what follows we shall see how each of these descriptions aids us in the computation of ideal-observer performance.

From object domain to data domain If we have either a statistical or a constructive specification of a random object, the next step is to transform it into the data domain. For constructive models, this step is straightforward in principle; one generates the random object and uses it to simulate the random image. Simulation methods are discussed in Sec. 14.4.

To discuss transformation of the PDF, we need to distinguish linear from nonlinear imaging systems. A general rule for nonlinear transformation of bivariate PDFs is given in (C.104), but it does not extend usefully to high-dimensional multivariate problems since the Jacobian cannot be evaluated. So far as the authors can see, there is no hope of transforming an object PDF through a nonlinear imaging system.

The transformation rules for linear systems are most easily expressed in terms of characteristic functions and functionals. If $\bar{\mathbf{g}}(\mathbf{f}) = \mathcal{H}\mathbf{f}$, with \mathcal{H} a linear CD operator, then we know from (8.96) that the characteristic function for the random vector $\bar{\mathbf{g}}$ under hypothesis H_j is given by

$$\psi_{\bar{\mathbf{g}}|H_j}(\boldsymbol{\xi}) = \Psi_{\mathbf{f}|H_j}(\mathcal{H}^\dagger \boldsymbol{\xi}), \quad (14.69)$$

where $\boldsymbol{\xi}$ is an $M \times 1$ vector, $\psi_{\bar{\mathbf{g}}|H_j}(\boldsymbol{\xi})$ is the characteristic function for $\bar{\mathbf{g}}$, and $\Psi_{\mathbf{f}|H_j}(\boldsymbol{\sigma})$ is the characteristic functional of the object \mathbf{f} , with $\boldsymbol{\sigma}$ being a vector in the same Hilbert space as \mathbf{f} , *e.g.*, $\boldsymbol{\sigma}$ corresponds to a function $\sigma(\mathbf{r})$.

If we write $\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}$ and assume that \mathbf{n} is object-independent, then we know from (8.335) that

$$\psi_{\mathbf{g}|H_j}(\boldsymbol{\xi}) = \psi_{\mathbf{n}}(\boldsymbol{\xi}) \psi_{\bar{\mathbf{g}}|H_j}(\boldsymbol{\xi}) = \psi_{\mathbf{n}}(\boldsymbol{\xi}) \Psi_{\mathbf{f}|H_j}(\mathcal{H}^\dagger \boldsymbol{\xi}). \quad (14.70)$$

For Poisson noise, (8.339) tells us that

$$\psi_{\mathbf{g}|H_j}(\boldsymbol{\xi}) = \Psi_{\mathbf{f}|H_j}[\mathcal{H}^\dagger \boldsymbol{\Gamma}(\boldsymbol{\xi})], \quad (14.71)$$

where

$$[\boldsymbol{\Gamma}(\boldsymbol{\xi})]_m = \frac{-1 + \exp(-2\pi i \xi_m)}{-2\pi i}. \quad (14.72)$$

Expressions for the data PDFs can be obtained by performing an inverse MD Fourier transform on each expression for $\psi_{\mathbf{g}|H_j}(\boldsymbol{\xi})$.

For signal-known-exactly tasks, it follows from the Fourier shift theorem that

$$\psi_{\mathbf{g}|H_2}(\boldsymbol{\xi}) = \exp(-2\pi i \boldsymbol{\xi}^\dagger \mathbf{s}) \psi_{\mathbf{g}|H_1}(\boldsymbol{\xi}), \quad (14.73)$$

where \mathbf{s} is the nonrandom signal in data space. Thus it suffices to know the no-signal or background-only characteristic function in this case.

Estimation of object statistics In many cases we can express the object statistics in parametric form. For example, with stationary lumpy backgrounds the width of a single lump and the number of lumps per unit area (or volume) fully describe the random process. Similarly, if the object statistics are specified in terms of the outputs of bandpass channels, we could assume that the univariate characteristic function for the n^{th} channel has the Lévy form $\psi_n(\xi) = \exp(-b_n|\xi|^{q_n})$; if we assume further that the channel outputs are statistically independent, then the multivariate object statistics are specified by the sets $\{b_n\}$ and $\{q_n\}$.

We can use the freedom in choosing these parameters to create a wide variety of random object fields. Moreover, if we can estimate the parameters from a training set of real images, we can tailor the object description to a particular physical situation. The problem is that the training set will consist of *images*, and we want to find the parameters for describing *objects*, in spite of the blur and noise associated with whatever imaging system was used to form the images.

A way of estimating the object parameters from blurred, noisy images was devised by Kupinski *et al.* (2003a). They assumed that the object characteristic functional under the no-signal hypothesis was known except for some parameter vector α , so it could be written as $\Psi_{\mathbf{f}|H_1}(\mathbf{s}; \alpha)$. The corresponding characteristic function in the data domain could then be obtained by one of the transformation rules given above; for example, (14.71) applies with Poisson noise, and

$$\psi_{\mathbf{g}|H_1}(\boldsymbol{\xi}; \alpha) = \Psi_{\mathbf{f}|H_1}[\mathcal{H}^\dagger \boldsymbol{\Gamma}(\boldsymbol{\xi}); \alpha]. \quad (14.74)$$

Given a set of signal-absent training images $\{\mathbf{g}_n, n = 1, \dots, N_s\}$, Kupinski *et al.* formed the *empirical characteristic function* for the data, which is basically a Monte Carlo estimate of $\psi_{\mathbf{g}|H_1}(\boldsymbol{\xi}; \alpha)$, defined by

$$\widehat{\psi}(\boldsymbol{\xi}) \equiv \frac{1}{N_s} \sum_{n=1}^{N_s} \exp(-2\pi i \boldsymbol{\xi}^t \mathbf{g}_n). \quad (14.75)$$

The estimation procedure was then basically minimization of the norm of the difference between the known $\widehat{\psi}(\boldsymbol{\xi})$ and the known analytic form $\psi_{\mathbf{g}|H_1}(\boldsymbol{\xi}; \alpha)$ from (14.74), minimization being carried out by varying α . In practice a weighted least-squares norm was used, taking advantage of the fact that all characteristic functions are unity at $\boldsymbol{\xi} = 0$, so the variance of the estimate $\widehat{\psi}(\boldsymbol{\xi})$ is zero at that point. Moreover, a set of channels was applied to each \mathbf{g}_n to reduce the dimensionality and ease the computational burden. For details, see Kupinski *et al.* (2003a).

The beauty of this procedure is that it gives a statistical description of the underlying objects, independent of the imaging system. Thus, even though a particular imaging system, say one described by an operator \mathcal{H}_0 , was used to obtain the training images, the characteristic function for another system, described by a general \mathcal{H} , can be found from (14.74) once α has been estimated. If we can devise a way of computing ideal-observer performance from this information, we can in principle vary \mathcal{H} and optimize the imaging system for the class of objects from which the training set was drawn.

Estimation of the likelihood ratio In an ideal-observer study, the basic quantity to be calculated is the likelihood ratio, defined by

$$\Lambda(\mathbf{g}) = \frac{\text{pr}(\mathbf{g}|H_2)}{\text{pr}(\mathbf{g}|H_1)} = \frac{\int d\mathbf{f} \text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}|H_2)}{\int d\mathbf{f} \text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}|H_1)}. \quad (14.76)$$

The integrals here are over a potentially infinite-dimensional Hilbert space, but they can be reduced to M dimensions (where M is the number of measurements) by observing that $\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}[\mathbf{g}|\bar{\mathbf{g}}(\mathbf{f})]$. If we use (8.351) to decompose the object into background and signal parts,

$$\mathbf{f} = \mathbf{f}_b + \mathbf{f}_s, \tag{14.77}$$

and (for a linear system) transform the background and signal into data space as

$$\bar{\mathbf{g}} \equiv \mathbf{b} + \mathbf{s}, \quad \mathbf{b} \equiv \mathcal{H}\mathbf{f}_b, \quad \mathbf{s} \equiv \mathcal{H}\mathbf{f}_s, \tag{14.78}$$

then we can write the likelihood ratio as [*cf.* (13.166)]

$$\Lambda(\mathbf{g}) = \frac{\int_{-\infty}^{\infty} d^M b \text{pr}(\mathbf{g}|H_2, \mathbf{b}) \text{pr}(\mathbf{b})}{\int_{-\infty}^{\infty} d^M b \text{pr}(\mathbf{g}|H_1, \mathbf{b}) \text{pr}(\mathbf{b})}. \tag{14.79}$$

A useful alternative form of the likelihood ratio is given by (13.169) and (13.170) as

$$\Lambda(\mathbf{g}) = \langle \Lambda_{\text{BKE}}(\mathbf{g}, \mathbf{b}) \rangle_{\mathbf{b}|\mathbf{g}, H_1}, \tag{14.80}$$

where the subscript BKE indicates background-known-exactly, and

$$\Lambda_{\text{BKE}}(\mathbf{g}, \mathbf{b}) \equiv \frac{\text{pr}(\mathbf{g}|H_2, \mathbf{b})}{\text{pr}(\mathbf{g}|H_1, \mathbf{b})}. \tag{14.81}$$

The advantage of this form is that $\Lambda_{\text{BKE}}(\mathbf{g}, \mathbf{b})$ is easy to calculate. In fact, for nonrandom signals it is just the ratio of two conditional densities like (14.67) or (14.68). Note, however, that the required average in (14.80) is with respect to the posterior density on the background, $\text{pr}(\mathbf{b}|\mathbf{g}, H_1)$; we shall learn shortly how to do this average by Monte Carlo methods.

One way of evaluating the performance of the ideal observer on a signal-detection task is to generate sets of signal-present and signal-absent sample images, estimate the likelihood ratio of each image and form an ROC curve. Methods discussed in Sec. 14.2.4 can then be used to estimate the area under the curve or ideal-observer AUC.

A useful surrogate for ideal-observer AUC is the likelihood-generating function evaluated at the origin. We know from (13.97) that this quantity is given by

$$G(0) = -4 \ln \left\{ \int d^M g [\text{pr}(\mathbf{g}|H_1) \text{pr}(\mathbf{g}|H_2)]^{\frac{1}{2}} \right\}. \tag{14.82}$$

We can use $G(0)$ to estimate AUC by [*cf.* (13.20) and (13.96)]

$$\text{AUC} \approx \frac{1}{2} + \frac{1}{2} \text{erf} \left(\sqrt{\frac{G(0)}{2}} \right). \tag{14.83}$$

If the log-likelihood ratio is normally distributed or $G(0)$ is large (which means that AUC approaches 1), then this result is exact. Clarkson and Barrett (2000) have found it to be an excellent approximation in a variety of cases with practical values of AUC.

Monte Carlo methods Perusal of expressions such as (14.79) or (14.82) shows that computation of ideal-observer performance in nontrivial cases requires evaluation of huge-dimensional integrals. In Sec. 10.4.5 we introduced the concept of Monte Carlo simulation and commented that it was useful in numerical evaluation of multidimensional integrals. As we shall show, Monte Carlo integration is a very valuable tool in ideal-observer evaluations, but in fact we need to move beyond the simple Monte Carlo methods of Sec. 10.4.5 to the more sophisticated and powerful approach of Markov-chain Monte Carlo (MCMC). Book-length treatments of MCMC are given by Robert and Casella (1999) and Gilks *et al.* (1996). We begin here, however, with simple Monte Carlo integration to illustrate the principles and problems.

To evaluate the numerator or denominator in the likelihood ratio as given in (14.76), we must in principle integrate over an infinite-dimensional space, though we could also use (14.79) to reduce it to M dimensions (which is of little consolation if M is of order 10^6). If, however, we can simulate a set of objects $\{\mathbf{f}_n, n = 1, \dots, N_s\}$, then we can approximate those integrals by [cf. (10.300)]

$$\text{pr}(\mathbf{g}|H_j) = \int d\mathbf{f} \text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}|H_j) \approx \frac{1}{N_s} \sum_{n=1}^{N_s} \text{pr}(\mathbf{g}|\mathbf{f}_n), \quad (14.84)$$

where the sample must be drawn from $\text{pr}(\mathbf{f}|H_j)$. That is, if H_2 denotes signal-present and H_1 denotes signal-absent, the simulations must include the signal and background for $j = 2$ but only the background for $j = 1$.

Recall that $\text{pr}(\mathbf{g}|\mathbf{f}_n)$ in (14.84) is a known function, for example given by (14.67) or (14.68). In essence, the Monte Carlo integration associates this known function with every sample point $\mathcal{H}\mathbf{f}_n$ in the data space. The method is thus reminiscent of *kernel estimation*, a technique often used to estimate probability densities from a discrete set of samples. The key difference is that choosing the kernel in kernel estimation is a black art. The kernel must be broad enough to fill in the gaps between samples, yet not so broad as to smooth out essential details in the density being estimated. No such issue arises with (14.84); the form of the kernel is dictated by the physics of the problem, and its width is dictated by the noise level.

This is not to say that (14.84) is a panacea. The kernel $\text{pr}(\mathbf{g}|\mathbf{f}_n)$ falls off rapidly as $\mathcal{H}\mathbf{f}_n$ gets farther from the particular \mathbf{g} for which $\Lambda(\mathbf{g})$ is being calculated. If the noise level is small, most randomly chosen $\mathcal{H}\mathbf{f}_n$ will be so far from \mathbf{g} that $\text{pr}(\mathbf{g}|\mathbf{f}_n)$ will be zero to computer precision, and few of the samples will make any contribution to the sum in (14.84). Even though the sum will asymptotically approach $\text{pr}(\mathbf{g}|H_j)$ as N_s goes to infinity, and the estimator is unbiased for all N_s , the variance can be huge for practical finite values of N_s . The problem gets worse as M gets larger or as the noise level gets smaller.

One way to ameliorate this problem in some cases is by *importance sampling*. Suppose we know an analytic form for $\text{pr}(\mathbf{f}|H_j)$, say as a Gaussian mixture or in terms of independent components. Then we are free to rewrite the data density as

$$\text{pr}(\mathbf{g}|H_j) = \int d\mathbf{f} \frac{\text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}|H_j)}{q(\mathbf{f})} q(\mathbf{f}), \quad (14.85)$$

where $q(\mathbf{f})$ is a probability density function (*i.e.*, a nonnegative function normalized to unity) with a support large enough that dividing by zero does not become an

issue. We can then approximate the data density as

$$\text{pr}(\mathbf{g}|H_j) \approx \frac{1}{N_s} \sum_{n=1}^{N_s} \frac{\text{pr}(\mathbf{g}|\mathbf{f}_n) \text{pr}(\mathbf{f}_n|H_j)}{q(\mathbf{f}_n)}, \quad (14.86)$$

where now the samples are drawn from $q(\mathbf{f})$. For this modification to be useful, we must choose $q(\mathbf{f})$ so that the samples in data space, $\mathcal{H}\mathbf{f}_n$, are clustered near the actual \mathbf{g} . In simulation studies, we can do this by taking advantage of the knowledge of how we produced \mathbf{g} in the first place. If we did so by simulating some particular object \mathbf{f}_0 , then we know what this object was and can use this knowledge in computing the likelihood ratio. For example, if we describe objects by their independent components, with expansion coefficients $\{\alpha_k\}$, then the initial object \mathbf{f}_0 is described by $\{\alpha_{k0}\}$, and the importance sampler can generate random objects by random perturbations about $\{\alpha_{k0}\}$. So long as the perturbations are large enough to adequately sample the integrand, the sum in (14.86) is still an unbiased estimator of $\text{pr}(\mathbf{g}|H_j)$, and the variance is greatly reduced by using the prior knowledge of the point about which to take samples. A related approach, suggested by Zhang *et al.* (2001a), is to draw the samples from $\text{pr}(\mathbf{g}|\mathbf{f})$, renormalized as a density on \mathbf{f} .

Markov-chain Monte Carlo Direct Monte Carlo integration as sketched above has limited applicability because of the need for an analytic form for $\text{pr}(\mathbf{f}|H_j)$ in the importance sampler. A more general technique is MCMC, which will be discussed in the context of image reconstruction in Sec. 15.4.8. As we shall see there, the essence of MCMC is to propose random perturbations in the vector that is the variable of integration, and to accept or reject the proposed perturbations with a carefully chosen rule such that the sequence of accepted perturbations forms a Markov chain, and the equilibrium PDF for the chain is precisely the one from which we wish to sample.

For ideal-observer studies, MCMC is particularly applicable to the expression for the likelihood ratio given in (14.80). A Monte Carlo implementation of this formula is

$$\Lambda(\mathbf{g}) \approx \frac{1}{N_s} \sum_{n=1}^{N_s} \frac{\text{pr}(\mathbf{g}|H_2, \mathbf{b}_n)}{\text{pr}(\mathbf{g}|H_1, \mathbf{b}_n)}, \quad (14.87)$$

where the samples \mathbf{b}_n are drawn from the posterior $\text{pr}(\mathbf{b}|\mathbf{g}, H_1)$.

To sample from the posterior, we can use a Metropolis-Hastings algorithm, which we shall discuss in more detail in Sec. 15.4.8. As applied to the present problem, the basic idea is to generate a sequence of samples of the background \mathbf{b} in such a way that the samples are drawn from some target density $\pi(\mathbf{b})$ such as the posterior $\text{pr}(\mathbf{b}|\mathbf{g})$. If the current background in the sequence is $\mathbf{b}^{(k)}$, a new trial background \mathbf{b}' is generated from a proposal density $q(\mathbf{b}'|\mathbf{b}^{(k)})$, which can depend on the current state. The probability of accepting this proposed change is [*cf.* (15.328)]

$$\text{Pr}(acc) = \min \left\{ 1, \frac{\pi(\mathbf{b}') q(\mathbf{b}^{(k)}|\mathbf{b}')}{\pi(\mathbf{b}^{(k)}) q(\mathbf{b}'|\mathbf{b}^{(k)})} \right\}. \quad (14.88)$$

If the change is accepted, we set $\mathbf{b}^{(k+1)} = \mathbf{b}'$; otherwise $\mathbf{b}^{(k+1)} = \mathbf{b}^{(k)}$. By a detailed-balance argument (see Sec. 15.4.8), it can be shown that the equilibrium distribution is indeed $\pi(\mathbf{b})$. Note that only ratios of target densities are required; if $\pi(\mathbf{b})$ is the posterior, then we can write it as $\text{pr}(\mathbf{b}|\mathbf{g}) \propto \text{pr}(\mathbf{g}|\mathbf{b}) \text{pr}(\mathbf{b})$. The constant

of proportionality cancels out in (14.88), and we do not need to know the normalization of the posterior. We do, however, need to know the ratios $\text{pr}(\mathbf{b}')/\text{pr}(\mathbf{b}^{(k)})$.

Kupinski *et al.* (2003b) showed how this approach could be applied to likelihood-ratio calculations with a lumpy background model. Two types of perturbations to the background were allowed: changes in the location of a particular lump and changes in the number of lumps. This procedure was used to compare three rather stylized pinhole imaging systems in terms of ideal-observer AUC for an SKE task. By running the Markov chain multiple times, the variance in the estimate of the AUC was estimated. In subsequent work, Park *et al.* (2003) extended this method to random signals.

Channelized ideal observer We have mentioned low-dimensional representations of object statistics, but we can also consider dimensionality reduction in data space as a way of facilitating ideal-observer studies. Though dimensionality reduction would also be called feature extraction in pattern recognition, we have several advantages in assessment of image quality that we do not have in pattern recognition. As we discussed in the context of the channelized Hotelling observer in Sec. 14.3.2, we can consider SKE tasks where all details of the signal are known, we can construct backgrounds with known statistical properties, and we can simulate noise-free samples with these statistics.

Armed with this information, we can construct so-called efficient channels in such a way that the performance of the Hotelling observer operating on the channel outputs is a good approximation to that of the true Hotelling observer operating on the original data \mathbf{g} . For example, if we consider a rotationally symmetric signal in a known location in a statistically isotropic background, we can use rotationally symmetric channels defined by Laguerre-Gauss functions. Gallas and Barrett (2003) demonstrated that only 5–10 such channels were needed for good estimates of Hotelling-observer performance; we anticipate that a similar result will hold for ideal observers when we have a similar amount of prior information, but this hypothesis has not yet been confirmed.

Suppose we have a set of linear channels that we believe, based on our knowledge of the classification task, might be efficient with respect to the ideal observer. To check this possibility, we need to compute the likelihood ratio on the channel outputs for a training set of signal-present and signal-absent images and then create an ROC curve. Recent work by Subok Park and Matthew Kupinski offers some possible ways of computing the likelihood ratio. Though this work is unpublished at this writing, we sketch the main ideas here with the permission of the originators.

The approaches suggested by Park and Kupinski apply to situations where we have analytic expressions for the characteristic functions of the data \mathbf{g} but no PDFs, yet still want to compute a likelihood ratio (LR). The basic idea is to reduce the dimensionality of the data by use of a set of P channels and then attempt to compute the LR on the channel outputs rather than on \mathbf{g} itself.

As Park formulated the problem, the PD channel output vector is given by

$$\mathbf{v} = \mathbf{T}\mathbf{g} = \mathbf{T} \{ \mathcal{H}\mathbf{f} + \mathbf{n} \} , \quad (14.89)$$

and the characteristic function for \mathbf{v} under hypothesis j (in the case of Poisson noise) is given by an extension of (14.71) as

$$\psi_{\mathbf{v}|H_j}(\boldsymbol{\omega}) = \Psi_{\mathbf{f}|H_j} [\mathcal{H}^\dagger \mathbf{\Gamma} (\mathbf{T}^\dagger \boldsymbol{\omega})] , \quad (14.90)$$

where $\boldsymbol{\omega}$ is a $P \times 1$ vector. It is assumed that P is relatively small and that $\psi_{\mathbf{v}|H_j}(\boldsymbol{\omega})$ can be computed analytically. The likelihood ratio for a given \mathbf{v} is¹²

$$\Lambda(\mathbf{v}) = \frac{\int d^P \boldsymbol{\omega} \psi_{\mathbf{v}|H_2}(\boldsymbol{\omega}) \exp(2\pi i \boldsymbol{\omega}^\dagger \mathbf{v})}{\int d^P \boldsymbol{\omega} \psi_{\mathbf{v}|H_1}(\boldsymbol{\omega}) \exp(2\pi i \boldsymbol{\omega}^\dagger \mathbf{v})}. \quad (14.91)$$

Since P is small, Park proposed doing these integrals as FFTs. Kupinski refined the idea by suggesting Monte Carlo integration with importance sampling:

$$\begin{aligned} \int d^P \boldsymbol{\omega} \psi_{\mathbf{v}|H_j}(\boldsymbol{\omega}) \exp(2\pi i \boldsymbol{\omega}^\dagger \mathbf{v}) &= \int d^P \boldsymbol{\omega} \frac{\text{pr}(\boldsymbol{\omega})}{\text{pr}(\boldsymbol{\omega})} \psi_{\mathbf{v}|H_j}(\boldsymbol{\omega}) \exp(2\pi i \boldsymbol{\omega}^\dagger \mathbf{v}) \\ &\approx \frac{1}{N} \sum_{n=1}^N \frac{\psi_{\mathbf{v}|H_j}(\boldsymbol{\omega}_n) \exp(2\pi i \boldsymbol{\omega}_n^\dagger \mathbf{v})}{\text{pr}(\boldsymbol{\omega}_n)}, \end{aligned} \quad (14.92)$$

where the samples $\boldsymbol{\omega}_n$ are drawn from $\text{pr}(\boldsymbol{\omega})$. Kupinski also suggested using a few sample images to determine the mean and covariance of \mathbf{v} and then constructing a *PD* Gaussian with these estimated parameters to use as $\text{pr}(\boldsymbol{\omega})$.

Much further work is needed to validate this approach and explore possible choices for the channels, but if efficient linear channels in the ideal-observer sense exist, it opens up many new avenues for evaluating imaging systems with the ideal observer and classification tasks.

Nonlinear features Several nonlinear approaches to dimensionality reduction have been suggested by Hongbin Zhang. Zhang *et al.* (2001a) discusses features derived from the ideal observer and based on $\Lambda_{\text{BKE}}(\mathbf{g}, \mathbf{b})$ as defined in (14.81). Rather than attempt to average this expression over the posterior on the backgrounds, as required by (14.80), Zhang reasoned that a useful set of features for an SKE classification task could be defined as

$$\theta_p = \Lambda_{\text{BKE}}(\mathbf{g}, \hat{\mathbf{b}}_p), \quad (p = 1, \dots, P), \quad (14.93)$$

where $\hat{\mathbf{b}}_p$ is some estimate of the background at the known signal location. Specifically, he argued that the background was likely to be slowly varying compared to a small signal, so he suggested that $\hat{\mathbf{b}}_p$ be taken as a smoothed version of \mathbf{g} , with different p corresponding to different widths of the smoothing filter. The resulting values of θ_p would not immediately be the ideal-observer discriminant function, but Zhang suggested that an artificial neural network might find a good approximation to the likelihood ratio in the *PD* space.

In related work, Zhang also suggested using a set of wavelets centered on the known signal location, followed by a nonlinear point transformation on each wavelet coefficient (Zhang *et al.*, 2001b). He suggested an iterative algorithm to train the nonlinear transformation so that the outputs would follow a *PD* multivariate normal law. Then, when a new image is passed through the same transformation, the likelihood ratio can readily be calculated (see Sec. 13.2.8).

¹²Even though the channels are linear, this likelihood ratio will usually be a nonlinear functional of the channelized data \mathbf{v} ; it should not be confused with the AUC-optimal linear observer introduced in Sec. 13.2.12.

Checking the results We have sketched a number of approximate methods for estimating AUC for the ideal observer. How do we know if the results are correct? That is, how can we estimate the bias and variance of an estimate of ideal-observer AUC?

Variance in the estimate comes from two sources. First, as with any observer study, there is a variance arising from the random selection of images, or *cases* in medical parlance. Second, whenever the likelihood ratio is evaluated by using Monte Carlo or Markov-chain Monte Carlo methods to average over backgrounds, there is a variance associated with the random selection of backgrounds. This kind of variance is analogous to internal noise in the human observer; if the Monte Carlo calculation is repeated with the same image but a different random-number seed, it will not return the same value for the likelihood ratio.

Both kinds of variance can be estimated in simulation studies just by repeating the study many times, with different sets of images or with the same images but different random-number seeds. Alternatively, variance can be analyzed with MRMC methods as discussed in Sec. 14.2.4 or by using resampling methods as discussed in Sec. 14.3.2.

Bias is much more difficult to assess since we do not know what systematic errors we might be making in the likelihood-ratio calculation. To study the bias, Clarkson *et al.* (2003) proposed a set of consistency checks that must be satisfied in an ROC study if the test statistic is indeed a likelihood ratio. For example, we know from (13.85) that

$$\frac{\text{pr}(\Lambda|H_2)}{\text{pr}(\Lambda|H_1)} = \Lambda, \quad (14.94)$$

and in fact this relation holds if and only if Λ is a likelihood ratio (Clarkson and Barrett, 2000). It follows from (14.94) that

$$2(1 - \text{AUC}_\Lambda) = \int_0^\infty d\Lambda_t [\text{FPF}(\Lambda_t)]^2, \quad (14.95)$$

where $\text{FPF}(\Lambda_t)$ is the false-positive fraction for threshold Λ_t . Again, this relation holds if and only if Λ is a likelihood ratio (Clarkson *et al.*, 2003).

Other useful relations are derived from moment-generating functions and from the likelihood-generating function. The moment-generating function for the log-likelihood ratio λ under hypothesis H_j is defined by (C.56) as

$$M_j(\beta) \equiv \langle \exp(\beta\lambda) \rangle_{\mathbf{g}|H_j} = \langle \Lambda^\beta \rangle_{\mathbf{g}|H_j}. \quad (14.96)$$

From (13.79) we know that $M_j(\beta)$, must satisfy

$$M_1(\beta + 1) = M_2(\beta), \quad (14.97)$$

from which it follows that $M_1(1) = 1$. Moreover, a plot of $M_1(\beta)$ vs. β must be concave upward and pass through the points (0,1) and (1,1) as in Fig. 13.9. Once again, these properties are unique to the ideal observer.

Finally, a number of investigators have derived inequalities relating AUC to the likelihood-generating function (Clarkson, 2002; Clarkson and Barrett, 2000; Shapiro, 1999; Burnashev, 1998).

One example is

$$\frac{1}{2}G(0) \leq -\ln[2(1 - \text{AUC}_\Lambda)] \leq \frac{1}{2}G(0) + \sqrt{G(0) - \frac{1}{8}G''(0)}, \quad (14.98)$$

where $G(\beta)$ is the likelihood-generating function and primes denote derivatives.

If we have a set of simulated or real sample images and a way of estimating the likelihood ratio for each, we can check the validity of these relationships. For example, we can use no-signal images to estimate $M_1(\beta)$ directly from its definition (14.96) and see if it indeed passes through $(1, 1)$. Similar numerical methods can be devised for each of the relations that must be satisfied for the ideal observer.

If the relations are not verified, we must look for some error in our calculation of the likelihood ratio. If they are satisfied, we can have confidence that the test statistic we are calculating is *some* likelihood ratio, though not necessarily the likelihood ratio we think we are calculating, namely the one applicable to the image data. Clarkson *et al.* (2003) admit the possibility that the algorithm is finding a good estimate of some other likelihood ratio, but say they have a “natural tendency to regard (that) possibility as unlikely.”

One case where it is quite likely, however, is when linear or nonlinear features have been extracted from the original image data for dimensionality reduction. Then the Markov chain or other algorithm applied to the features may indeed give a good estimate of the likelihood ratio on the features, and all of the consistency checks mentioned above will be passed, but there is no guarantee that this likelihood ratio will give the same performance as one calculated on the original image data; the consistency checks do not ensure that the features preserve the information content of the images.

14.3.4 Estimation tasks

Compared to the large literature on model observers for detection and classification tasks in image-quality assessment, much less attention has been given to computational methods for estimation tasks, and there is much less agreement about what one should be computing in the first place. Of course, there is a huge body of work on estimation of pixel values in image processing and reconstruction, but we have argued in Sec. 13.3.2 that there is no meaningful way of relating accuracy of the pixel values to image quality. We shall discuss image reconstruction further in the next chapter, but for now we concentrate on estimation problems other than reconstruction.

Thus, by “estimation task” we mean estimation of one or a few parameters characteristic of the object being imaged and (unlike pixel values) of direct relevance to the purpose for which the image was obtained. Our goal here is to survey some of the computational methods that can be used for assessment of performance on such tasks.

Since the parameter being estimated is determined by the object being imaged, we write it as $\Theta(\mathbf{f})$. Boldface is used since the parameter will often be a vector, though almost always a low-dimensional one; when we intend a scalar parameter, we shall denote it as $\Theta(\mathbf{f})$. Upper case is used for $\Theta(\mathbf{f})$ since we use θ for several other things, including expansion coefficients (*e.g.*, pixel coefficients) in approximate object representations like (7.27), and that is definitely not what we mean here.

We emphasize here that we are viewing the parameters to be estimated as characteristics of the object. This is in contrast to the view of Sec. 13.3 where we were concerned with parameters characterizing the probability density function of the data. The relationship between the two viewpoints is subtle, yet critical for

assessing image quality on the basis of estimation tasks; we shall return to it at several points below.

Dichotomies Two useful dichotomies for the parameters are linear vs. nonlinear and estimable vs. nonestimable. The imaging systems that deliver the data from which the estimates are derived can also be categorized as linear or nonlinear. The estimators themselves can be linear or nonlinear functionals of the data, and they can be either biased or unbiased.

We encountered linear parameters in Sec. 7.1.4 when we discussed moment errors. In brief, a linear parameter is a linear functional of the object. If the components of $\Theta(\mathbf{f})$ are derived linearly from the object, we know from (7.33) that they can be written as

$$\Theta_n(\mathbf{f}) = \int_{-\infty}^{\infty} d^a r \chi_n^*(\mathbf{r}) f(\mathbf{r}) = \chi_n^\dagger \mathbf{f}. \quad (14.99)$$

Equations of this form will be used in Chap. 15 for discussing image reconstruction, but here we should think of the components Θ_n merely as weighted integrals of the object. If the weighting function $\chi_n(\mathbf{r})$ is constant over some spatial region, we refer to $\Theta_n(\mathbf{f})$ as a region-of-interest integral, and its estimate $\hat{\Theta}_n(\mathbf{g})$ as a region-of-interest estimator. Of course, the estimate depends on the data \mathbf{g} while the parameter itself depends on \mathbf{f} but not on \mathbf{g} .

An important class of nonlinear parameters occurs in *mensuration tasks*, where the goal is to measure some physical dimension of a portion of the object. Examples include the area of an agricultural field in aerial photography, volume of the left ventricle in cardiology, and distance to a target in radar.

As we saw in Sec. 13.3.1, a parameter is said to be *estimable* or *identifiable* with respect to some data set if there is an estimator of it that is unbiased for all true values of the parameter. In terms of the likelihood $\text{pr}(\mathbf{g}|\Theta)$, a parameter is estimable if different values of the parameter lead to different likelihoods.

The imaging system that acquires the data \mathbf{g} may be linear or nonlinear as defined in Chaps. 1 and 7. The distinction rests on the form of the *mean* data; the system is linear if $\bar{\mathbf{g}}$ is a linear functional of \mathbf{f} . We denote a general linear system by the operator \mathcal{H} , so $\bar{\mathbf{g}} = \mathcal{H}\mathbf{f}$.

For a linear system, we can be more precise about estimability, because in that case we can divide object space \mathbb{U} into subspaces called measurement space and null space, and any object can be uniquely decomposed as

$$\mathbf{f} = \mathbf{f}_{meas} + \mathbf{f}_{null}. \quad (14.100)$$

We know from the discussion in Sec. 14.3.3 that the probability density function on the data in most cases is fully determined by the mean data, so for a linear system we have

$$\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}(\mathbf{g}|\bar{\mathbf{g}}(\mathbf{f})) = \text{pr}(\mathbf{g}|\mathcal{H}\mathbf{f}) = \text{pr}(\mathbf{g}|\mathbf{f}_{meas}). \quad (14.101)$$

A general definition of estimability in this case is that $\Theta(\mathbf{f})$ is estimable if and only if $\Theta(\mathbf{f}) = \Theta(\mathbf{f}_{meas})$ for all \mathbf{f} . If this condition is met, then a change in \mathbf{f}_{meas} leads to a different $\Theta(\mathbf{f})$ and a different likelihood $\text{pr}(\mathbf{g}|\Theta)$. Another definition of estimability is that $\Theta(\mathbf{f})$ is estimable if and only if $\text{pr}(\mathbf{g}|\Theta_1) = \text{pr}(\mathbf{g}|\Theta_2)$ implies that $\Theta_1 = \Theta_2$.

We can go a step further for a linear parameter. We can decompose the templates $\chi_n(\mathbf{r})$ into measurement and null components, and the n^{th} component of the parameter vector can be written as

$$\Theta_n(\mathbf{f}) = \chi_{n,meas}^\dagger \mathbf{f}_{meas} + \chi_{n,null}^\dagger \mathbf{f}_{null}. \quad (14.102)$$

Then $\Theta(\mathbf{f}) = \Theta(\mathbf{f}_{meas})$ for all \mathbf{f} if and only if $\chi_{n,null} = 0$ for all n . Otherwise a change in \mathbf{f}_{null} would give a different value of the parameter but the same mean data and hence the same likelihood. Note that it is not necessary that the system have no null space, just that the templates have no components in that space. Since null components tend to involve high spatial frequencies, linear parameters derived from large, blobby templates are more likely to be estimable than ones derived from small or highly structured templates. In particular, as we shall discuss in more detail in the next chapter, integrals of the object over small pixels are almost never estimable.

The final dichotomies involve the estimator itself, which can be linear or nonlinear and biased or unbiased. Linear estimators were discussed briefly in Sec. 13.3, but considerable emphasis was placed there on maximum-likelihood (ML) estimators. Like the likelihood ratio used in ideal-observer classification problems, ML estimators are usually nonlinear functionals of the data. An exception in both cases occurs with Gaussian data. For Gaussian data with equal covariances under the two hypotheses, the ideal observer computes a test statistic (the log-likelihood ratio) that is linear in the data, and for Gaussian data and any linear parameter, the ML estimator is also linear in the data. In most interesting cases, however, neither the log-likelihood ratio nor the ML estimator is linear.

If the parameter is estimable, there exists an unbiased estimator, but we may not know it, or we may choose not to use it; Bayesian estimation, for example, deliberately introduces a bias toward the prior. Thus we must distinguish biased from unbiased estimators even for estimable parameters.

Performance metrics: MSE and EMSE From the discussion in Sec. 13.3.1, a natural choice for a figure of merit is the mean-square error or MSE, defined for a scalar parameter in (13.280) and for a vector in (13.286) or (13.287).

For estimable parameters, MSE has much to recommend it. It can be computed for any chosen object and estimator, it takes into account both bias and variance, and it is a scalar that can be used for system optimization. One drawback is that MSE is defined by averaging the error with respect to the density $\text{pr}(\mathbf{g}|\Theta)$, so it will depend on the true value of Θ in general. One solution to this problem is simply to plot $\text{MSE}(\Theta)$ vs. Θ , much in the same manner that one can plot SKE detectability as a function of signal location or other parameters [see (13.209)].

With nonestimable parameters, MSE is more problematical. Since null components of the object influence $\Theta(\mathbf{f})$ but not $\bar{\mathbf{g}}(\mathbf{f})$ in that case, many different objects can give the same mean data but different true values of Θ , and it is quite arbitrary which true value one associates with a given data set. Indeed, if there are no other constraints, it is usually possible to find an object so that *any* estimator of a nonestimable parameter is unbiased; whether that object is one that would ever be encountered is another matter. As we shall see in Sec. 15.1.4, positivity constraints limit the magnitude of null functions and alleviate issues of estimability, but they don't eliminate them.

Perhaps the best solution to defining a scalar figure of merit for estimates of nonestimable parameters¹³ is to use the *ensemble mean-square error* or *EMSE* defined in (13.281) for scalars or (13.288) for vectors. The vector definition can be rewritten for our purposes as

$$\text{EMSE} = \left\langle \left\langle \|\hat{\Theta} - \Theta\|^2 \right\rangle_{\mathbf{g}|\Theta} \right\rangle_{\Theta} = \left\langle \left\langle \|\hat{\Theta} - \Theta(\mathbf{f})\|^2 \right\rangle_{\mathbf{g}|\mathbf{f}} \right\rangle_{\mathbf{f}}. \quad (14.103)$$

In the last form, the average is over some ensemble of objects. For any particular object in the ensemble, a bias and hence an MSE can be defined, and the ensemble-average MSE is the quadratic error norm specific to the imaging system, the estimator *and* the chosen ensemble. Note that the use of an average over objects in the figure of merit does not imply that this same information was used in the estimator. The quantity $\hat{\Theta}(\mathbf{g})$ might have been obtained by Bayesian methods, but it might also be an ML estimate or some other one that eschews prior information.

The question that remains is what ensemble to use in the averaging. The Bayesian answer would be to average over the prior, and indeed to use that same prior in the estimation process in order to minimize the EMSE. To a pragmatist, there are several difficulties with this approach. First, in practice we might not have enough verifiable prior information (as opposed to subjective or noninformative priors) that we would be willing to build it into the inference process. In practice, the only computationally tractable priors for Bayesian estimation might be some noninformative prior like entropy or simple analytic expressions such as conjugate priors¹⁴ or the regularizing functions to be discussed in Sec. 15.3.3. Even if we were willing to use one of these analytic priors to do the estimation, there is no reason to think that samples drawn from it would bear any relation to the true distribution of $\Theta(\mathbf{f})$ or \mathbf{f} , so it would be hard to have any confidence (belief) in the MSE computed from that prior.

What pragmatists can do well, however, is to perform realistic simulations (*i.e.*, ones consistent with a belief system honed in the field, laboratory or clinic), and these simulations can be used to compute sample approximations to the EMSE defined in (14.103). Specifically, if a set of sample objects $\{\mathbf{f}_n, n = 1, \dots, N_s\}$ is generated, then we can approximate the EMSE by

$$\widehat{\text{EMSE}} = \frac{1}{N_s} \sum_{n=1}^{N_s} \left\langle \|\hat{\Theta} - \Theta(\mathbf{f}_n)\|^2 \right\rangle_{\mathbf{g}|\mathbf{f}_n}. \quad (14.104)$$

The remaining average can be performed either analytically or by additional Monte Carlo simulations of \mathbf{g} for a fixed \mathbf{f}_n .

Why ML? And how? As we saw in Secs. 13.3.4–13.3.6, ML estimators have many desirable properties. We know that ML estimators are efficient (*i.e.*, they achieve

¹³In spite of the terminology, nonestimable parameters can indeed be estimated. An estimate is merely a number associated with a data set. To be perverse, one could associate the number 3 with *any* data set. Then an estimate would be given for all \mathbf{g} no matter whether the parameter was estimable, and in fact the variance of the estimate would be zero. The bias would, however, be completely meaningless.

¹⁴A conjugate prior is one chosen purely for mathematical convenience, to make the posterior have the same mathematical form as the prior. Unless one believes that nature is constructed for the convenience of statisticians, there is no reason to ascribe any degree of belief to conjugate priors.

the minimum possible variance as given by the Cramér-Rao bound) if any efficient estimator exists. Also, ML estimators are asymptotically efficient, asymptotically unbiased and asymptotically normally distributed. In the statistics literature, “asymptotic” refers to accumulating N i.i.d. data sets and letting $N \rightarrow \infty$, but it can have a broader meaning. All of the nice asymptotic properties of ML estimators apply if the variance of additive Gaussian noise goes to zero or if the number of counts in a photon-limited measurement gets large. Thus there is considerable motivation for using ML estimators, especially if we can get into one of these asymptotic regimes.

It is not obvious how we can perform ML estimation in general, since we seldom know the likelihood $\text{pr}(\mathbf{g}|\Theta)$ directly. Instead, as discussed in Sec. 14.3.3, we usually know the conditional density $\text{pr}(\mathbf{g}|\mathbf{f})$ or $\text{pr}[\mathbf{g}|\bar{\mathbf{g}}(\mathbf{f})]$; for direct imaging and Gaussian and Poisson noise, they are given by (14.67) and (14.68), respectively.

The general relation between the conditional densities on the data and the likelihood can be expressed either as an integral over the object space or an integral over data space:

$$\text{pr}(\mathbf{g}|\Theta) = \int d\mathbf{f} \text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}|\Theta) = \int d^M \bar{\mathbf{g}} \text{pr}(\mathbf{g}|\bar{\mathbf{g}}) \text{pr}(\bar{\mathbf{g}}|\Theta). \quad (14.105)$$

These forms are equivalent whenever the conditional probability on the data is determined solely by its mean, which is the case with our usual Gaussian or Poisson noise models, with or without post-acquisition data processing (see Sec. 14.3.3).

One situation where we can easily go from these conditional densities to the likelihood is in the estimation counterpart of the SKE/BKE problem. Suppose we decompose the object into background and signal as in (14.77), and we assume that the signal is known to be present but that it is characterized by some unknown parameter vector Θ . For a linear system, we can write the mean data for background and signal, respectively, as

$$\mathbf{b} \equiv \mathcal{H}\mathbf{f}_b, \quad \mathbf{s}(\Theta) \equiv \mathcal{H}\mathbf{f}_s(\Theta). \quad (14.106)$$

For example, in medical imaging $\mathbf{f}_s(\Theta)$ might describe a spherical tumor with unknown center coordinates, gray level and diameter. In military reconnaissance, it might refer to a tank with unknown coordinates and heading.

If the background is known exactly and the signal is known except for these parameters, then

$$\text{pr}(\bar{\mathbf{g}}|\Theta) = \delta[\bar{\mathbf{g}} - \mathbf{b} - \mathbf{s}(\Theta)], \quad (14.107)$$

and the likelihood becomes

$$\text{pr}(\mathbf{g}|\Theta) = \text{pr}(\mathbf{g}|\bar{\mathbf{g}}) \Big|_{\bar{\mathbf{g}}=\mathbf{b}+\mathbf{s}(\Theta)}. \quad (14.108)$$

Explicit expressions for the likelihood ratio in the case of direct imaging can be found by substituting $\bar{\mathbf{g}} = \mathbf{b} + \mathbf{s}(\Theta)$ into (14.67) or (14.68). Since the number of parameters is small, there is no difficulty in maximizing the likelihood numerically.

Random backgrounds Just as in the signal-detection problem, the BKE assumption in estimation is oversimplified and can be misleading. It is much more realistic to consider random, cluttered backgrounds when we want to estimate signal parameters. We can regard the background components as a set of nuisance parameters,

in the sense that they do not enter into the overall cost or Bayes risk associated with the estimation problem. As we learned in Sec. 13.3.8, the optimal strategy for this problem is to marginalize over the nuisance parameters, at least if we have a believable way of generating or approximating the prior density or drawing realistic samples. The likelihood is then given by

$$\text{pr}(\mathbf{g}|\Theta) = \int d^M b \text{pr}(\mathbf{g}|\Theta, \mathbf{b}) \text{pr}(\mathbf{b}), \quad (14.109)$$

where $\text{pr}(\mathbf{g}|\Theta, \mathbf{b})$ is to be computed from (14.108). This form is quite similar to the likelihood expressions encountered in Sec. 14.3.3 [*cf.* (14.84)–(14.86)], and similar Monte Carlo and Markov-chain Monte Carlo methods can be devised to evaluate it (Kupinski *et al.*, 2003c). As in the detection case, direct sampling of backgrounds from $\text{pr}(\mathbf{b})$ is unlikely to work well since a randomly chosen \mathbf{b} will probably lead to a vanishingly small $\text{pr}(\mathbf{g}|\Theta, \mathbf{b})$, but importance sampling can be used as in (14.85). If an analytic form is known for $\text{pr}(\mathbf{b})$, samples \mathbf{b}_n can also be drawn from the BKE likelihood $\text{pr}(\mathbf{g}|\Theta, \mathbf{b})$, renormalized as a density on \mathbf{b} , and the likelihood estimate is proportional to $\frac{1}{N} \sum_{n=1}^N \text{pr}(\mathbf{b}_n)$.

For a detailed survey of Monte Carlo methods in ML estimation, see Geyer and Thompson (1992).

PDFs of the estimates Monte Carlo methods can also be used to study the distribution of the estimates themselves. If we simulate multiple data sets with the same true value, say $\Theta = \Theta_0$, and compute $\hat{\Theta}$ for each, then we have, in effect, drawn samples from $\text{pr}(\hat{\Theta}|\Theta_0)$. From these samples we can estimate the bias, variance, MSE and any other figure of merit we might devise.

In many problems, it is also possible to compute $\text{pr}(\hat{\Theta}|\Theta_0)$ directly. Building on earlier work by Müller *et al.* (1990, 1995), Abbey *et al.* (1998) developed a method for approximating the density of maximum-likelihood and MAP estimates under a Gaussian noise model. They showed that the method was directly applicable to estimating parameters such as tumor volume from medical images, and they found that the predicted analytic PDFs were in good agreement with Monte Carlo simulation.

Rogala and Barrett (1997, 1998a, b, c) applied Abbey's method to a combination interferometer/ellipsometer where the goal was to estimate surface height and the real and imaginary parts of the refractive index at all points on a metal surface. Again, the analytic results were confirmed by Monte Carlo simulation.

Cramér-Rao bounds Rather than using the performance of a particular estimator as a figure of merit, it is also possible to use various performance bounds that might be easier to compute. In particular, the Cramér-Rao bound, introduced in Sec. 13.3.5, sets a lower limit to the variance of an unbiased estimator. For an unbiased estimator, the Cramér-Rao bound is given in (13.371) or (13.372), and for a biased estimator, the appropriate forms are (13.376) and (13.377). Both the biased and unbiased form are derived from the Fisher information matrix.

Kupinski *et al.* (2003c) developed MCMC methods to estimate the Fisher information matrix for the problem of estimating the position, width and amplitude of a Gaussian signal in a lumpy background. They did not assume that the signal was always present, so their treatment applied to a hybrid detection/estimation

problem, but the figure of merit was based only on the estimation performance, marginalized over the probability of detection.

Approaches based on the Cramér-Rao bound are attractive, but they have their limitations. For one thing, if more than one parameter is to be estimated, it is not clear how to combine the individual bounds into a single scalar figure of merit that can be used for system optimization. Second, in many problems no efficient estimator exists, and it is not clear in practice how far actual variance will be from the bound. Similarly, it is often the case that no unbiased estimator exists, so use of the unbiased form of the bound can be misleading; the biased form (13.376) is less useful since it requires knowledge of the bias gradient (derivative of the bias with respect to the parameter). Considerable work has been done at the University of Michigan on variance bounds in which the norm of the bias gradient is constrained, though mostly in the context of estimation of pixel values (Gorman and Hero, 1990; Hero and Fessler, 1994; Hero *et al.*, 1996).

14.4 SOURCES OF IMAGES

Simulated images play an important role in the practical assessment of image quality. They can be used to get a subjective impression of the effects of changing parameters of the imaging system, and they can serve as input for objective studies with either model observers or humans. If the simulations are realistic, they may even be preferable to real images since there is no question about the true state of the object. Most importantly, simulations can be used to assess imaging systems that do not exist, so they are essential to any program of systematic optimization.

Realistic simulations involve computer implementations of the object, the image-formation process and the detector, and they must accurately reflect both the deterministic and stochastic aspects of each of these components. The art of good simulation is thus necessarily specific to both the imaging system and the use to which the simulation will be put. Nevertheless, it is our goal in this section to give some general guidelines on the simulation process, with reference to specific systems only as examples. We shall refer to the methods for representing deterministic and random objects given in Chaps. 7 and 8, along with material on the simulation of image formation provided in Chap. 10.

In Secs. 14.4.1 and 14.4.2 we survey methods for deterministic and stochastic simulation of objects, and in Secs. 14.4.3 and 14.4.4 we treat deterministic and stochastic simulation of image formation. Finally, in Sec. 14.4.5 we discuss the gold-standard problem that arises when using real images instead of simulated ones.

14.4.1 Deterministic simulation of objects

In Sec. 7.1 we emphasized that real objects are functions, but we also acknowledged that numerical computations require approximate discrete representations. In all fields of image science, there is considerable emphasis on linear representations, and we know from (7.27) that the general form of such a representation is

$$f_a(\mathbf{r}) = \sum_{n=1}^N \theta_n \phi_n(\mathbf{r}). \quad (14.110)$$

Thus object simulation involves two steps: choosing the expansion functions $\phi_n(\mathbf{r})$ and choosing the coefficients θ_n .

It is all but universal in simulation studies to choose the expansion functions as pixels or voxels, for two reasons. First, if we humans are simply inventing the simulated objects, it is easiest for us to think in terms of spatial variables. Pixels and voxels are discretizations of our natural visual domain, and it would be much harder for us to think in terms of, say, Fourier basis functions. Second, as we shall see below, we may also want to use images from some high-resolution imaging system as objects for another system of lower resolution. Since the first system is designed to present data to humans, it is likely to provide us with digital data in a pixel or voxel representation. Thus we have a ready-made discrete simulation if we stick with those expansion functions.

When the goal of the simulation is to evaluate imaging systems, it is not so much the simulated objects as the resulting simulated images that interest us. Our goal is to use the discrete representations of objects and systems to produce images that are as near as possible to those that would be obtained with actual continuous objects and continuous-to-discrete systems (see Sec. 7.4.3). That means that we should take N in (14.110) as large as possible. The only cost to increasing the number of pixels and voxels, in most cases, is increased computational time, and that commodity continues to plummet in price. In particular, we do not need to worry about whether the resulting system matrix is highly non-square and hence leads to an underdetermined inverse problem. In this section we are concerned only with accurate simulation of the forward problem; issues associated with choice of representation in inverse problems are discussed in detail in the next chapter.

Geometric objects The easiest way to get started in object simulation is to use superpositions of simple geometric shapes (circles, squares, ellipses...). In a pixel representation, the coefficients θ_n are assumed to have the same value for all pixels within one elemental shape, but generally different values within different elements. If the number of pixels N is large, we need not worry too much about pixels that straddle the border between elements. By using a range of sizes for the elemental shapes, we can get a simulated object that has small structures to challenge the spatial resolution of a simulated imaging system and large uniform structures with which to study system uniformity, radiometric accuracy and noise properties.

Such seemingly naive simulated objects have proven particularly valuable in tomographic imaging. They are known as *mathematical phantoms* in that field, and some have been so durable that they are commonly referred to by the name(s) of the investigators who devised them. Thus we have the Shepp-Logan phantom (an arrangement of ellipses somewhat resembling a 2D cross-section of the human brain; Shepp and Logan, 1974) and the Defrise phantom (a 3D set of thin parallel disks meant to challenge certain cone-beam tomographic systems; Defrise and Clack, 1994).

Geometrical shapes can also be manipulated to mimic much more complicated objects. For example, Tsui *et al.* (1993) devised a 3D representation of the human torso that includes a static model of the heart, and Pretorius *et al.* (1997) extended the work to a beating heart. This so-called MCAT (mathematical cardiac torso) phantom has become a *de facto* standard in simulation of nuclear-medicine cardiac studies.

The mathematical theory that treats efficient ways of representing and manipulating geometrical forms within the computer is called *computational geometry*. Two useful textbooks in this emerging field are O'Rourke (1998) at an undergraduate level and the more comprehensive graduate-level text by Preparata and Shamos (1985).

Digitized real objects Useful though these geometric objects may be, they do not capture the complexity of object variation from pixel to pixel within a given geometric element, and for this reason they may not give accurate results when used for the objective assessment of image quality. One way around this difficulty is stochastic simulation, discussed in Sec. 14.4.2, but another approach is use of real image data.

As mentioned above, we might have access to high-resolution images of objects that we also wish to image with a lower-resolution system. Often the high-resolution system will measure fundamentally different parameters of the object, or it might be that the higher-resolution system is more expensive or more invasive than the system under development. Under these circumstances, the higher-resolution system might not be one we would use in practice, but we can nevertheless use the images it produces to guide the development of the new system.

An example of considerable interest for medical imaging is the Visible Human Project. In this project a human cadaver was imaged with computed tomography at high spatial resolution and high (but irrelevant) radiation dose. High-resolution magnetic resonance imaging was also performed, and then literal tomograms¹⁵ were obtained by slicing the cadaver into thin layers and photographing each.

The CT images obtained in this project have higher resolution and lower noise than any obtainable with living patients, so they can serve directly as objects for simulation studies of new CT systems. The MRI images are less useful for this purpose since the object in MRI is specified in a complicated way by three distinct scalar fields, the spin density and two relaxation times (see Prologue and Sec. 7.1.1). Any particular image represents some nonlinear combination of these three components and cannot be used to simulate objects for imaging systems that respond to other combinations. The optical images are useful mainly because they accurately delineate borders of the organs, so they provide an alternative to the stylized geometric shapes discussed above. The actual gray levels (or colors) do not, however, correspond to anything that would be seen with any real medical imaging system.

For many further details on the Visible Human images and their applications, the reader may consult the proceedings of conferences that have been held on the project (Banvard, 2000).

Similarly, Zubal *et al.* (1994) at Yale have developed torso and brain phantoms by starting with high-resolution CT images and painstakingly labelling different anatomical regions by hand. To simulate objects in lower-resolution nuclear-medicine simulations, these labelled regions can be assigned different gray levels, corresponding to uptakes of some radiopharmaceutical of interest.

Computer graphics Perhaps the greatest impetus to progress in image simulation today is computer games and the closely related field of virtual reality. Since

¹⁵Greek *τομοσ* = slice.

the everyday reality we see around us consists mainly of surface reflections from opaque objects, virtual reality and computer graphics are particularly useful for simulating such objects. Useful books in this area include works by Neelamkavil (1987), Anand (1993), Sillion and Puech (1994), Glassner (1995) and Rogers (1998). Graphics-related journals and magazines include: IEEE Transactions on Visualization and Computer Graphics, IEEE Computer Graphics and Applications and IEEE Multimedia; ACM Transactions on Modeling and Computer Simulation and ACM Transactions on Graphics, and Computer Vision, Graphics and Image Processing (CVGIP).

14.4.2 Stochastic simulation of objects

In Sec. 8.4 we discussed a wide variety of statistical models for objects. Each of these models provides a PDF that at least partially describes the random variation in objects, and stochastic simulation of objects amounts to drawing sample functions (or vectors) from those PDFs. Often the first thing we need to simulate is the overall shape of the object or of key components in the object; see Chap. 8 for a brief discussion of the statistical description of shape. Then we need to add in a random texture.

Random textures Methods of generating samples of texture fields with specified statistics were discussed in Sec. 8.4.4, and the literature on computer graphics can provide additional approaches. A common approach in image simulation is to assume that the texture is stationary within the boundaries of a single geometric element of the simulated object.

How accurately the texture needs to be simulated depends critically on the purpose of the simulation. If the task used to assess image quality is detection of a low-contrast lesion in a medical image, then, as we have noted earlier in this chapter, the texture results from anatomical variations that may, in fact, constitute the main noise source limiting task performance, so accurate modeling is essential. On the other hand, if measurement noise is high or if the task is estimation or mensuration, then task performance might be relatively insensitive to fine details of the object structure.

We urge the reader to be skeptical of simulations that omit texture modeling, particularly if the goal of the simulations is to provide input for image reconstruction. As we shall see in the next chapter, any reconstruction algorithm involves a choice of how much fine detail to attempt to reconstruct. Often this choice is made on the basis of claimed prior information, and the most common such claim amounts to saying that the object contains little or no fine detail. At the extreme, it may be asserted that the object is piecewise constant within boundaries of regions such as organs. Of course, it is easily possible to simulate objects and hence tomographic data consistent with this assertion, but the simulations then provide essentially no information about how the algorithms would perform on tasks that are sensitive to fine details.

Random signals In signal-detection studies it is useful to think of the object as a superposition of signal and background (see Sec. 8.4.5), and the signal component might be particularly amenable to simulation. In medical imaging, for example, a common task is tumor detection, and it might suffice to model the tumor as a small

sphere or ellipsoid of low contrast. When the task is discrimination between types of tumors or between benign and malignant lesions, however, it may be necessary to include other features such as spicules (needle-like protrusions from the body of the tumor), but these too can be incorporated in realistic simulations.

Simulated signals may be superimposed on simulated or real backgrounds. As we saw in Sec. 8.4.5, the signal can sometimes be regarded as simply added to background, and in those cases we can maintain separate files of simulated signals and real or simulated backgrounds, adding them together in various combinations as needed. Moreover, when we are dealing with linear systems, we can choose to add the images rather than the objects (see Sec. 8.5.4). This makes it possible to add simulated signals to actual images of normal (signal-absent) objects as seen through real imaging systems. Since normal images are much easier to acquire and verify than abnormal ones, this approach can be very beneficial in avoiding the gold-standard problem.

14.4.3 Deterministic simulation of image formation

Linear systems Once we have a discrete object representation, it is generally straightforward to compute its mean image through a linear imaging system by matrix multiplication. The only real difficulty is in formulating the matrix, and that problem is specific to the imaging modality. We shall give an example of how to construct the matrix for emission computed tomography in Sec. 17.2.6.

We emphasize again, however, that it is important in simulation studies to sample the object finely, especially in image-reconstruction problems. If the reconstruction algorithm assumes that the object consists of voxels of a certain size, and the data are generated on precisely this same assumption, then a false consistency may result. When the same matrix is used in data simulation and reconstruction, and the resulting images are good in some sense, all that has been proved is that the matrix is nonsingular; no useful conclusions can be drawn about the true CD system or about real data. Simulation studies that use the same matrix for both a forward problem and its inverse problem should be regarded with strong suspicion.

Sparseness of the H matrix Though the \mathbf{H} matrix used in simulation may be huge, it is often very sparse, with most of its elements equal to or very near zero. In direct-imaging systems, for example, the point response function $h_m(\mathbf{r})$ will tend to be highly concentrated; for any chosen source point \mathbf{r} , only a small subset of the detector pixels will receive radiation. (Indeed, this is essentially a definition of direct imaging.) When such systems are represented by matrices, the same thing holds: for any chosen n , H_{mn} is nonzero for only a small subset of m . Put another way, each column of \mathbf{H} is mostly zero, no matter how many columns we choose to use. The zero elements need not be stored, and of course there is never any point in multiplying by zero.

Indirect-imaging systems may also result in sparse matrices. In tomography, for example, radiation is received from points along or near a thin pencil through the object (at least when scatter is neglected). Conversely, for any chosen object point and any projection direction, only a small subset of the detector elements receive radiation. In this case elements in one column of \mathbf{H} are indexed by both the detector index and the projection direction, but nevertheless only a small fraction

of the elements in each column are nonzero. For more discussion of this point in the context of emission computed tomography, see Sec. 17.2.6.

Shift-invariance Another structure that we might consider using is shift-invariance. As we have discussed in Sec. 7.2.3, it may be reasonable to describe certain CC systems with shift-invariant point spread functions. When the output of such a system is sampled with a regular detector array, and the object is represented by a regular grid of the same spacing, it is tempting to say that the system exhibits discrete shift-invariance and hence that the images are convolutions that can be computed efficiently with fast Fourier transforms or FFTs.

There are several problems with this approach. The first is that discrete convolutions (with N samples in 1D) are described by modulo- N arithmetic (see Sec. 3.6.2). The result is an entirely unphysical wrap-around such that images that disappear from one edge of the detector as the object point is shifted magically reappear on the other side. Various stratagems can be employed to minimize this effect, but their adequacy is seldom verified.

The second problem is that any real CC system must have some departures from strict shift-invariance. In a lens system with aberrations, for example, the form of the PSF varies with field angle. This problem is incompatible with any convolutional description. It can be minimized by restricting the object field and/or the image field, but then wrap-around effects may become more significant.

Finally, a great hazard of working with FFTs and discrete convolutions is that it entices the user to choose the number of samples in object space to be the same as the number of samples in image space. As we stressed above, accurate simulation of CD systems requires fine sampling of the object. The FFT approach to simulation requires sacrificing accuracy for speed; this tradeoff becomes increasingly difficult to justify as computers get faster, and it is especially questionable when only one or a few images are to be simulated.

These warnings do not imply that we should ignore approximate shift-invariance when constructing an \mathbf{H} matrix or performing simulation studies. If neighboring columns of \mathbf{H} are nearly equal but for a shift, we can take advantage of this structure and reduce the computation time needed to find the matrix and the memory needed to store it. For an example in the context of emission computed tomography, see Sec. 17.2.6.

Deterministic transport calculations In principle, the Boltzmann transport equation, discussed in detail in Secs. 10.3 and 10.4, allows us to compute the image of any object where the radiation can be considered particle-like, which for electromagnetic radiation means that interference and diffraction, polarization and quantum-mechanical effects such as squeezing can be neglected. To oversimplify, the domain of the Boltzmann equation is the same as that of geometric optics.

14.4.4 Stochastic simulation of image formation

Stochastic simulation was introduced in Sec. 10.4.5 as a broad class of methods in which some quantity is estimated by performing random experiments, either physically or in a computer. These methods can be applied to the generation of samples of noisy data for use in psychophysical experiments and model observer calculations.

Detectors and image noise So far we have discussed ways of computing or estimating the mean data $\{\bar{g}_m\}$, but for many purposes we need to simulate the actual noisy data $\{g_m\}$, so we must also be able to simulate the noise contributions $\{n_m\}$.

For simple noise processes, we can just call an appropriate random-number generator to generate a noisy image. For example, many detector arrays are dominated by electronic noise, which we know from the discussion in Chap. 12 to be usually well described by Gaussian probability laws. Moreover, we can often argue from physical grounds that the noise in different detector elements is statistically independent, so the noise can be simulated by calling an independent Gaussian random-number generator at each element. Similarly, if Poisson noise dominates, we can first calculate the mean number of counts at each element by deterministic methods and then call a Poisson random-number generator with this mean.

Some detectors generate excess noise as a result of a random amplification process (see Secs. 11.4), and the detector therefore introduces noise correlations. To accurately simulate a noisy image in this case, we must draw random vectors from a multivariate PDF, or we must simulate the amplification process itself.

In summary, for the results of an evaluation study to be valid, it is crucial that realistic object models and accurate models of the imaging system be employed. Particularly when the investigation involves an imaging system or a task for which model and human observer data have not been compared before, performance estimates based on simulated data sets and model observers should be verified using real data and human observers.

14.4.5 Gold standards

Conventional ROC analysis requires knowledge of the truth status of the images in order to score observer responses as correct or incorrect. Thus standard ROC methods are not directly applicable when the truth status of the images is unknown. The requirement that independent truth status be known can lead to case-selection bias that can favor one system over another.

Even when a method for establishing the truth status of the images exists, giving a so-called “gold standard,” the method is more often a bronze standard rather than gold. New modalities are often evaluated with an older technology as the gold standard, even though the new modality may allow for the detection of subtle objects missed when using images from the older device. In medical applications, biopsy proof is the gold standard, but even biopsy is not perfect. Biopsy needles can miss their mark, and pathologists have been shown to make mistakes as well. Pathologist is another name for a human observer performing a classification task, so the process should be amenable to objective evaluation based on task performance. But what would be the gold standard?

Given the need to keep score of the observer’s performance using a specified figure of merit, it is clear that simulations offer an added advantage—they solve the *ground truth* problem. For simulated images, the truth state of the objects are known because this information is in the hand of the investigator.

In this section we shall describe the effect of inaccurate gold standards on ROC methods and present approaches to the evaluation of imaging systems in the absence of ground truth. As we shall see, methods for the assessment of imaging systems in the absence of ground truth exist, but the uncertainty in the estimate of

the system's performance is much larger than what is achieved when ground truth is known.

Truth by expert panel One approach to the establishment of truth is the use of an expert panel of observers. This method raises a multitude of questions and concerns regarding the number of experts to be used, how they will be chosen, and how their responses will be combined to establish "truth." Revesz *et al.* (1983) showed that the ranking of 3 systems could be made to favor any one of the 3, depending on the way in which the expert opinions were used to determine truth.

Mixture-distribution analysis Mixture-distribution analysis is based on the assumption that experts are likely to be correct when they agree. Kundel and Polansky (1997) suggested the use of a mixture-distribution analysis as an alternative to ROC methods when ground truth is not available. The method is based on dichotomizing the images into groups on the basis of the extent of a set of observers' agreement on them. It is assumed that the image groups represent different levels of case difficulty; *i.e.*, lower agreement indicates harder cases while higher agreement indicates easy cases. The number of groups is arbitrary. Thus the underlying model is a mixture distribution with a user-defined number of groups. Given the observer's ratings, an expectation-maximization (EM) method can be used to estimate the proportion of images in each group and the probability of truth given a certain level of agreement. Having estimated the truth status, the reader ratings can be used to determine the ROC curve.

Kundel and Polansky (1997) have compared mixture-distribution analysis to the results of an ROC analysis, where the ROC method used a separate expert panel to determine truth. Both methods gave similar estimates for the percentage of correct diagnoses for the task of image interpretation in chest radiography. Kundel and Polansky (1998) have shown that the results are fairly robust to the number of groups used in the model. The method may be especially useful in the evaluation of CAD algorithms; Kundel *et al.* (2001) recently demonstrated the use of the mixture-distribution approach for the evaluation of CAD in mammography. Recent emphasis on lung cancer screening programs using high-resolution CT raises the spectre of a very large number of potential lesions in the images for each patient; biopsy proof is simply not viable. Mixture-distribution analysis may be useful for the assessment of adjunctive CAD algorithms for this application.

See Polansky (2000) for a tutorial on the mixture-distribution method and other agreement-based approaches.

ROC analysis without truth of diagnosis It is not possible to perform an ROC evaluation of a single imaging system in the absence of ground truth because the problem is underdetermined. However, if each object has associated with it ratings from images obtained on two or more modalities, Henkelman *et al.* (1990) demonstrated that an EM algorithm can be used to estimate the class prevalences and the model parameters of a mixture distribution for the underlying objects.

The EM model makes the assumption that there are two underlying distributions for the decision variables, one for each class, and the distributions are correlated by an unknown amount. The dimensionality of each distribution is equal to the number of modalities under test. The EM algorithm estimates the relative proportion of each distribution (the prevalences), the locations of the observer's thresholds

corresponding to each rating level along the decision axis for each modality, and the parameters specifying the distributions. For example, the use of a 5-point rating scale for 2 medical imaging modalities involves the estimation of 10 category boundaries, one disease prevalence and, in the case of a bivariate normal model for the distributions, the difference in means of the two distributions, their widths in two dimensions, and their correlations. Thus, given a sufficient number of images and observers, the estimation problem becomes tractable.

In a commentary on the Henkelman approach, Begg and Metz (1990) point out that the method breaks down if the imaging systems have low AUC (Henkelman *et al.* restricted their investigations to systems with an $AUC \geq 0.92$). Begg and Metz suggest that each system must have an AUC of 0.80 or better for this technique to be applicable.

The work of Henkelman *et al.* has been extended by Beiden *et al.* (2000b), who performed Monte Carlo simulations to determine the uncertainties in the EM estimates of AUC obtained in the absence of ground truth. These authors found that many more patients were required in the truth-unknown case to yield estimates of AUC with standard deviations of those determined in the truth-known case, for the particular choice of true underlying distributions they investigated.

More investigation is required to better understand the usefulness of the EM approach to the no-gold-standard problem in ROC analysis in order to better understand the impact of the forms of the underlying distributions, the number of samples, the number of observers, the model assumptions made in the EM algorithm, and so on. Henkelman *et al.* suggest that the estimation problem may become better conditioned as the number of imaging modalities increases. More research is required to investigate this issue as well. Nonimaging diagnostic tests, including pathology readings, might also be included as additional modalities along with one or more imaging tests in the EM procedure.

Evaluation of estimation performance without a gold standard The issue of ground truth arises also in evaluating imaging systems on the basis of estimation tasks. For example, cardiac ejection fraction (the fraction of the blood expelled on each beat) can be measured by many different methods, including SPECT, planar nuclear medicine, MRI, ultrasound, CT and biplanar projection x rays. Each of these methods has significant errors, and none is universally accepted (except by its practitioners) as the “gold standard.” When a new method is developed, it is customary (perhaps even mandatory) to publish a plot of ejection fractions obtained by the new method against ones obtained on the same patients with some older method. Ideally such plots would show a high correlation, with regression slopes near one and intercepts near zero. It is not uncommon, however to find slopes around 0.6-0.8 and intercepts around 0.2-0.3. Something is wrong with one or both methods, but there appears to be no way of telling which without a gold standard.

It would be desirable to regress the estimates obtained from each modality against the true value of the parameter rather than against another estimate, and in fact it is possible to do so if each patient is studied on each of two or more modalities (Hoppin *et al.*, 2002; Kupinski *et al.*, 2002). The basic assumption is that there exists a linear relation between the mean value of the estimates and the true value for each patient (though nonlinear relations can also be used). If θ_{pm} is the estimate obtained from patient p on modality m , and Θ_p is the true value for

that patient, the assumed relation is

$$\theta_{pm} = a_m \Theta_p + b_m + n_{pm}, \quad (14.111)$$

where n_{pm} is a zero-mean random variable. For simplicity, Hoppin *et al.* assumed that n_{pm} was normally distributed, but this does not appear to be critical. It was also assumed that n_{pm} was statistically independent of $n_{p'm'}$ for $p \neq p'$ or $m \neq m'$, and that the random variables for different patients but the same modality had the same variance. If P patients are each studied on M modalities, there are a total of PM measurements and $3M$ unknowns, namely the M values of a_m and b_m as well as the variances of n_{pm} for each m .

The basic idea is to estimate the $3M$ unknowns from the PM measurements by maximum-likelihood methods. With the assumptions made about n_{pm} it is straightforward to write down a probability density function on the measurements conditional on the unknown parameters and on the true values Θ_p , but of course we don't know these true values. Therefore Hoppin *et al.* assumed that the Θ_p were drawn independently from some parametric density $\text{pr}(\Theta_p|\boldsymbol{\alpha})$, where $\boldsymbol{\alpha}$ is a vector of unknown parameters describing the density. For example, since ejection fraction is defined on 0-1, a natural choice for $\text{pr}(\Theta_p|\boldsymbol{\alpha})$ is a beta distribution, which has two free parameters. These two parameters are of course unknown, so they are simply added to the list of parameters to be estimated. For example, with three modalities and the beta distribution, there are a total of $3M + 2 = 11$ unknowns, but if 100 patients are studied, there are 300 measurements.

This method has been well validated in simulation studies, and it has been placed on a firm theoretical footing by calculation of the Fisher information matrix. Not only does it give accurate estimates for the desired regression parameters, it also gives good values for the nuisance parameters contained in $\boldsymbol{\alpha}$.

Inverse Problems

In an imaging context, a *forward problem* is to determine the image produced by a given object. One might think that the corresponding *inverse problem* would be to determine the object that produced a given image. Were that so, this chapter would be quite short. As we have emphasized in previous chapters, imaging systems have null functions, and infinitely many different objects can produce the same image. It is virtually never possible to determine *the* object. A less ambitious goal is just to learn something about the object, perhaps to characterize it with a finite set of parameters in an approximate object description. It is in this sense that we shall understand the term *inverse problem*. Excellent general discussions of inverse problems are given by Sabatier (1987, 1991), Bertero (1989), Pike and Bertero (1992), Engl *et al.* (1996), Kirsch (1996), Glasko (1988) and Boccacci (1998).

Various terms are used for particular inverse problems. The term *image reconstruction* can be used quite generally for almost any inverse problem in imaging, but it is usually used in a tomographic context, meaning reconstruction from projection data. An *inverse-source* problem (Baltes *et al.*, 1978) is one where the unknown object is a radiation source, and an *inverse scattering* problem (Fiddy, 1992) is one where the unknown is a distribution of scatterers, such as variations in refractive index. When the object is reconstructed from a blurred and noisy direct image, the terms *deblurring* and *deconvolution* are often used (even when the forward problem is not a convolution). Closely associated with deconvolution is *system identification*, which refers to a situation in which a signal from a known source propagates through some linear system, and the problem is to characterize the system. The even more difficult problem of *blind deconvolution* arises when neither the input nor the system response is known, and it is nevertheless desired to characterize the input, the system or both.

Many inverse problems can also be cast as *estimation* problems, especially when the statistics of the data are taken into account. In this view, the goal is usually to estimate pixel values or other parameters of the object. Many of the

principles of estimation theory, introduced in Chap. 13, will recur in this chapter.

In Sec. 15.1, we give an overview of several basic issues in image reconstruction, including the key concept of estimability. In Sec. 15.2 we discuss various ways of deriving linear operators that can be applied to image data to give a reconstructed image in one step. In Sec. 15.3 we formulate solutions to inverse problems as minimization of some functional of the solution and the data. One component of this functional is a measure of the discrepancy between the actual measured data and the data that would be produced by some approximate object representation. Minimization of this term alone would force the solution to be consistent with the data, but strict agreement with noisy data will inevitably yield noisy and unsatisfactory images, so some means of backing off from strict data agreement is required. The general term for noise control is *regularization*, and in Sec. 15.3 we impose regularization by adding another term to the objective functional. In Sec. 15.4, some specific iterative algorithms for finding this minimum are discussed, and the statistical properties of the resulting images are derived.

15.1 BASIC CONCEPTS

Several basic concepts that run through this chapter are introduced here. In Sec. 15.1.1 we present a useful taxonomy of inverse problems. In Sec. 15.1.2 we recognize that most inverse problems are approached by adopting a discrete representation of the object, but a number of often overlooked problems arise when we do so. One such problem is that the coefficients in this representation may not be uniquely determined even by noise-free data. This leads to a discussion of *estimability* in Sec. 15.1.3. In Sec. 15.1.4 we begin to examine some of the implications of the fact that many physical objects cannot assume negative values. Finally, in Sec. 15.1.5 we present some remarks on applying the general principles of objective, task-based assessment of image quality, as introduced in Chap. 14, to inverse problems.

15.1.1 Classifications of inverse problems

Classification by data type We have previously classified forward problems as CC, CD and DD, depending on whether the object and the image data were discrete vectors (D) or functions of a continuous variable (C). Usually nature dictates that the object is continuous in this sense, and the nature of digital image acquisition dictates that the image is discrete, so the CD model is the natural one. When we want to include a reconstruction step, however, we can choose to produce either a function or a finite vector. If we want to think of the data-acquisition system plus the reconstruction algorithm as one big imaging system, we must expand our classification scheme, adding another C or D to specify whether the output of the reconstruction is continuous or discrete. Some interesting cases are:

- CCC:** This designation refers to a CC system for the forward problem followed by a CC mapping to the reconstruction. Hence it applies to an integral equation and its analytic solution.
- CCD:** Again we have a CC system for the forward problem, but now with a reconstruction algorithm that produces a discrete vector. This designation would apply to numerical inversion of an integral transform.

CDD: This is the usual case in image reconstruction, where discrete data are reconstructed on a discrete grid.

CDDC: This designation could apply to image reconstruction on a discrete grid followed by display as a continuous luminance pattern.

CDC: This refers to direct reconstruction of functions without adopting a discrete object model (see Sec. 15.2.2).

DDD: Pure simulation.

DDDC: Simulation plus display.

Linear vs. nonlinear reconstructions We can further distinguish linear and nonlinear operations in both the forward and inverse step. Linear and nonlinear forward mappings were discussed in Chap. 7, so we concentrate here on the inverse mapping.

If we denote the reconstruction by $\hat{\mathbf{f}}$, whether it be continuous or discrete, and if the reconstruction can be performed with a linear operator \mathcal{O}_{lin} , we can write

$$\hat{\mathbf{f}} = \mathcal{O}_{lin} \mathbf{g}. \quad (15.1)$$

For a discrete reconstruction from discrete data (CDD or DDD), the operator \mathcal{O}_{lin} is a matrix; for a continuous reconstruction from discrete data, it is a DC operator as discussed in Sec. 7.3.6.

If the operations involved in reconstruction of $\hat{\mathbf{f}}$ from \mathbf{g} are nonlinear, we can write generically

$$\hat{\mathbf{f}} = \mathcal{O}_{nl} \mathbf{g}, \quad (15.2)$$

where \mathcal{O}_{nl} is some nonlinear operator. Nonlinear reconstruction operators can be applied to data obtained from either linear or nonlinear imaging systems.

One example where it is possible to state a simple operational form for \mathcal{O}_{nl} is when point nonlinearities are applied following an otherwise linear reconstruction. In the notation of Sec. 7.5, we can write

$$\hat{\mathbf{f}} = \Phi\{\mathcal{O}_{lin} \mathbf{g}\}, \quad (15.3)$$

where $\Phi\{\cdot\}$ is a nonlinear functional applied pointwise. A simple example is where $\Phi\{x\} = x \text{ step}(x)$, so that the effect of Φ is to clip negative values.

Implicit and iterative solutions Equations (15.1) and (15.2) suggest direct, one-step reconstructions, where some operator is applied once to the data to get a solution. Often, however, the desired $\hat{\mathbf{f}}$ is found by minimizing some scalar-valued functional $Q(\mathbf{f}, \mathbf{g})$ that depends on the object and the data. Various terms for $Q(\mathbf{f}, \mathbf{g})$ can be found in the literature, including *objective function* (or functional), *merit function*, *penalty function*, *cost function* and *energy* (the latter designation arising from analogies to statistical mechanics).

We encountered one example of an implicit reconstruction procedure in Chap. 1 when we discussed least-squares reconstruction in a DDD context. As we saw in (1.191), the solution in that case can be written as

$$\hat{\mathbf{f}} = \underset{\mathbf{f}}{\operatorname{argmin}} Q(\mathbf{f}, \mathbf{g}), \quad (15.4)$$

where, in the least-squares case, $Q(\mathbf{f}, \mathbf{g}) = \|\mathbf{g} - \mathbf{H}\hat{\mathbf{f}}\|^2$. The argmin notation means that $\hat{\mathbf{f}}$ is the vector \mathbf{f} for which $Q(\mathbf{f}, \mathbf{g})$ is minimum. Since this minimization is performed for a given \mathbf{g} , the resulting $\hat{\mathbf{f}}$ is a function of \mathbf{g} . In the least-squares case,

the $\hat{\mathbf{f}}$ found by minimizing Q is a linear (or at least affine) function of \mathbf{g} [cf. (1.195) or (1.200)], but more generally $\hat{\mathbf{f}}$ is a nonlinear function of \mathbf{g} .

Implicit formulations often lead to iterative algorithms for finding the $\hat{\mathbf{f}}$ that minimizes the functional. In these algorithms, successive estimates $\hat{\mathbf{f}}^{(k)}$ are generated according to a recursion rule with the general form,

$$\hat{\mathbf{f}}^{(k+1)} = \mathcal{O}^{(k)} \left\{ \hat{\mathbf{f}}^{(k)}, \mathbf{g} \right\}, \quad (15.5)$$

where $\mathcal{O}^{(k)} \left\{ \hat{\mathbf{f}}^{(k)}, \mathbf{g} \right\}$ is some operator with two operands, so that its output at each step depends (often nonlinearly) on both the previous estimate $\hat{\mathbf{f}}^{(k)}$ and the original data \mathbf{g} . The superscript on \mathcal{O} indicates that the operator itself can change as the iteration proceeds. Often the recursion rule (15.5) will be chosen so that the argmin solution of (15.4) will coincide with $\hat{\mathbf{f}}^{(\infty)}$.

15.1.2 Discretization dilemma

In Chap. 7 we discussed in detail various approximate object representations. The general form of a linear approximation to an object function was given in (7.27) as

$$f_a(\mathbf{r}) = \sum_{n=1}^N \theta_n \phi_n(\mathbf{r}), \quad (15.6)$$

where the subscript a denotes *approximate*, and $\{\phi_n(\mathbf{r}), n = 1, \dots, N\}$ is any convenient set of expansion functions. In a more compact operator notation, (15.6) becomes

$$\mathbf{f}_a = \mathcal{D}_\phi^\dagger \boldsymbol{\theta}, \quad (15.7)$$

where \mathcal{D}_ϕ is a CD discretization operator and \mathcal{D}_ϕ^\dagger is its adjoint (hence a DC operator).

If the coefficients $\{\theta_n\}$ in (15.6) are derived linearly from the object, we know from (7.33) that they can be written as

$$\theta_n = \int_{\infty} d^q r \chi_n^*(\mathbf{r}) f(\mathbf{r}), \quad (15.8)$$

or in operator form as

$$\boldsymbol{\theta} = \mathcal{D}_\chi \mathbf{f}. \quad (15.9)$$

Mapping a discrete object representation through a CD system In Sec. 7.3 we saw how object functions map through a linear CD system to form discrete data. If the CD system acquires M noisy measurements, the discrete data vector \mathbf{g} is an $M \times 1$ random vector given by

$$\mathbf{g} = \mathcal{H} \mathbf{f} + \mathbf{n}, \quad (15.10)$$

where \mathcal{H} is the linear CD operator defined in Sec. 7.3.1 and \mathbf{n} is an $M \times 1$ noise vector. A simple mathematical tautology allows us to write

$$\mathbf{g} = \mathcal{H} \mathbf{f}_a + \mathcal{H} \mathbf{f} - \mathcal{H} \mathbf{f}_a + \mathbf{n} \equiv \mathbf{H} \boldsymbol{\theta} + \boldsymbol{\epsilon}, \quad (15.11)$$

where the overall error $\boldsymbol{\epsilon}$ (modeling error plus noise) is given by

$$\boldsymbol{\epsilon} = \mathcal{H} \mathbf{f} - \mathcal{H} \mathbf{f}_a + \mathbf{n}, \quad (15.12)$$

and the system matrix \mathbf{H} is given in operator form by (7.307):

$$\mathbf{H} \equiv \mathcal{H}\mathcal{D}_\phi^\dagger. \quad (15.13)$$

More specifically, the elements of \mathbf{H} are given by (7.304):

$$H_{mn} = \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}) \phi_n(\mathbf{r}). \quad (15.14)$$

Thus the $(mn)^{th}$ element is the n^{th} expansion function as imaged onto the m^{th} detector element.

Considerations on choosing a discretization scheme The linear discretization problem boils down to selecting two sets of functions, $\{\phi_n(\mathbf{r})\}$ and $\{\chi_n(\mathbf{r})\}$, or equivalently, two sets of Hilbert-space vectors $\{\phi_n\}$ and $\{\chi_n\}$. These vectors affect the accuracy with which $f_a(\mathbf{r})$ approximates the actual object $f(\mathbf{r})$, and they also affect the form and dimensions of the system matrix \mathbf{H} as well as the size and nature of the error vector ϵ . Finally, through (15.8), the set $\{\chi_n\}$ affects the meaning of the parameters $\{\theta_n\}$ that we want to determine.

There are several ways we can approach the problem of choosing $\{\phi_n\}$ and $\{\chi_n\}$. We might say at the outset that we are interested in certain functionals of the object, such as pixel values, and select the functions $\{\chi_n\}$ accordingly. That would leave us free to choose $\{\phi_n\}$ by some other criterion, such as minimizing the data-space modeling error $\mathcal{H}\mathbf{f} - \mathcal{H}\mathbf{f}_a$. Unfortunately, as we shall discover in Sec. 15.1.3, most functionals that we might choose to estimate do not admit of an unambiguous estimate. That is, we cannot determine them from the data even in the absence of noise.

Alternatively, we might want to construct as accurate a representation of the object as possible for a specified number of terms in the expansion (15.6). In Secs. 7.1.4 and 7.1.5, we learned how to choose $\{\chi_n\}$ for minimum object error once $\{\phi_n\}$ was specified. In particular, if $\{\phi_n\}$ is an orthonormal set, then $\{\chi_n\}$ should be chosen to be the same orthonormal set if representational accuracy is our concern.

The choice of $\{\phi_n\}$ itself might be dictated by statistical considerations. If we consider a statistical ensemble of objects, then the ensemble-average representational error is minimized by using the N eigenfunctions of the object covariance matrix corresponding to the N largest eigenvalues as $\{\phi_n\}$. As noted in Sec. 7.1.4, this representation is called the Karhunen-Loève or KL expansion. One problem is that we do not usually have enough information about the ensemble to be able to compute the eigenvectors needed in a KL expansion.

No matter how we choose $\{\phi_n\}$, representational accuracy can be improved by increasing the number of terms N in the representation. The rank of the matrix \mathbf{H} , however, cannot exceed the rank R of the CD operator \mathcal{H} , which in turn cannot exceed the number of measurements M . Whenever N exceeds R , therefore, the problem of finding θ when given \mathbf{g} is underdetermined. Moreover, the nature of the effective noise term is unknown, except that $\epsilon \rightarrow \mathbf{n}$ as $N \rightarrow \infty$ with any sensible choice of expansion functions.

We are thus faced with a conundrum: If we use an accurate object model (large N), we cannot possibly find all the coefficients, and if we use a less accurate model ($N \leq R$), we make unknown modeling errors before even starting to estimate coefficients, and the approximate object \mathbf{f}_a may not resemble the actual object \mathbf{f} ,

even if the coefficients can be determined exactly. It is the view of the authors that the only satisfactory way to resolve this problem is via task-based assessment of image quality, as introduced in Chap. 14 and discussed further in Sec. 15.1.5.

15.1.3 Estimability

If $N < R$ in a linear expansion like (15.6), the number of unknowns is less than the rank of the system operator, but it is still not evident that we can estimate the coefficients $\{\theta_n\}$ from the data \mathbf{g} , even in the absence of noise. The coefficients may not be *estimable parameters*. The concept of estimability was briefly introduced in Sec. 13.3; we shall revisit the subject here from the viewpoint of image reconstruction.

Estimability of a single linear parameter Consider a scalar parameter θ defined by the linear functional,

$$\theta = \int_{\infty} d^q r \chi^*(\mathbf{r}) f(\mathbf{r}). \quad (15.15)$$

For a mental image, think of θ as the integral of the object over a region defined by a 0-1 function $\chi(\mathbf{r})$, but the mathematics will be more general. If we are given a noise-free data vector $\mathbf{g} = \mathcal{H}\mathbf{f}$, where \mathcal{H} is a linear CD operator, we would like to know whether we can determine θ uniquely from \mathbf{g} . An equivalent question is whether we can find an unbiased estimate of θ when zero-mean noise is present.

To answer these questions, note that we can write θ as a scalar product in object space:

$$\theta = (\boldsymbol{\chi}, \mathbf{f}). \quad (15.16)$$

If the system operator \mathcal{H} is linear, we can define two orthogonal subspaces of object space, called measurement space and null space, with the latter defined as the space of all vectors \mathbf{a}_{null} such that $\mathcal{H}\mathbf{a}_{null} = 0$. The vectors \mathbf{f} and $\boldsymbol{\chi}$ can be uniquely decomposed as

$$\mathbf{f} = \mathbf{f}_{meas} + \mathbf{f}_{null}, \quad (15.17)$$

$$\boldsymbol{\chi} = \boldsymbol{\chi}_{meas} + \boldsymbol{\chi}_{null}. \quad (15.18)$$

Since these two subspaces are orthogonal, we can write

$$\theta = (\boldsymbol{\chi}_{meas}, \mathbf{f}_{meas}) + (\boldsymbol{\chi}_{null}, \mathbf{f}_{null}). \quad (15.19)$$

Since the data vector is insensitive to null components, the first term represents what one can learn about θ from noise-free data, and the second term is the component of θ that cannot be measured with the system in question. This term is zero if *either* $\mathbf{f}_{null} = 0$ *or* $\boldsymbol{\chi}_{null} = 0$. The first condition is often satisfied in simulation studies but seldom in reality; we have no control over the object our imaging system is pointed at, so we cannot assert that $\mathbf{f}_{null} = 0$. We can, however, choose the function $\chi(\mathbf{r})$ defining θ , so we can make the error zero by choosing it so that $\boldsymbol{\chi}_{null} = 0$.

If $\boldsymbol{\chi}_{null} = 0$, the associated parameter θ is said to be *estimable* or *identifiable*. If θ is not estimable, there is an inevitable error of unknown magnitude arising from the second term in (15.19). Objects differing by null functions will give the same data, and hence the same value for any estimate derived from the data, even though they might have vastly different true values for θ .

There are various equivalent mathematical statements of the estimability condition. A linear parameter $\theta = (\boldsymbol{\chi}, \mathbf{f})$ is estimable if and only if

$$\boldsymbol{\chi}_{null} = 0, \quad (15.20)$$

or

$$\mathcal{P}_{meas}\boldsymbol{\chi} = \boldsymbol{\chi}, \quad (15.21)$$

where \mathcal{P}_{meas} is the orthogonal projector onto measurement space. As we saw in Chap. 1, this projector is given by $\mathcal{H}^+\mathcal{H}$, where \mathcal{H}^+ is the Moore-Penrose pseudoinverse of the CD operator \mathcal{H} . Thus we can also state the estimability condition as

$$\mathcal{H}^+\mathcal{H}\boldsymbol{\chi} = \boldsymbol{\chi}. \quad (15.22)$$

Finally, we can also say that θ is estimable if there exists a set of coefficients B_m such that

$$\chi(\mathbf{r}) = \sum_{m=1}^M B_m h_m(\mathbf{r}). \quad (15.23)$$

This equation implies estimability since measurement space is spanned by the point response functions $\{h_m(\mathbf{r})\}$, so a function in the form of (15.23) lies entirely in measurement space and cannot have null components.

Since null components of an imaging system usually contain high spatial frequencies, a large blobby template will be more likely to lead to an estimable parameter than a small or structured one. In particular, integrals of the object over small pixels are unlikely to be estimable.

Nonlinear parameters All of these conditions apply to linear functionals, which are the subject of this section, but for completeness we also give an estimability condition that is applicable to nonlinear parameters (see also Sec. 13.3.1). If $\theta(\mathbf{f})$ is an arbitrary (possibly nonlinear) functional of \mathbf{f} , we say that it is estimable if

$$\theta(\mathbf{f}) = \theta(\mathbf{f}_{meas}). \quad (15.24)$$

That is, $\theta(\mathbf{f})$ is completely determined by the measurement component of \mathbf{f} , so the null space is irrelevant. It is straightforward to show that (15.24) is equivalent to (15.20) if θ is linear.

Vector of linear parameters So far, we have considered a single parameter θ , but now we extend the discussion to the vector $\boldsymbol{\theta}$ defined by (15.9). The estimability conditions (15.21)–(15.23) now generalize to

$$\mathcal{P}_{meas}\boldsymbol{\chi}_n = \boldsymbol{\chi}_n, \quad n = 1, \dots, N, \quad (15.25)$$

$$\mathcal{H}^+\mathcal{H}\boldsymbol{\chi}_n = \boldsymbol{\chi}_n, \quad n = 1, \dots, N, \quad (15.26)$$

$$\chi_n(\mathbf{r}) = \sum_{m=1}^M B_{nm} h_m(\mathbf{r}), \quad n = 1, \dots, N. \quad (15.27)$$

In terms of the discretization operator \mathcal{D}_χ , (15.26) can also be written as

$$\mathcal{D}_\chi\mathcal{H}^+\mathcal{H} = \mathcal{D}_\chi, \quad (15.28)$$

and (15.27) becomes

$$\mathcal{D}_\chi = \mathbf{B}\mathcal{H}, \quad (15.29)$$

where \mathbf{B} is the $N \times M$ matrix with elements B_{nm} . By comparison of (15.28) and (15.29), \mathbf{B} is given explicitly by

$$\mathbf{B} = \mathcal{D}_\chi \mathcal{H}^+. \quad (15.30)$$

Since the dimensionality of measurement space is the rank R of the system operator, it is not possible to satisfy these conditions for N linearly independent parameters unless $N \leq R$. Conversely, a set of N estimable parameters must be linearly dependent if $N > R$.

Natural pixels in inverse problems It follows from (15.27) that all of the θ_n are estimable if $B_{mn} = \delta_{mn}$ for $n \leq N \leq M$, so that $\chi_n(\mathbf{r}) = h_n(\mathbf{r})$. If we take $N = M$ and assume that $h_n(\mathbf{r})$ is real, this means that $\mathcal{D}_\chi = \mathcal{H}$ and $\mathbf{B} = \mathcal{H}\mathcal{H}^+$, and (15.29) in this case is just the Penrose equation, $\mathcal{H} = \mathcal{H}\mathcal{H}^+\mathcal{H}$. Thus, if we use the point response functions to define our parameters, we need not worry about null functions or estimability. Buonocore *et al.* (1981) refer to the $h_n(\mathbf{r})$ as *natural pixels*.

We encountered natural pixels in Sec. 7.4.3, where we showed that the modeling error $\mathcal{H}\mathbf{f} - \mathcal{H}\mathbf{f}_a$ could be made zero if we chose the set $\{\phi_n(\mathbf{r})\}$ to coincide with the natural pixels. Now we are using natural pixels for a different purpose, to ensure estimability. These two goals are not contradictory; a set of estimable pixels with zero modeling error can be achieved in two distinct ways:

$$\mathcal{D}_\chi = \mathcal{H}, \quad \mathcal{D}_\phi^\dagger = \mathcal{H}^+, \quad \mathbf{H} = \mathcal{H}\mathcal{H}^+, \quad (15.31)$$

or

$$\mathcal{D}_\phi = \mathcal{H}, \quad \mathcal{D}_\chi = \mathcal{H}^{\dagger+}, \quad \mathbf{H} = \mathcal{H}\mathcal{H}^\dagger. \quad (15.32)$$

The reader should prove that both of these options imply estimability and that both allow us to write $\mathcal{H}\mathbf{f} = \mathbf{H}\boldsymbol{\theta}$ without approximation.

With (15.31), the parameters $\{\theta_n\}$ are easy to interpret, since they are just scalar products with the natural pixels, but the matrix \mathbf{H} may be hard to compute since it requires a pseudoinverse of a CD operator. With (15.32), on the other hand, the elements of \mathbf{H} are given by [*cf.* (7.340)]

$$H_{mn} = [\mathcal{H}\mathcal{H}^\dagger]_{mn} = \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}) h_n^*(\mathbf{r}). \quad (15.33)$$

Thus each H_{mn} is determined by the overlap between two natural pixels, so it is relatively easy to compute since no pseudoinverse is needed, but it is not so clear what the parameters mean. Even if $h_n(\mathbf{r})$ is nonnegative everywhere, some or all of the kernels associated with $\mathcal{H}^{\dagger+}$ will have negative values, and some of the resulting integrals $\hat{\theta}_n$ may go negative as well (even for nonnegative objects).

Subspace constraints and estimability We have always taken object space to be some \mathbb{L}_2 space, but we have acknowledged that not all vectors in this space should be construed as realizable objects (see Sec. 7.1.2). As we shall discuss below, we may know that real objects cannot be negative, and this constraint will cause us to revise our view of estimability. Even without a positivity constraint, however, we may be able to restrict our attention to some subset of the vectors in object space.

For example, if an object is described by a spatio-temporal function $f(\mathbf{r}, t)$, we may know on physical grounds that the rate of temporal change is bandlimited, in which case we could restrict attention to a Paley-Wiener subspace (see Sec. 3.5.1). Similarly, if $f(\mathbf{r}, t)$ represents the response to some stimulus applied at $t = 0$, then we would know that the function is causal, so $f(\mathbf{r}, t) = 0$ for $t \leq 0$, and this also limits the object to a subspace of the spatio-temporal \mathbb{L}_2 space.

It is more difficult to find examples of purely spatial functions that are limited *a priori* to subspaces. Of course, it is often necessary to approximate the object by a function in a subspace as in (15.6), but this is not the same thing as saying that all realizable objects lie in this space. In particular, virtually all objects we might want to image have sharp edges, so we cannot assume they are spatially bandlimited.

On the rare occasions where we do know with certainty that the object is confined to some subspace, we can define a projector onto that subspace as \mathcal{P}_{sub} and write $\mathbf{f} = \mathcal{P}_{sub}\mathbf{f}$. As an exercise, the reader may show that the estimability condition in this case becomes $\mathcal{P}_{sub}\mathcal{P}_{null}\chi = 0$, which could be much easier to satisfy than the original condition.

Bayesian view of estimability As discussed in the Prologue and in Sec. 8.4, we may be able to make statements about the prior PDF on the object, $\text{pr}(\mathbf{f})$. Partial information about this density is called a stochastic model. Sometimes there is a frequentist justification for the stochastic model, and sometime it is a purely Bayesian statement of beliefs. In either case, we may be able to use the model to say something about the magnitude of the error term in (15.19). For example, if a Bayesian believes that the objects of interest contain no null functions for some particular imaging system, then there is no need for an estimability condition; $(\chi_{null}, \mathbf{f}_{null})$ is zero if *either* χ_{null} or \mathbf{f}_{null} is zero. An unfortunate corollary of this belief is that it implies that it is not necessary to build better imaging systems. If the system at hand captures all of the information about the objects, why attempt to capture more? In particular, if the objects have no fine details beyond those in some assumed prior, why try to build a system with better spatial resolution?

A Bayesian could also use the assumed prior to compute the average error $(\chi_{null}, \langle \mathbf{f}_{null} \rangle)$. So long as this quantity is negligible, the Bayesian could assume that the parameter (χ, \mathbf{f}) is estimable. The only hazard is in trying to convince someone with a different belief system that the assumptions are valid. The skeptical non-Bayesian would need only to collect a few sample objects and compute the scalar product to check the model.

15.1.4 Positivity

As we discussed in Chap. 7, many physical objects are constrained by their nature to be nonnegative functions. For example, the object being imaged in nuclear medicine or fluorescence microscopy is the concentration of a tracer, and concentrations by definition cannot be negative. Similarly, in incoherent optical imaging, the object is a radiant exitance or a transmittance, neither of which can be negative. As we shall see, many reconstruction algorithms enforce this physical reality and yield only nonnegative images. Such algorithms are said to enforce a *positivity constraint*, though strictly speaking it should be *nonnegativity* since most of them do admit zero values. We shall often use a common but loose parlance and speak of positivity when an object or image is restricted to be greater than *or equal* to zero.

In Chaps. 1 and 7, we viewed a linear imaging system as an operator \mathcal{H} that maps from a Hilbert space \mathbb{U} to a Hilbert space \mathbb{V} . As we have noted many times, the object space is divided into two subspaces, called measurement space and null space, and the data space is divided into consistency space and inconsistency space. In this section we discuss the implications of positivity for these spaces. Later, in the context of specific algorithms, we shall consider the effects of a positivity constraint on reconstructed images.

Positivity and null functions Consider an object function satisfying $f(\mathbf{r}) \geq 0$ for all \mathbf{r} . Like any other vector in \mathbb{U} , this object can be decomposed uniquely into measurement and null components. It is not true, however, that $f_{meas}(\mathbf{r})$ and $f_{null}(\mathbf{r})$ are nonnegative; only their sum is so constrained. In fact, it is almost always the case that the null component of a nonnegative object will contain negative values. The reason for this statement can be seen by considering a Fourier decomposition of the object (perhaps a Fourier series like (7.13) if the object has finite support). Almost any imaging system is capable of correctly responding to the low-frequency terms, so the null components will consist solely of higher frequencies. If the zero-frequency term is in measurement space, all null functions must satisfy

$$\int_{\mathbf{S}_f} d^q r f_{null}(\mathbf{r}) = 0, \quad (15.34)$$

which implies that $f_{null}(\mathbf{r})$ must have both positive and negative values.

Estimability revisited As we saw above, estimability is closely related to null functions. Suppose \mathbf{f}_1 and \mathbf{f}_2 are two objects that differ by a null function, so that $\mathcal{H}\mathbf{f}_1 = \mathcal{H}\mathbf{f}_2$. A linear parameter θ defined as in (15.16) can, in general, take on very different values for these two objects. We can define $\theta_1 = (\boldsymbol{\chi}, \mathbf{f}_1)$ and $\theta_2 = (\boldsymbol{\chi}, \mathbf{f}_2)$. If $\boldsymbol{\chi}$ has a null component, then $\theta_2 - \theta_1$ can be arbitrarily large, and any estimate derived from the data can have an arbitrarily large bias. To avoid this problem, we must choose $\boldsymbol{\chi}$ to be free of null functions.

The situation changes, however, if we consider only nonnegative objects. In that case, there are various ways to set bounds on null functions, which in turn lead to bounds on the bias of θ . Full details can be found in Clarkson and Barrett (1997, 1998a), and only a simple special case will be treated here.

We consider the usual linear CD system for which, in the absence of noise,

$$g_m = \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}) f(\mathbf{r}), \quad (15.35)$$

and we define the point sensitivity function $s(\mathbf{r})$ as in (7.232) by

$$s(\mathbf{r}) = \sum_{m=1}^M h_m(\mathbf{r}). \quad (15.36)$$

Suppose first that $s(\mathbf{r})$ is a constant s_0 , independent of \mathbf{r} . Then, if $f_1(\mathbf{r})$ and $f_2(\mathbf{r})$ produce the same data, we have

$$\sum_{m=1}^M g_m = s_0 \int_{\mathbf{S}_f} d^q r f_1(\mathbf{r}) = s_0 \int_{\mathbf{S}_f} d^q r f_2(\mathbf{r}). \quad (15.37)$$

Since the objects are nonnegative, we can add absolute-value signs inside the integrals, obtaining

$$\int_{\mathbf{S}_f} d^q r |f_1(\mathbf{r})| = \int_{\mathbf{S}_f} d^q r |f_2(\mathbf{r})|. \quad (15.38)$$

Thus two nonnegative objects that give the same data must have the same \mathbb{L}_1 norm if $s(\mathbf{r})$ is a constant. Since the difference $\mathbf{f}_2 - \mathbf{f}_1$ is a null function \mathbf{f}_{null} , it follows from the triangle inequality (see Sec. 1.1.2) that

$$\int_{\mathbf{S}_f} d^q r |f_{null}(\mathbf{r})| \leq 2 \int_{\mathbf{S}_f} d^q r |f_j(\mathbf{r})|, \quad (15.39)$$

where j can be either 1 or 2.

A more general expression that does not require $s(\mathbf{r})$ to be constant was derived by Clarkson and Barrett (1997); they found that

$$\int_{\mathbf{S}_f} d^q r |f_{null}(\mathbf{r})| \leq \left(1 + \frac{s_{max}}{s_{min}}\right) \int_{\mathbf{S}_f} d^q r |f_j(\mathbf{r})|, \quad (15.40)$$

where s_{max} and s_{min} are, respectively, the maximum and minimum values of $s(\mathbf{r})$ over the object support.

To relate this result to the parameter θ , note that

$$\theta_2 - \theta_1 = (\boldsymbol{\chi}, \mathbf{f}_2 - \mathbf{f}_1) = (\boldsymbol{\chi}, \mathbf{f}_{null}) = (\boldsymbol{\chi}_{null}, \mathbf{f}_{null}), \quad (15.41)$$

where the last step follows since the measurement and null spaces are orthogonal. Thus

$$\begin{aligned} |\theta_2 - \theta_1| &= |(\boldsymbol{\chi}_{null}, \mathbf{f}_{null})| = \left| \int_{\mathbf{S}_f} d^q r \chi_{null}(\mathbf{r}) f_{null}(\mathbf{r}) \right| \\ &\leq \int_{\mathbf{S}_f} d^q r |\chi_{null}(\mathbf{r}) f_{null}(\mathbf{r})| \leq \max_{\mathbf{r}} \{|\chi_{null}(\mathbf{r})|\} \int_{\mathbf{S}_f} d^q r |f_{null}(\mathbf{r})|. \end{aligned} \quad (15.42)$$

With (15.40), we have, finally,

$$|\theta_2 - \theta_1| \leq \max_{\mathbf{r}} \{|\chi_{null}(\mathbf{r})|\} \left(1 + \frac{s_{max}}{s_{min}}\right) \int_{\mathbf{S}_f} d^q r |f_j(\mathbf{r})|. \quad (15.43)$$

If $\chi(\mathbf{r})$ has no null component, the right-hand side is zero and we are back to the usual definition of estimability: Two objects that give the same data give the same value for the parameter θ . If $\chi(\mathbf{r})$ does have a null component, however, the positivity constraint gives us a bound on how large the difference between θ_1 and θ_2 can be. This bound gets smaller as the null component of $\chi(\mathbf{r})$ gets smaller (in peak value), as the system sensitivity gets more uniform and as the object itself gets weaker (and hence θ gets smaller).

Positivity and data consistency We have defined consistency space \mathbb{V}_{con} as the range of $\boldsymbol{\mathcal{H}}$, which is a subset of the overall data space \mathbb{V} . Every vector in consistency space can be realized as the (noise-free) image through the operator $\boldsymbol{\mathcal{H}}$ of some object in the domain \mathbb{U} of $\boldsymbol{\mathcal{H}}$. Fundamentally, this domain is constrained only by the definition of the Hilbert space \mathbb{U} ; for example, it might consist of all square-integrable functions of some specified support. Many of the vectors in this domain,

however, may not be physically realizable objects. For example, we may know that physical objects are nonnegative. We can define a *positive consistency set* \mathbf{V}_+ as the set of all noise-free images of nonnegative objects. Thus \mathbf{V}_+ is a subset of \mathbb{V}_{con} . Note that it is not correct to say that \mathbf{V}_+ is a *subspace* of \mathbb{V}_{con} since it does not satisfy the requirements for a linear vector space (see Sec. 1.1.1). In particular, multiplying an image of a positive object by a negative number would remove it from the set.

Moment cone Another name for \mathbf{V}_+ is *moment cone*. To see how this name arises, consider first a unit point source $\delta(\mathbf{r} - \mathbf{r}_0)$ (and ignore the fact that it is not square-integrable). The image of this source is a point in \mathbf{V}_+ . To be precise, for this object and a CD model of the imaging system as in (15.35),

$$g_m = [\mathcal{H} \delta(\mathbf{r} - \mathbf{r}_0)]_m = h_m(\mathbf{r}_0). \tag{15.44}$$

If we vary \mathbf{r}_0 , we generate a set of points in data space. For example, if we scan object space in raster-like¹ fashion, we generate a line of points in data space as shown in Fig. 15.1a.

Fig. 15.1 Construction of the moment cone. Three of the M dimensions of data space are shown, and the object is a 2D delta function $\delta(\mathbf{r} - \mathbf{r}_0)$. The line shown is traced out as the point \mathbf{r}_0 is scanned back and forth over the object space. As drawn, all three detectors receive radiation for all \mathbf{r}_0 .

Now add a second point source and renormalize the object to unit strength. The new object, $\beta \delta(\mathbf{r} - \mathbf{r}_0) + (1 - \beta) \delta(\mathbf{r} - \mathbf{r}_1)$ with $0 \leq \beta \leq 1$, is nonnegative everywhere, so its image must lie in \mathbf{V}_+ . This object is a convex combination of the two point objects $\delta(\mathbf{r} - \mathbf{r}_0)$ and $\delta(\mathbf{r} - \mathbf{r}_1)$, and since the system is linear, the resulting point in data space is the same convex combination, $\beta \mathcal{H} \delta(\mathbf{r} - \mathbf{r}_0) + (1 - \beta) \mathcal{H} \delta(\mathbf{r} - \mathbf{r}_1)$. (Recall the definition of a convex set of points: If \mathbf{g}_0 and \mathbf{g}_1 are both in the set, then so is $\beta \mathbf{g}_0 + (1 - \beta) \mathbf{g}_1$ for $0 \leq \beta \leq 1$.) Thus we can include in \mathbf{V}_+ all image points within the convex set generated this way with all \mathbf{r}_0 , \mathbf{r}_1 and β (see Fig. 15.1b). We shall call this set $\mathbf{V}_+^{(2)}$ since it is the set of image points generated by unit-strength, nonnegative objects consisting of pairs of point sources.

¹The word raster comes from the Latin *rastrum*, rake, so it suggests a set of lines all moving in the same direction, as in a TV raster. The back-and-forth pattern in Fig. 15.1 is called a *boustrophedonic* scan, referring to an ancient method of writing in which the lines run in alternating directions. The root *bou* occurs also in bovine, and the boustrophedon is the pattern of an ox plowing a field.

If we add a third point source and renormalize the object to have an integral of unity, the new image point will also lie in $\mathbf{V}_+^{(2)}$ since it is just a convex combination of the image of the third point and the image obtained when the first two are present simultaneously; both of these images are in the convex set $\mathbf{V}_+^{(2)}$, and by the definition of convexity the image of the new three-point object must lie in it also. We can extend this argument to an arbitrary number of point sources and hence to a general positive object of unit integral; the image of all of these objects lies in $\mathbf{V}_+^{(2)}$.

To remove the restriction that the objects must integrate to one, consider what happens when an object is scaled, $\mathbf{f} \rightarrow \alpha\mathbf{f}$, with $\alpha \geq 0$ so that a nonnegative object remains nonnegative. Since the system is linear, the image is scaled similarly, $\mathbf{g} \rightarrow \alpha\mathbf{g}$. Thus, when we consider all α from 0 to ∞ , each point in the convex set discussed above becomes a line extending from the origin through the original point to infinity (see Fig. 15.1b). Carrying out this extension for all points in $\mathbf{V}_+^{(2)}$, we generate a cone of points as shown in Fig. 15.1c. This cone is the positive consistency set \mathbf{V}_+ . It is known as the *moment cone* since each data component is a weighted integral or moment of the object function.

In summary, the moment cone, a convex cone with vertex at the origin in data space, is the set of all noise-free images of nonnegative objects. It is a subset of consistency space or the range of \mathcal{H} . Moreover, if each $h_m(\mathbf{r})$ is nonnegative for all \mathbf{r} , the moment cone is a subset of the *positive orthant* of data space, *i.e.*, the set of all \mathbf{g} such that $g_m \geq 0$ for all m .

15.1.5 Choosing the best algorithm

We have already seen that there are many choices to be made in formulating and solving an inverse problem. If we adopt a discrete model, we must directly or indirectly select the sets $\{\phi_n\}$ and $\{\chi_n\}$. If we use an implicit formulation, we must choose the objective functional, and if we use an iterative algorithm, we must select the iteration rule and the number of iterations. We must choose whether or not to enforce positivity. In addition, many algorithms have various other free parameters, called things like regularization parameters, acceleration parameters or hyperparameters.

There is a large literature on choosing these parameters and optimizing a reconstruction algorithm, and we shall discuss several aspects of the problem in the remainder of this chapter. In our view, however, any meaningful discussion of image quality must ultimately relate back to the intended use of the image, that is, to the task and the observer. The general principles enunciated in Chap. 14 on assessment of image quality apply equally well to the assessment and optimization of reconstruction algorithms.

For classification tasks, the observer is most often a human, and the reconstruction algorithm serves only to transduce the original data into a form where it is useful to a human observer. Under these conditions, assessment and optimization of an algorithm must necessarily take into account the properties and limitations of human visual perception. For classification tasks to be performed by human observers, image quality can be measured *only* by psychophysical studies or mathematical model observers that predict the outcome of such studies.

The ideal observer is generally useless for evaluating algorithms since its performance is usually invariant to algorithm. The performance of the ideal observer on a detection task can be evaluated on the raw data \mathbf{g} , before any algorithm, and the algorithm cannot improve the performance (see Sec. 13.2.7). Virtually by definition, if the algorithm were useful, it would be incorporated into the detection strategy employed by the ideal observer; otherwise, that observer would not be ideal.

A similar conclusion holds for the Hotelling observer. It was shown in Sec. 13.2.12 that the Hotelling trace is invariant to any invertible linear algorithm, *i.e.*, one where it is possible to go backwards from the reconstruction to the original data. Thus neither the ideal nor the Hotelling observer tells us very much about the algorithm if the task is classification and the end user will be a human; their only use in evaluating algorithms is to make sure that no information is lost.

The situation is rather different for estimation tasks, which are rarely performed by humans. Instead, some kind of image-analysis program is used to extract quantitative information from images, *i.e.*, to estimate some parameter of the object. If we denote the parameter of interest by $\Theta(\mathbf{f})$, where the capitalization of theta serves to distinguish it from the vector of coefficients, then the output of the analysis program is $\hat{\Theta}$. The input to the program could be the raw image data \mathbf{g} , in which case the output would be some (possibly nonlinear) function $\hat{\Theta}_{raw}(\mathbf{g})$. Often, however, it is easier to perform the analysis using a reconstructed image as the data. In that case, two successive estimation steps are needed, one to obtain the input to the image-analysis program and one carried out in that program. The final estimate would be written as $\hat{\Theta}_{recon}(\hat{\theta})$, and its accuracy could, as usual, be evaluated in terms of the bias, variance or mean-squared error (MSE). For more on how to compute MSE, see Sec. 14.3.4. A unique specification of bias and MSE presupposes, of course, that $\Theta(\mathbf{f})$ is estimable, which pixel values rarely are. Some of the problems in defining an MSE on pixel values are discussed in Sec. 13.3.2.

Since the accuracy of $\hat{\Theta}(\hat{\theta})$ depends on the noise in the data, on the reconstruction algorithm and on the final estimation procedure, the MSE can be used to assess the quality of any combination of these steps. If we consider a fixed imaging system and reconstruction algorithm, for example, the MSE of $\hat{\Theta}(\hat{\theta})$ would be interpreted, as it traditionally is in the statistics literature, as the performance of the final estimate. For assessing reconstruction algorithms in terms of estimation tasks, however, we can consider the imaging system and the image-analysis program as fixed, and then the MSE is a figure of merit for the reconstruction.

No matter which task and observer we pick, task performance depends on the statistical properties of the data. For tasks performed on reconstructed images, that means that we need to know the statistical properties of the images, and much of this chapter is devoted to this goal. In particular, for classification tasks and linear observers, we know from Sec. 13.2.12 that the performance can be computed from the mean vector and the covariance matrix, so we concentrate in what follows on calculation of these quantities for reconstructed images.

15.2 LINEAR RECONSTRUCTION OPERATORS

We shall now discuss various linear operators that can be applied to a data set to yield a reconstructed image in one step. Since the operators are linear, the resulting images will seldom satisfy the positivity constraint.

Section 15.2.1 deals with the CDD problem of finding the coefficients in an approximate object expansion from discrete data. In Sec. 15.2.2 we look at various ways of getting a continuous estimate either from the discrete coefficients or directly; thus this section deals with CDC inverse problems.

In Sec. 15.2.3 we consider a broad class of imaging systems that can be called *Fourier samplers* since the data consist of discrete samples of the object Fourier transform. These systems will provide a concrete example of the formalism developed in Sec. 15.2.2.

In Sec. 15.2.4 we begin to examine the relation between CC operators and CD operators. Specifically, we consider situations where a CC operator with a known inverse might be a reasonable description of an imaging system in the limit of very fine sampling in the data space. We then investigate the actual CDD inverse problem using the known solution to the CCC problem as a starting point.

In Sec. 15.2.5, we examine CCC problems in which the adjoint operator \mathcal{H}^\dagger has a null space. Such operators arise frequently in tomographic problems, and their properties have implications for practical (*i.e.*, CDD) tomographic reconstruction algorithms.

Finally, the effect of noise on estimates obtained with linear reconstruction operators is discussed in Sec. 15.2.6.

15.2.1 Matrix operators for estimation of expansion coefficients

In this section we view the reconstruction process as estimation of the coefficients $\{\theta_n\}$ in an approximate object expansion. Since there are N coefficients and M measurements, we seek an $N \times M$ reconstruction matrix that will yield an estimate of $\boldsymbol{\theta}$ in a single matrix-vector multiply. If the coefficients are estimable parameters (see Sec. 15.1.3), it is reasonable to require that the matrix give the correct values in the absence of noise; that condition will be the starting point for this discussion, and it will lead to pseudoinverse matrices. As the reader might expect from Chap. 1, pseudoinverse solutions have poor noise performance, but we postpone until Sec. 15.2.6 a discussion of ways of dealing with this problem.

Let us suppose that the parameters $\{\theta_n\}$ are estimable and hence that (15.27) holds. The matrix \mathbf{B} defined in that equation and given explicitly in (15.30) is, in fact, just the kind of reconstruction matrix we are seeking. We can define estimates of θ_n by

$$\hat{\theta}_n \equiv \sum_{m=1}^M B_{nm} g_m. \quad (15.45)$$

In the absence of noise,

$$\begin{aligned} \hat{\theta}_n &= \sum_{m=1}^M B_{nm} \int_{\infty} d^q r h_m(\mathbf{r}) f(\mathbf{r}) = \int_{\infty} d^q r \left[\sum_{m=1}^M B_{nm} h_m(\mathbf{r}) \right] f(\mathbf{r}) \\ &= \int_{\infty} d^q r \chi_n(\mathbf{r}) f(\mathbf{r}) = \theta_n, \end{aligned} \quad (15.46)$$

where the last line has used (15.8). Hence the matrix \mathbf{B} is the reconstruction operator, yielding $\hat{\boldsymbol{\theta}} = \boldsymbol{\theta}$ exactly in the absence of noise. With zero-mean additive noise, $\hat{\boldsymbol{\theta}}$ is an unbiased estimate, where $\langle \hat{\theta}_n \rangle = \theta_n$ for all n . These conclusions require, however, that $\boldsymbol{\theta}$ be estimable.

We can restate the results of the last paragraph more succinctly in operator form. With (15.30), (15.10), (15.28) and the assumption that $\mathbf{n} = 0$,

$$\mathbf{B}\mathbf{g} = \mathcal{D}_\chi \mathcal{H}^+ \mathbf{g} = \mathcal{D}_\chi \mathcal{H}^+ \mathcal{H}\mathbf{f} = \mathcal{D}_\chi \mathbf{f} = \boldsymbol{\theta}. \quad (15.47)$$

Thus we can get $\boldsymbol{\theta}$ by first applying the pseudoinverse operator \mathcal{H}^+ to \mathbf{g} , then discretizing the result with \mathcal{D}_χ , but only if $\boldsymbol{\theta}$ is estimable and there is no noise.

Bias for nonestimable parameters What happens if $\boldsymbol{\theta}$ is not estimable, but we pretend it is and apply \mathbf{B} anyway? Then we get (still without noise)

$$\mathbf{B}\mathbf{g} = \mathcal{D}_\chi \mathcal{H}^+ \mathcal{H}\mathbf{f} = \mathcal{D}_\chi \mathbf{f}_{meas} \neq \boldsymbol{\theta}. \quad (15.48)$$

For some particular object, we can determine the error (bias) in this procedure. The error norm is

$$\|\mathbf{B}\mathbf{g} - \boldsymbol{\theta}\| = \|\mathcal{D}_\chi(\mathbf{f}_{meas} - \mathbf{f})\| = \|\mathcal{D}_\chi \mathbf{f}_{null}\|. \quad (15.49)$$

To evaluate this expression exactly, we have to know \mathbf{f}_{null} , but it is interesting to try to set a bound analogous to (15.43) that involves only χ_{null} and not \mathbf{f}_{null} . For a scalar parameter θ , $\mathcal{D}_\chi = \chi^\dagger$, and

$$|\chi^\dagger \mathcal{H}^+ \mathbf{g} - \theta| = |\chi^\dagger \mathbf{f}_{null}|. \quad (15.50)$$

Since null and measurement spaces are orthogonal, we can write the scalar product as $\chi^\dagger \mathbf{f}_{null} = \chi_{null}^\dagger \mathbf{f}_{null} = \chi_{null}^\dagger \mathbf{f}$. Then we have

$$\begin{aligned} |\chi^\dagger \mathcal{H}^+ \mathbf{g} - \theta| &= \left| \int_{\mathbf{S}_f} d^q r \chi_{null}(\mathbf{r}) f(\mathbf{r}) \right| \\ &\leq \int_{\mathbf{S}_f} d^q r |\chi_{null}(\mathbf{r}) f(\mathbf{r})| \leq \max_{\mathbf{r}} \{ |\chi_{null}(\mathbf{r})| \} \int_{\mathbf{S}_f} d^q r |f(\mathbf{r})|. \end{aligned} \quad (15.51)$$

Note that we are now computing the error between θ for a particular object and its pseudoinverse estimate, not between the θ values for two objects that give the same data as in (15.43); this difference accounts for the absence of the factor involving s_{max}/s_{min} here.

A tighter bound can be stated if $\chi_{null}(\mathbf{r})$ has compact support, at least approximately. If we can define a region $\mathbf{S}(\chi_{null})$ in object space such that $\chi_{null}(\mathbf{r}) \simeq 0$ for \mathbf{r} outside this region, then the integrals in (15.51) are restricted to this region, and we find

$$|\chi^\dagger \mathcal{H}^+ \mathbf{g} - \theta| \leq \max_{\mathbf{r}} \{ |\chi_{null}(\mathbf{r})| \} \int_{\mathbf{S}(\chi_{null})} d^q r |f(\mathbf{r})|. \quad (15.52)$$

Note that the integral here is less than or equal to the one in (15.51), so the bound is tighter.

Matrix pseudoinverses In practice, it may be difficult to implement the pseudoinverse of the CD operator \mathcal{H} , as required in (15.48), and we should not have to since the objective is to go from one vector (\mathbf{g}) to another ($\hat{\boldsymbol{\theta}}$). It may be much more convenient to compute the matrix \mathbf{H} and try to solve the problem $\mathbf{g} = \mathbf{H}\boldsymbol{\theta} + \boldsymbol{\epsilon}$ directly, without worrying about the meaning of $\boldsymbol{\theta}$, but what do we get this way? It seems to be tacitly assumed in much of the literature that some sort of matrix pseudoinversion will suffice to recover $\mathcal{D}_\phi \mathbf{f}$, at least from noise-free data. For example, in a pixel basis one might hope that a matrix constructed from pixels will suffice to recover integrals of the object over pixels. It is rarely the case that this hope will be fulfilled.

Suppose we choose some arbitrary set of expansion functions $\{\phi_n\}$ and define $\mathbf{H} = \mathcal{H}\mathcal{D}_\phi^\dagger$. Even in the absence of measurement noise, all we can say in general about the pseudoinverse solution is that

$$\mathbf{H}^+ \mathbf{g} = [\mathcal{H}\mathcal{D}_\phi^\dagger]^+ \mathcal{H} \mathbf{f}. \quad (15.53)$$

To the extent that this is an estimate of some parameter $\boldsymbol{\theta}$, it must be the one defined by $\mathcal{D}_\chi = [\mathcal{H}\mathcal{D}_\phi^\dagger]^+ \mathcal{H}$, and there is no evident way to simplify this expression. In particular, it is not true in general that $[\mathcal{H}\mathcal{D}_\phi^\dagger]^+$ is the same as $\mathcal{D}_\phi^{\dagger+} \mathcal{H}^+$.

There is, however, one circumstance under which $\mathbf{H}^+ \mathbf{g}$ becomes more transparent. Suppose $\{\phi_n\}$ is an orthonormal basis for measurement space, for example the first R singular vectors of \mathcal{H} (see Sec. 7.4.3). In that case, $\mathcal{D}_\phi^\dagger = \mathcal{D}_\phi^+$ (by the orthonormality) and $\mathcal{D}_\phi^+ \mathcal{D}_\phi = \mathcal{H}^+ \mathcal{H} = \mathcal{P}_{meas}$, the projector onto measurement space. Then we can apply a theorem quoted in Sec. 1.6.3 for the pseudoinverse of a product:

$$(\mathbf{X}\mathbf{Y})^+ = (\mathbf{X}^+ \mathbf{X}\mathbf{Y})^+ (\mathbf{X}\mathbf{Y}\mathbf{Y}^+)^+. \quad (15.54)$$

With this theorem and the assumption that $\{\phi_n\}$ is an orthonormal basis for measurement space, we can rewrite (15.53) as

$$\mathbf{H}^+ \mathbf{g} = [\mathcal{H}\mathcal{D}_\phi^+]^+ \mathcal{H} \mathbf{f} = \mathcal{D}_\phi \mathbf{f}. \quad (15.55)$$

In this special case, therefore, application of a matrix pseudoinverse to noise-free data yields scalar products of the object with the same expansion functions used to form \mathbf{H} . These scalar products are necessarily estimable parameters since the functions $\{\chi_n(\mathbf{r})\}$, which are the same as $\{\phi_n(\mathbf{r})\}$ in this case, lie entirely in measurement space.

Natural pixels and matrix pseudoinverses We can also use the natural pixels as expansion functions, which is how they were introduced by Buonocore *et al.* (1981). Since natural pixels span measurement space, we might expect them to simplify the calculations in much the same way as the singular functions of \mathcal{H} ; we give up the orthonormality but gain an advantage since the expansion functions are given up front and it is easy to compute \mathbf{H} .

If we take $\mathcal{D}_\phi = \mathcal{H}$ as in (15.32), the system matrix $\mathbf{H} = \mathcal{H}\mathcal{H}^\dagger$. In the absence of noise, application of \mathbf{H}^+ to \mathbf{g} yields

$$\hat{\boldsymbol{\theta}} = \mathbf{H}^+ \mathbf{g} = [\mathcal{H}\mathcal{H}^\dagger]^+ \mathcal{H} \mathbf{f} = \mathcal{H}^{\dagger+} \mathbf{f}, \quad (15.56)$$

where the last step follows from (1.148) with \mathcal{H} and \mathcal{H}^\dagger interchanged. The last form in (15.56) will be recognized as the $\boldsymbol{\theta}$ defined by the operator \mathcal{D}_χ given in (15.32). Thus application of the matrix pseudoinverse now yields the same result as a CD pseudoinverse followed by discretization as in (15.47).

Because \mathcal{D}_χ involves a pseudoinverse in this case, it is not easy to interpret the resulting parameters $\hat{\theta}_n$; in particular, they are not scalar products with natural pixels. We shall return to the interpretation of (15.56) in Sec. 15.2.2.

15.2.2 Reconstruction of functions from discrete data

Since the object of interest in most imaging situations is a function $f(\mathbf{r})$, one possible goal of image reconstruction would be to produce another function $\hat{f}(\mathbf{r})$ that resembles $f(\mathbf{r})$ in some way. If we have obtained estimates $\{\hat{\theta}_n\}$ of the expansion coefficients, a straightforward way to construct such an estimate is [cf. (15.6)]

$$\hat{f}(\mathbf{r}) = \sum_{n=1}^N \hat{\theta}_n \phi_n(\mathbf{r}), \tag{15.57}$$

or, in operator notation,

$$\hat{\mathbf{f}} = \mathcal{D}_\phi^\dagger \hat{\boldsymbol{\theta}}. \tag{15.58}$$

There is, however, no rule that says we have to use the functions $\{\phi_n(\mathbf{r})\}$ in this step; we could use some entirely different set $\{\psi_n(\mathbf{r})\}$ and define

$$\hat{\mathbf{f}} = \mathcal{D}_\psi^\dagger \hat{\boldsymbol{\theta}}. \tag{15.59}$$

For example, if we display a set of estimates $\{\hat{\theta}_n\}$ on a computer screen, the functions $\{\psi_n(\mathbf{r})\}$ might be uniform square pixels even if pixels played no role in defining $\{\theta_n\}$ in the first place.

Moreover, it may not be necessary to perform the intermediate step of estimating $\boldsymbol{\theta}$ at all. If $\hat{\boldsymbol{\theta}}$ is a linear function of \mathbf{g} , then the $\hat{\mathbf{f}}$ defined in (15.59) is also a linear function of \mathbf{g} , so we can write

$$\hat{\mathbf{f}} = \mathcal{O} \mathbf{g}, \tag{15.60}$$

where \mathcal{O} is a linear DC operator. Denoting the kernel of this operator as $o_m(\mathbf{r})$, we can write

$$\hat{f}(\mathbf{r}) = \sum_{m=1}^M g_m o_m(\mathbf{r}). \tag{15.61}$$

In this view, the reconstruction operator consists of the set of functions $\{o_m(\mathbf{r})\}$.

Backus-Gilbert method Backus and Gilbert (1968) proposed a method for obtaining pseudoinverses of CD operators without adopting any discrete object representation. They assumed that $\mathcal{H}\mathcal{H}^\dagger$ was invertible, or that $R = M$, but this assumption is not always warranted. Therefore the treatment here is based on the identity (1.149), which allows us to write

$$\mathcal{H}^+ \mathbf{g} = \mathcal{H}^\dagger \left[\mathcal{H}\mathcal{H}^\dagger \right]^+ \mathbf{g}. \tag{15.62}$$

Since $\mathcal{H}\mathcal{H}^\dagger$ is a matrix, its pseudoinverse can be computed by SVD (discussed later in this section) or by iterative methods (discussed in Secs. 1.7 and 15.4). Then, since \mathcal{H}^\dagger is a DC operator, a reconstructed image is given by

$$\hat{f}(\mathbf{r}) = [\mathcal{H}^+ \mathbf{g}](\mathbf{r}) = \sum_{n=1}^M [(\mathcal{H}\mathcal{H}^\dagger)^+ \mathbf{g}]_n h_n^*(\mathbf{r}) = \sum_{m=1}^M \sum_{n=1}^M [(\mathcal{H}\mathcal{H}^\dagger)^+]_{nm} g_m h_n^*(\mathbf{r}). \quad (15.63)$$

The last expression has the form of (15.61) with

$$o_m(\mathbf{r}) = \sum_{n=1}^M [(\mathcal{H}\mathcal{H}^\dagger)^+]_{nm} h_n^*(\mathbf{r}). \quad (15.64)$$

Thus a continuous reconstructed image can be obtained either by superimposing the functions $o_m(\mathbf{r})$ with data values g_m as weights or by superimposing the point response function $h_n(\mathbf{r})$ with pseudoinverse values $[(\mathcal{H}\mathcal{H}^\dagger)^+ \mathbf{g}]_n$ as weights.

Relation of Backus-Gilbert to natural pixels There is no need to select a discrete object representation in the Backus-Gilbert method, but it can be interpreted after the fact in terms of natural pixels. In fact, (15.63) is just the natural-pixel expansion formed by using the estimated coefficients $\{\hat{\theta}_n\}$ specified in (15.56). If we take the expansion functions $\{\phi_n(\mathbf{r})\}$ to coincide with the point response functions $\{h_n(\mathbf{r})\}$ (or their complex conjugates if the PRFs are complex), then $\mathcal{D}_\phi = \mathcal{H}$. The adjoint operator \mathcal{D}_ϕ^\dagger is then the same as \mathcal{H}^\dagger , which is often referred to as *back-projection*, especially in a tomographic context; it serves to project a vector in the M -dimensional data space back into the infinite-dimensional object space (see Sec. 7.3.2).

If we define \mathbf{H} as $\mathcal{H}\mathcal{H}^\dagger$ and apply its pseudoinverse to \mathbf{g} , we obtain

$$\hat{\mathbf{f}} = \mathcal{D}_\phi^\dagger \hat{\boldsymbol{\theta}} = \mathcal{H}^\dagger \hat{\boldsymbol{\theta}} = \mathcal{H}^\dagger [(\mathcal{H}\mathcal{H}^\dagger)^+ \mathbf{g}], \quad (15.65)$$

which is identical to the Backus-Gilbert result. To gain more insight into this result, suppose there is no noise so that $\mathbf{g} = \mathcal{H}\mathbf{f}$. Then we have

$$\hat{\mathbf{f}} = \mathcal{H}^\dagger [(\mathcal{H}\mathcal{H}^\dagger)^+ \mathcal{H}\mathbf{f}] = \mathcal{H}^+ \mathcal{H}\mathbf{f} = \mathbf{f}_{meas}, \quad (15.66)$$

where we have used (1.149) and (1.166). Thus either the natural-pixel estimate $\hat{\boldsymbol{\theta}}$ when backprojected into object space or the direct Backus-Gilbert estimate reduces in the no-noise limit to \mathbf{f}_{meas} , which is all we can ever expect from the given data.

SVD methods The Backus-Gilbert method can also be formulated in terms of singular-value decomposition (Bertero *et al.*, 1985, 1988). For background on SVD of CD operators, see Secs. 1.6.2 and 7.3.2.

From (1.131) we know that

$$\mathcal{H}^+ = \sum_{n=1}^R \frac{1}{\sqrt{\mu_n}} \mathbf{u}_n \mathbf{v}_n^\dagger, \quad (15.67)$$

where \mathbf{v}_n is an $M \times 1$ eigenvector of the matrix $\mathcal{H}\mathcal{H}^\dagger$, \mathbf{u}_n is an eigenfunction of the CC operator $\mathcal{H}^\dagger \mathcal{H}$, and μ_n is their common eigenvalue. If we can find the

eigenvectors of $\mathcal{H}\mathcal{H}^\dagger$ by numerical means, the eigenfunctions of $\mathcal{H}^\dagger\mathcal{H}$ corresponding to nonzero eigenvalues can be found by (7.253):

$$\frac{1}{\sqrt{\mu_n}} [\mathcal{H}^\dagger \mathbf{v}_n](\mathbf{r}) = u_n(\mathbf{r}), \quad n = 1, \dots, R. \quad (15.68)$$

Thus

$$\hat{f}(\mathbf{r}) \equiv [\mathcal{H}^+ \mathbf{g}](\mathbf{r}) = \sum_{n=1}^R \frac{1}{\sqrt{\mu_n}} (\mathbf{v}_n^\dagger \mathbf{g}) u_n(\mathbf{r}). \quad (15.69)$$

Since $\mathbf{v}_n^\dagger \mathbf{g}$ is just the coefficient β_n in an SVD expansion of \mathbf{g} , we see that we can get a pseudoinverse reconstruction by superimposing the eigenfunctions with weight $\beta_n/\sqrt{\mu_n}$.

Another way of looking at this result is to recall the SVD expansion for the original object $f(\mathbf{r})$:

$$f(\mathbf{r}) = \sum_{n=1}^{\infty} \alpha_n u_n(\mathbf{r}). \quad (15.70)$$

To put (15.69) in a similar format, we write

$$\hat{f}(\mathbf{r}) = \sum_{n=1}^R \hat{\alpha}_n u_n(\mathbf{r}), \quad (15.71)$$

where $\hat{\alpha}_n$ is an estimate of the coefficient α_n given by

$$\hat{\alpha}_n = \frac{\beta_n}{\sqrt{\mu_n}}, \quad n \leq R. \quad (15.72)$$

This estimate is plausible since we know from (1.209) that the imaging equation, $\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}$, in the SVD domain takes the form,

$$\beta_n = \sqrt{\mu_n} \alpha_n + \gamma_n, \quad (15.73)$$

where γ_n is a coefficient in the SVD expansion of \mathbf{n} . Thus

$$\hat{\alpha}_n = \alpha_n + \frac{\gamma_n}{\sqrt{\mu_n}}, \quad n \leq R, \quad (15.74)$$

so $\hat{\alpha}_n = \alpha_n$ for $n \leq R$ in the absence of noise. That means, once again, that $\hat{\mathbf{f}} = \mathbf{f}_{meas}$ in the no-noise limit. With noise, however, the second term in (15.74) can be quite large since μ_n will often be very small for n near R . Methods for dealing with this problem are discussed in Sec. 15.3.

15.2.3 Reconstruction from Fourier samples

Many imaging systems, including various optical interferometers and most magnetic resonance imagers, directly measure Fourier components of the object at discrete spatial frequencies. In this section we analyze such systems as a way of illustrating the ideas introduced in Sec. 15.2.2.

We assume throughout this section that the object $f(\mathbf{r})$ has finite support \mathbf{S}_f . If we define a support function $s(\mathbf{r})$ (not to be confused with the sensitivity function

used earlier) that takes the value 1 for points \mathbf{r} inside \mathbf{S}_f and zero for points outside, then $f(\mathbf{r})s(\mathbf{r}) = f(\mathbf{r})$. We now define a *Fourier sampler* as a CD system where

$$[\mathcal{H}\mathbf{f}]_m = \int_{\infty} d^q r s(\mathbf{r}) f(\mathbf{r}) \exp[-2\pi i \boldsymbol{\rho}_m \cdot \mathbf{r}], \quad (15.75)$$

where $\{\boldsymbol{\rho}_m, m = 1, \dots, M\}$ is a set of discrete frequencies at which the system takes measurements. There is no implication that these frequencies fall on a regular grid.

The kernel of \mathcal{H} is given by

$$h_m(\mathbf{r}) = s(\mathbf{r}) \exp[-2\pi i \boldsymbol{\rho}_m \cdot \mathbf{r}]. \quad (15.76)$$

The adjoint is given by

$$[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) = \sum_{m=1}^M g_m s(\mathbf{r}) \exp[2\pi i \boldsymbol{\rho}_m \cdot \mathbf{r}]. \quad (15.77)$$

The matrix $\mathcal{H}\mathcal{H}^\dagger$ has elements

$$[\mathcal{H}\mathcal{H}^\dagger]_{mk} = \int_{\infty} d^q r s(\mathbf{r}) \exp[-2\pi i (\boldsymbol{\rho}_m - \boldsymbol{\rho}_k) \cdot \mathbf{r}] = S(\boldsymbol{\rho}_m - \boldsymbol{\rho}_k), \quad (15.78)$$

where $S(\boldsymbol{\rho}) = \mathcal{F}_q\{s(\mathbf{r})\}$. If we define a matrix \mathbf{S} (not to be confused with the support set \mathbf{S}_f) with elements $S_{mk} = S(\boldsymbol{\rho}_m - \boldsymbol{\rho}_k)$, then

$$\mathcal{H}\mathcal{H}^\dagger = \mathbf{S}. \quad (15.79)$$

Since the Fourier transform of the support function is usually known analytically, it is straightforward to compute this matrix.

Pseudoinverse Depending on the choice of the sample frequencies $\{\boldsymbol{\rho}_m\}$, the matrix \mathbf{S} may be invertible, but in any case its pseudoinverse exists and can presumably be computed with no great difficulty. Then the pseudoinverse of \mathcal{H} can be calculated from (1.149), which in the present problem becomes

$$\mathcal{H}^+ = \mathcal{H}^\dagger (\mathcal{H}\mathcal{H}^\dagger)^+ = \mathcal{H}^\dagger \mathbf{S}^+. \quad (15.80)$$

A pseudoinverse reconstruction from a noise-free data vector \mathbf{g} is thus

$$[\mathcal{H}^+ \mathbf{g}](\mathbf{r}) = \sum_{m=1}^M [\mathbf{S}^+ \mathbf{g}]_m s(\mathbf{r}) \exp[2\pi i \boldsymbol{\rho}_m \cdot \mathbf{r}]. \quad (15.81)$$

We see that a superposition of plane waves, weighted by the values $[\mathbf{S}^+ \mathbf{g}]_m$ and truncated by the support function, gives $[\mathcal{H}^+ \mathbf{g}](\mathbf{r})$ at all points \mathbf{r} .

Van de Walle *et al.* (2001) have used this approach to reconstruct magnetic resonance images from Fourier samples on irregular grids.

Nyquist sampling Let us examine the solution (15.81) in the case where the Fourier samples fall on a regular grid and satisfy the Nyquist condition. (Recall from Sec. 3.5.4 that the Nyquist condition for sampling in the Fourier domain depends on the *spatial* support of the object; there is no need for the object to be bandlimited.)

If the support is a cube of side L and if the sampled frequencies fall on a cubic lattice of spacing $1/L$, then $S(\boldsymbol{\rho})$ is a q D sinc function, and $S(\boldsymbol{\rho}_m - \boldsymbol{\rho}_k)$ vanishes unless $m = k$, so we can write

$$[\mathcal{H}\mathcal{H}^\dagger]_{mk} = S_{mk} = L^q \delta_{mk}. \tag{15.82}$$

In this case, \mathbf{S} is proportional to the $M \times M$ unit matrix, so (15.81) becomes

$$[\mathcal{H}^+ \mathbf{g}](\mathbf{r}) = \frac{1}{L^q} \sum_{m=1}^M \mathbf{g}_m s(\mathbf{r}) \exp[2\pi i \boldsymbol{\rho}_m \cdot \mathbf{r}]. \tag{15.83}$$

Now all we have to do is superimpose truncated plane waves weighted by data values. If we are content to observe the resulting function on a regular grid of points, the final formula is precisely a multidimensional discrete Fourier transform as introduced in Sec. 3.6.6.

15.2.4 Discretization of analytic inverses

In many inverse problems, we would be able to perform the inverse if only we sampled finely enough. An example is computed tomography, where the data are samples of the Radon transform of a function. The inverse Radon transform was derived in Sec. 4.4, but it requires that we know the data for a continuous set of projection angles and as a function of a continuous variable at each angle; instead we know only a discrete set of data values.

Another example occurs when a system performs a linear shift-invariant operation on the object. We know that the system operator, in a CC sense, is then a convolution: $g(\mathbf{r}) = f(\mathbf{r}) * h(\mathbf{r})$. If we knew the full function $g(\mathbf{r})$, we could perform a Fourier transform, obtaining $G(\boldsymbol{\rho}) = H(\boldsymbol{\rho}) F(\boldsymbol{\rho})$, and then divide through by the transfer function $H(\boldsymbol{\rho})$ to get $F(\boldsymbol{\rho})$, at least for frequencies where $H(\boldsymbol{\rho}) \neq 0$. An inverse Fourier transform would then recover $f(\mathbf{r})$ or a good approximation to it. As in the Radon example, however, we need to consider what happens when we have available only a finite set of points from the convolution output and when we cannot neglect noise.

Consider the CC problem $\mathbf{y} = \mathcal{L}\mathbf{f}$, where \mathcal{L} is a nonsingular linear operator with a known inverse. Instead of observing the function \mathbf{y} , however, we observe a discrete, noisy data vector \mathbf{g} given by

$$\mathbf{g} = C \mathcal{D}_w \mathbf{y} + \mathbf{n}, \tag{15.84}$$

where C is a constant related to the sensitivity of the system and the exposure time, and \mathcal{D}_w is some appropriate discretization operator. In computed tomography, for example, the operator \mathcal{D}_w samples the projection angles and perhaps integrates over finite detector apertures. The discretization functions associated with \mathcal{D}_w are thus delta functions in angle and rect functions in the detector plane.

Since we have only a finite-dimensional data vector, we cannot determine the infinite-dimensional object; instead we attempt to estimate some vector related to \mathbf{f} by

$$\boldsymbol{\theta} = \mathcal{D}_\chi \mathbf{f}. \tag{15.85}$$

The discretization functions associated with \mathcal{D}_χ might, for example, be pixels.

Though we do not know \mathbf{y} , we can nevertheless write $\boldsymbol{\theta}$ as

$$\boldsymbol{\theta} = \mathcal{D}_\chi \mathcal{L}^{-1} \mathbf{y}. \tag{15.86}$$

We now insert the operator $\mathcal{D}_w^\dagger \mathcal{D}_w$ between \mathcal{L}^{-1} and \mathbf{y} and promptly subtract off the error we make in doing so; the result is

$$\boldsymbol{\theta} = \mathcal{D}_\chi \mathcal{L}^{-1} \mathcal{D}_w^\dagger \mathcal{D}_w \mathbf{y} + \mathcal{D}_\chi \mathcal{L}^{-1} [\mathbf{I} - \mathcal{D}_w^\dagger \mathcal{D}_w] \mathbf{y}. \quad (15.87)$$

We can now define a matrix \mathbf{O} by

$$\mathbf{O} = \mathcal{D}_\chi \mathcal{L}^{-1} \mathcal{D}_w^\dagger. \quad (15.88)$$

This matrix is a discretization of the (known) CC inverse operator \mathcal{L}^{-1} . Note that the discretization functions in the continuous data domain are generally different from those used in the object domain.

With this matrix, (15.87) becomes

$$\boldsymbol{\theta} = \mathbf{O} \mathcal{D}_w \mathbf{y} + \mathcal{D}_\chi \mathcal{L}^{-1} [\mathbf{I} - \mathcal{D}_w^\dagger \mathcal{D}_w] \mathbf{y}. \quad (15.89)$$

Comparison of the first term in this equation with (15.84) suggests that we define an estimate of $\boldsymbol{\theta}$ by

$$\hat{\boldsymbol{\theta}} = \frac{1}{C} \mathbf{O} \mathbf{g}. \quad (15.90)$$

Straightforward algebra shows that

$$\hat{\boldsymbol{\theta}} = \mathbf{O} \mathcal{D}_w \mathbf{y} + \frac{1}{C} \mathbf{O} \mathbf{n} = \boldsymbol{\theta} + \frac{1}{C} \mathbf{O} \mathbf{n} - \mathcal{D}_\chi \mathcal{L}^{-1} [\mathbf{I} - \mathcal{D}_w^\dagger \mathcal{D}_w] \mathcal{L} \mathbf{f}. \quad (15.91)$$

This reconstruction procedure thus gives the correct answer $\boldsymbol{\theta}$ plus a noise term plus an error term related to the discretization.

To understand the error term, recall from Sec. 7.1.3 that $\mathcal{D}_w^\dagger \mathcal{D}_w = \mathcal{D}_w^+ \mathcal{D}_w$ for orthonormal discretization functions. The operator $\mathcal{D}_w^\dagger \mathcal{D}_w$ is thus the projector onto the space spanned by the discretization functions [cf. (7.38)], and $\mathbf{I} - \mathcal{D}_w^\dagger \mathcal{D}_w$ is the projector onto its orthogonal complement. The error term is approximately zero if $\mathcal{D}_w^\dagger \mathcal{D}_w$ is a good approximation to the unit operator in the continuous data domain.

We must emphasize, however, that (15.91) is based on the data model (15.84); if that model is inaccurate, additional errors will arise. It is common to assume that data are described by simple discretization of an idealized CC operator, neglecting physical effects such as scattered radiation or detector blur. These effects must be taken into account when computing the overall error associated with some reconstruction matrix \mathbf{O} . In Chap. 17 we shall discuss both types of error in the context of emission computed tomography.

15.2.5 More on analytic inverses

In Sec. 15.2.4, we assumed that the inverse of the CC operator \mathcal{L} existed. Strictly speaking, all we really needed in that section was that the *left inverse* existed (see Sec. 1.3.4). In other words, we required that \mathcal{L} had no null functions so that we could retrieve \mathbf{f} uniquely from $\mathcal{L} \mathbf{f}$. In many cases of interest in imaging, especially in tomography, this condition is satisfied, but the adjoint operator \mathcal{L}^\dagger does have null functions. In the language of Sec. 1.5.2, there is a nontrivial *inconsistency space*. For such operators, as we shall now show, any continuous noise-free data must satisfy certain conditions called *consistency conditions*. As a consequence, the left inverse is not unique.

Consistency conditions Let $\tilde{v}_n(\mathbf{r}_d)$ denote a null function of \mathcal{L}^\dagger , and let $\tilde{\mathbf{v}}_n$ be the corresponding vector in the Hilbert space \mathbb{V} , so that

$$\mathcal{L}^\dagger \tilde{\mathbf{v}}_n = \mathbf{0}, \quad (15.92)$$

where $\mathbf{0}$ is a vector of zero length in object space \mathbb{U} . If we take the scalar product of this zero vector with any object \mathbf{f} , the result will be the scalar 0:

$$(\mathcal{L}^\dagger \tilde{\mathbf{v}}_n, \mathbf{f})_{\mathbb{U}} = 0. \quad (15.93)$$

By the definition of the adjoint [see (1.39)],

$$(\tilde{\mathbf{v}}_n, \mathcal{L}\mathbf{f})_{\mathbb{V}} = 0. \quad (15.94)$$

That is, if $\mathbf{g} = \mathcal{L}\mathbf{f}$ is a noise-free data vector, its scalar product with each of the $\tilde{\mathbf{v}}_n$ must vanish. Because of noise or other measurement errors, not all data vectors will satisfy these consistency conditions.

Varieties of left inverses It is common to preprocess a data vector before performing an inversion. If \mathcal{A} is a linear operator that maps data space \mathbb{V} to itself, the preprocessed data vector has the form

$$\mathbf{g}' = \mathcal{A}\mathbf{g}. \quad (15.95)$$

Applying \mathcal{L}^\dagger to the modified data vector \mathbf{g}' yields

$$\mathcal{L}^\dagger \mathbf{g}' = \mathcal{L}^\dagger \mathcal{A}\mathbf{g} = \mathcal{L}^\dagger \mathcal{A}\mathcal{L}\mathbf{f}, \quad (15.96)$$

where the latter form applies only in the noise-free case. Note that $\mathcal{L}^\dagger \mathcal{A}\mathcal{L}\mathbf{f}$ is in object space.

If we restrict \mathcal{A} so that $\mathcal{L}^\dagger \mathcal{A}\mathcal{L}$ is an invertible operator, then we can invert (15.96) to get

$$\mathbf{f} = [\mathcal{L}^\dagger \mathcal{A}\mathcal{L}]^{-1} \mathcal{L}^\dagger \mathcal{A}\mathbf{g}. \quad (15.97)$$

Thus any choice of \mathcal{A} satisfying the stated condition generates a left inverse. The reader may show that all of these inverses are identical if \mathcal{L}^\dagger has no null space.

Filtering before backprojection One interesting choice for \mathcal{A} is

$$\mathcal{A} = [\mathcal{L}\mathcal{L}^\dagger]^+. \quad (15.98)$$

With this choice, (15.96) becomes

$$\mathcal{L}^\dagger \mathcal{A}\mathbf{g} = \mathcal{L}^\dagger [\mathcal{L}\mathcal{L}^\dagger]^+ \mathbf{g} = \mathcal{L}^\dagger [\mathcal{L}\mathcal{L}^\dagger]^+ \mathcal{L}\mathbf{f}, \quad (15.99)$$

where the latter form is valid for noise-free data. By (1.149) we have

$$\mathcal{L}^\dagger \mathcal{A}\mathbf{g} = \mathcal{L}^+ \mathcal{L}\mathbf{f}, \quad (15.100)$$

which, without any assumptions on \mathcal{L} , is the measurement component of \mathbf{f} . If \mathcal{L} has no null functions, then

$$\mathcal{L}^\dagger \mathcal{A}\mathbf{g} = \mathbf{f}. \quad (15.101)$$

Thus no further filtering is required in object space when this \mathcal{A} is used; simple application of \mathcal{L}^\dagger to $\mathcal{A}\mathbf{g}$ yields \mathbf{f} .

As discussed in Sec. 4.4, \mathcal{L}^\dagger is referred to in the tomographic literature as *back-projection*, and (15.101) is an abstract formulation of the *filtered-backprojection* algorithm, with the data-space filter function given by (15.98). Explicit forms of this algorithm were given in Chap. 4.

The similarity between (15.99) and (15.62) should be noted; filtered backprojection is essentially the same thing as the Backus-Gilbert method, though the latter designation is usually restricted to reconstruction from discrete data, so of course the object is not recovered exactly.

15.2.6 Noise with linear reconstruction operators

All of the linear reconstruction operators discussed above were designed to extract the maximum possible information from a data set in the absence of noise. In the real world, of course, data are always corrupted by noise, and most of the art of image reconstruction is in developing ways to control that noise. In this section we begin to discuss the effects of noise on reconstructed images; the theme will continue throughout the chapter.

Discrete linear reconstructions Consider a linear CDD reconstruction problem in which an $N \times 1$ vector $\boldsymbol{\theta}$ of expansion coefficients is estimated by

$$\hat{\boldsymbol{\theta}} = \mathbf{O}\mathbf{g}, \quad (15.102)$$

where \mathbf{O} is an $N \times M$ matrix and \mathbf{g} is an $M \times 1$ data vector. Our objective is to derive the statistical properties of $\hat{\boldsymbol{\theta}}$ from those of \mathbf{g} .

For linear imaging systems, we know from (15.10) and (15.11) that \mathbf{g} can be expressed in two equivalent ways:

$$\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n} = \mathbf{H}\boldsymbol{\theta} + \boldsymbol{\epsilon}, \quad (15.103)$$

where \mathbf{n} describes the random measurement noise and $\boldsymbol{\epsilon}$ describes both measurement noise and modeling error. For present purposes the first of these forms is most useful since the properties of \mathbf{n} can be specified more easily than those of $\boldsymbol{\epsilon}$. In particular, \mathbf{n} is by definition a zero-mean random vector since $\mathcal{H}\mathbf{f}$ is the mean of \mathbf{g} for a particular object function \mathbf{f} . The vector $\boldsymbol{\epsilon}$, on the other hand, depends in a complicated way on the object and the system model.

Uncorrelated Gaussian noise In Chap. 12 we discussed a variety of noise mechanisms in radiation detectors. Many of these mechanisms, especially those discussed in Sec. 12.2, are well described by normal (Gaussian) statistics. If we have a discrete detector array dominated by one of these mechanisms, and if we assume that all elements in the array are identical and that each generates its own noise independently of the other elements, then a good description of the probability density function of \mathbf{n} may be

$$\text{pr}(\mathbf{n}) = (2\pi\sigma^2)^{-M/2} \prod_{m=1}^M \exp\left[-\frac{n_m^2}{2\sigma^2}\right]. \quad (15.104)$$

This form assumes that the mean of each component n_m is zero and that the variance of each is the same constant σ^2 . Thus the covariance matrix of \mathbf{n} is

$$\mathbf{K}_{\mathbf{n}} = \sigma^2 \mathbf{I}, \quad (15.105)$$

where \mathbf{I} is the $M \times M$ identity matrix. Using a notation introduced in Chap. 8, we say that $\mathbf{n} \sim \mathcal{N}(0, \sigma^2 \mathbf{I})$. In words, the noise is i.i.d. (independent, identically distributed) normal. The data vector itself is also independent normal but not zero mean; instead, $\mathbf{g} \sim \mathcal{N}(\mathcal{H}\mathbf{f}, \sigma^2 \mathbf{I})$.

We know from Sec. 8.3.3 that a linear transformation of a normal random vector yields another normal random vector. From (8.49) and (8.50), the mean and covariance of $\hat{\boldsymbol{\theta}}$ (both conditional on a specific \mathbf{f}) are given by

$$\mathbf{E}\{\hat{\boldsymbol{\theta}}|\mathbf{f}\} = \mathbf{O}\mathbf{E}\{\mathbf{g}|\mathbf{f}\} = \mathbf{O}\mathcal{H}\mathbf{f}, \quad (15.106)$$

$$\mathbf{K}_{\hat{\boldsymbol{\theta}}|\mathbf{f}} = \mathbf{O}\mathbf{K}_{\mathbf{n}}\mathbf{O}^\dagger = \sigma^2 \mathbf{O}\mathbf{O}^\dagger. \quad (15.107)$$

Thus $\hat{\boldsymbol{\theta}} \sim \mathcal{N}(\mathbf{O}\mathcal{H}\mathbf{f}, \sigma^2 \mathbf{O}\mathbf{O}^\dagger)$. To be precise, this normal distribution describes the conditional density $\text{pr}(\hat{\boldsymbol{\theta}}|\mathbf{f})$. The mean of this density depends on the actual object and the actual CD system operator \mathcal{H} , and it is generally not true that $\mathcal{H}\mathbf{f}$ equals $\mathbf{H}\boldsymbol{\theta}$, so we have not computed $\text{pr}(\hat{\boldsymbol{\theta}}|\boldsymbol{\theta})$. On the other hand, for fixed \mathbf{f} the modeling error is nonrandom, so $\mathbf{K}_{\mathbf{n}} = \mathbf{K}_{\boldsymbol{\epsilon}}$, and (15.107) is correct no matter how bad our system model is (so long as the noise model is correct).

In component form, the covariance matrix is

$$\left[\mathbf{K}_{\hat{\boldsymbol{\theta}}|\mathbf{f}}\right]_{nn'} = \mathbf{E}\{\Delta\hat{\theta}_n \Delta\hat{\theta}_{n'}|\mathbf{f}\} = \sigma^2 \sum_{m=1}^M O_{nm} O_{n'm}^*, \quad (15.108)$$

where $\Delta\hat{\theta}_n = \hat{\theta}_n - \mathbf{E}\{\hat{\theta}_n|\mathbf{f}\}$. The conditional variance of $\hat{\theta}_n$ then takes the simple form

$$\text{Var}\{\hat{\theta}_n|\mathbf{f}\} = \sigma^2 \left[\mathbf{O}\mathbf{O}^\dagger\right]_{nn} = \sigma^2 \sum_{m=1}^M |O_{nm}|^2. \quad (15.109)$$

Noise amplification — an example As an example of the formalism just developed, suppose that \mathbf{O} is the pseudoinverse of \mathbf{H} , which we can express in SVD form as

$$\mathbf{O} = \mathbf{H}^+ = \sum_{j=1}^R \frac{1}{\sqrt{\mu_j}} \mathbf{u}_j \mathbf{v}_j^\dagger, \quad (15.110)$$

where \mathbf{u}_j and \mathbf{v}_j are the singular vectors associated with \mathbf{H} . With this form, (15.107) becomes

$$\mathbf{K}_{\hat{\boldsymbol{\theta}}|\mathbf{f}} = \sigma^2 \mathbf{O}\mathbf{O}^\dagger = \sigma^2 \sum_{j=1}^R \frac{1}{\sqrt{\mu_j}} \mathbf{u}_j \mathbf{v}_j^\dagger \sum_{k=1}^R \frac{1}{\sqrt{\mu_k}} \mathbf{v}_k \mathbf{u}_k^\dagger. \quad (15.111)$$

Since $\mathbf{v}_j^\dagger \mathbf{v}_k = \delta_{jk}$ by the orthonormality of the singular vectors, we have

$$\mathbf{K}_{\hat{\boldsymbol{\theta}}|\mathbf{f}} = \sigma^2 \sum_{j=1}^R \frac{1}{\mu_j} \mathbf{u}_j \mathbf{u}_j^\dagger. \quad (15.112)$$

The conditional variance of the component $\hat{\theta}_n$ is given by

$$\text{Var} \{ \hat{\theta}_n | \mathbf{f} \} = [\mathbf{K}_{\hat{\theta} | \mathbf{f}}]_{nn} = \sum_{j=1}^R \frac{\sigma^2}{\mu_j} |u_{jn}|^2, \quad (15.113)$$

where u_{jn} is the n^{th} component of \mathbf{u}_j . Since μ_j decreases (often rapidly) as j increases, the variance is amplified because of division by small singular values.

Noise control in the SVD domain If we implement the pseudoinverse in the SVD domain, we can control the noise either by truncating the sum over j at some value less than R or by modifying the reconstruction operator in some way to avoid division by small μ_j . One possibility is to define

$$\mathbf{O} = \sum_{j=1}^R \frac{\sqrt{\mu_j}}{\mu_j + \eta} \mathbf{u}_j \mathbf{v}_j^\dagger, \quad (15.114)$$

where η is a positive constant. With this approach, the variance of $\hat{\theta}_n$ becomes

$$\text{Var} \{ \hat{\theta}_n \} = [\mathbf{K}_{\hat{\theta}}]_{nn} = \sum_{j=1}^R \frac{\sigma^2 \mu_j}{(\mu_j + \eta)^2} |u_{jn}|^2. \quad (15.115)$$

This option reduces the noise since the denominator is not allowed to approach zero; larger values for η lead to smaller variances. (Recall from Chap. 1 that μ_j is real and greater than zero for $j \leq R$.)

The use of a large η suppresses the singular components corresponding to small μ_j . These components usually correspond to fine details in the image since most imaging systems function essentially as low-pass filters, showing smaller response to higher spatial frequencies. Thus use of a large η will limit the spatial resolution in the reconstructed image. As with virtually any inverse problem, there is a parameter that sets the tradeoff between noise and resolution. (It would be a mistake, however, to assert that η sets the tradeoff between bias and variance; as we have seen in Sec. 15.1, bias is usually not well defined, and setting $\eta = 0$ seldom produces an unbiased estimate of anything.)

Noise control by smoothing Another way to control the noise with any reconstruction operator \mathbf{O} is to smooth the image after reconstruction. A Hermitian smoothing operator in the discrete reconstruction space is an $N \times N$ matrix \mathbf{S} satisfying $\mathbf{S}^\dagger = \mathbf{S}$. For simplicity, assume that \mathbf{S} commutes with $\mathbf{H}^\dagger \mathbf{H}$; in that case, as we saw in Chap. 6, \mathbf{S} is diagonal in the basis formed by the right singular vectors of \mathbf{H} , and we can write

$$\mathbf{S} = \sum_{j=1}^N s_j \mathbf{u}_j \mathbf{u}_j^\dagger. \quad (15.116)$$

For \mathbf{S} to serve as a smoothing filter, we should take s_j to be positive and to decrease with increasing j .

If we apply this operator after the reconstruction operator \mathbf{O} , we get

$$\hat{\theta}' = \mathbf{S} \hat{\theta} = \mathbf{S} \mathbf{O} \mathbf{g}. \quad (15.117)$$

For the example used above, where $\mathbf{O} = \mathbf{H}^+$, we have

$$\mathbf{SO} = \sum_{j=1}^R \frac{s_j}{\sqrt{\mu_j}} \mathbf{u}_j \mathbf{v}_j^\dagger. \quad (15.118)$$

The rolloff of s_j with increasing j can be used to counteract the noise amplification associated with small μ_j , but of course it also limits the fine detail in the image.

An advantage of post-reconstruction smoothing is that we can implement it without knowing the SVD of \mathbf{H} or \mathbf{O} . Any Hermitian operator, including simple discrete convolution with a nonnegative blur function, will serve to limit the noise amplification. Conversely, any modification of the SVD pseudoinverse that controls the noise can be interpreted as an equivalent smoothing operator. For example, (15.114) and (15.118) are identical if we take $s_j = \mu_j / (\mu_j + \eta)$.

Apodization A common name for a smoothing filter, especially when it is incorporated in the reconstruction operator, is *apodizing function*. In zoology, *apodal* means without feet, so to apodize is to cut off the feet. In the early development of radar, it was observed that some cutoff in the temporal frequency response was needed to control noise, but that a sharp cutoff led to sidelobes (feet) on the impulse response. Since these sidelobes could be confused with weak targets adjacent to a strong one, a smooth rolloff of the frequency response was found to be preferable to an abrupt cutoff. Much research has gone into studying the effects of different apodizing functions on target detection, and many of the filters developed for radar have found use in tomographic image reconstruction as well.

Poisson noise The discussion above requires some modification if the noise is Poisson rather than i.i.d. normal. As discussed in detail in Sec. 11.2, it is often an excellent model for an array of photon-counting detectors to assume that the components of \mathbf{g} are independent Poisson, so that the covariance matrix is given by

$$[\mathbf{K}_{\mathbf{g}|\mathbf{f}}]_{mm'} = [\mathcal{H}\mathbf{f}]_m \delta_{mm'}. \quad (15.119)$$

With this covariance for the data, the covariance and variance in the reconstruction are [cf. (15.108) and (15.109)]

$$[\mathbf{K}_{\hat{\boldsymbol{\theta}}|\mathbf{f}}]_{nn'} = \sum_{m=1}^M [\mathcal{H}\mathbf{f}]_m O_{nm} O_{n'm}^*, \quad (15.120)$$

$$\text{Var} \{ \hat{\theta}_n | \mathbf{f} \} = \sum_{m=1}^M [\mathcal{H}\mathbf{f}]_m |O_{nm}|^2. \quad (15.121)$$

With Poisson noise, we cannot say rigorously that $\hat{\boldsymbol{\theta}}$ is normally distributed, but a normal distribution is usually an excellent approximation, for two reasons. First, if $[\mathcal{H}\mathbf{f}]_m$ is large (greater than 10 or so), the Poisson can be well approximated by a Gaussian with variance equal mean. In that case, the reconstruction is a linear transformation of a normal random vector, yielding another normal random vector. Second, even if some of the $[\mathcal{H}\mathbf{f}]_m$ are small, $\hat{\boldsymbol{\theta}}$ may still be approximately normal as the result of the central-limit theorem. A linear reconstruction is equivalent to forming a weighted sum of the data values. The weighting changes the mean

and variance, but as we discussed in Sec. 8.3.4 any sum of independent random variables, not necessarily identically distributed ones, tends to a normal under broad conditions [see (8.211) *ff.* and Shiriyayev (1984)]. Since Poisson random variables are inherently independent, we should expect to get a good approximation to a normal when the reconstruction operator serves to add many Poisson data values with some weights. Moreover, strict independence is also not required for the central-limit theorem (Shiryayev, 1984), so a normal distribution for $\hat{\theta}$ can result from linear reconstruction with almost any data statistics.

Noise kernel and point response The variance expression for Poisson noise, (15.121), can be rewritten as

$$\text{Var} \{ \hat{\theta}_n | \mathbf{f} \} = \int_{\mathbf{s}_f} d^q r \, \aleph_n(\mathbf{r}) f(\mathbf{r}), \quad (15.122)$$

where

$$\aleph_n(\mathbf{r}) \equiv \sum_{m=1}^M |O_{nm}|^2 h_m(\mathbf{r}). \quad (15.123)$$

Because of the Poisson character of the noise and the linearity of the processing algorithm, there is a linear CD mapping from the object $f(\mathbf{r})$ to the variance in the reconstructed discrete image. The kernel of this mapping, $\aleph_n(\mathbf{r})$, is called the *noise kernel* (Barrett and Swindell, 1981, 1996). We emphasize that this linear mapping from object to variance holds only for Poisson noise where the noise covariance is given by (15.119). From (15.108), for example, we see that the variance in the reconstruction is independent of the object for the noise model of (15.105).

Equations (15.122) and (15.123) should be compared to similar expressions for the mean:

$$\bar{\theta}_n = \int_{\mathbf{s}_f} d^q r \, p_n(\mathbf{r}) f(\mathbf{r}), \quad (15.124)$$

where

$$p_n(\mathbf{r}) \equiv \sum_{m=1}^M O_{nm} h_m(\mathbf{r}). \quad (15.125)$$

Thus $p_n(\mathbf{r})$ is the overall CD point response function (PRF) mapping the object function through the CD system and the DD processing algorithm to the mean discrete image.

The formal difference between the noise kernel and the PRF is that $|O_{nm}|^2$ appears in the former and O_{nm} in the latter. In more practical terms, O_{nm} can have both positive and negative values and hence the filter can serve a sharpening function. In the noise kernel, on the other hand, $|O_{nm}|^2$ is confined to nonnegative values, so the variance distribution will be a blurred and discretized version of the object. We shall explore the nature of the noise kernel further in Sec. 17.3 in the context of emission computed tomography.

15.3 IMPLICIT ESTIMATES

As we noted in Sec. 15.1.1, image reconstruction is often framed in terms of minimization of a scalar-valued objective functional. The resulting images are often

referred to as *implicit estimates* or *implicit reconstructions* since there is no explicit formula for generating them. In Sec. 15.4 we shall discuss iterative algorithms for finding implicit estimates, but in this section we study some of their properties without regard to any particular algorithm.

15.3.1 Functional minimization

As given in (15.4), the objective functional depends on the data vector \mathbf{g} and the object \mathbf{f} , where the latter notation implies a vector in an infinite-dimensional Hilbert space. As we shall see in Sec. 15.3.5, it is indeed possible to carry out this minimization and find a continuous estimate $\hat{\mathbf{f}}$ without ever adopting a discrete representation, but it is much more common in the literature to first choose a discretization and then minimize with respect to the free parameters in that representation. With a linear representation like (15.6), then, the functional is redefined so that it depends on the coefficient vector $\boldsymbol{\theta}$ rather than the function \mathbf{f} .

An important consideration in choosing the objective functional is that it should encourage agreement between the actual measured data vector \mathbf{g} and the approximate data vector \mathbf{g}_a generated when the exact system operator operates on an approximate object representation. For a linear system, we know from (7.302) and (7.305) that $\mathbf{g}_a = \mathcal{H}\mathbf{f}_a = \mathbf{H}\boldsymbol{\theta}$, where \mathbf{H} is a matrix. A key component of the objective functional is thus some measure of the distance in data space between \mathbf{g} and $\mathbf{H}\boldsymbol{\theta}$, so we are led to define a *data-agreement functional* $Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta})$. In least-squares methods, this functional is just the squared Euclidean distance $\|\mathbf{g} - \mathbf{H}\boldsymbol{\theta}\|^2$, but many other choices are also possible. We shall survey some of them in Sec. 15.3.2.

Another key component of the functional is some means of controlling noise amplification. As we saw in Secs. 1.7.5 and 15.2.6, forcing exact agreement with the data is equivalent to dividing by small singular values, and any noise or other error in the data is thus multiplied by large numbers. One way of controlling this noise is to add another functional, called the *regularizing functional* to $Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta})$. Most often the regularizing functional depends only on $\boldsymbol{\theta}$, so we write

$$Q(\boldsymbol{\theta}, \mathbf{g}) = Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) + \eta Q_{reg}(\boldsymbol{\theta}). \quad (15.126)$$

The parameter η adjusts the relative weights of the two functionals and hence serves to control the tradeoff between data agreement and noise amplification. Several common forms for $Q_{reg}(\boldsymbol{\theta})$ will be discussed in Sec. 15.3.3.

Given the data-agreement and regularizing functionals, there are four distinct ways in which they can be used. The most common is simply to minimize $Q(\boldsymbol{\theta}, \mathbf{g})$, so that the estimate of $\boldsymbol{\theta}$ is given by

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta}}{\operatorname{argmin}} [Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) + \eta Q_{reg}(\boldsymbol{\theta})]. \quad (15.127)$$

If $Q(\boldsymbol{\theta}, \mathbf{g})$ is a strictly convex function of $\boldsymbol{\theta}$ for fixed \mathbf{g} , then the estimate $\hat{\boldsymbol{\theta}}$ defined by (15.127) will be unique. It will, however, be a random vector since different realizations of \mathbf{g} will yield different $\hat{\boldsymbol{\theta}}$.

The other three approaches use Q_{data} and Q_{reg} separately rather than in the sum $Q(\boldsymbol{\theta}, \mathbf{g})$. For example, we could minimize $Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta})$ subject to the constraint that $Q_{reg}(\boldsymbol{\theta})$ is less than some preset constant δ . Alternatively, we could

minimize $Q_{reg}(\boldsymbol{\theta})$ subject to a similar constraint on $Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta})$. Finally, we could minimize $Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta})$ subject to the constraint that $\boldsymbol{\theta}$ belong to some subset of its possible values. Given the freedom in choice of $Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta})$, $Q_{reg}(\boldsymbol{\theta})$ and the parameter η , there does not seem to be any particular advantage to these alternatives (other than possibly fitting into unexplored niches in the literature), so we shall confine our attention here to estimates of the form (15.127).

Positivity As discussed in Sec. 15.1.4, we often know on physical grounds that the object cannot be negative, and we may want to incorporate this information into our reconstruction. The easiest way to do so is to first choose our expansion functions $\phi_n(\mathbf{r})$ to be nonnegative and then to allow only nonnegative coefficients, $\theta_n \geq 0$ for all n . We can state the latter condition in vector form as $\boldsymbol{\theta} \geq 0$. With this constraint, we can restate the minimization principle as

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta} \geq 0}{\operatorname{argmin}} [Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) + \eta Q_{reg}(\boldsymbol{\theta})] . \quad (15.128)$$

This simple modification may require substantial changes in the algorithm used to find the minimum, a topic taken up in Sec. 15.4.

Inversions from nonlinear data As written, (15.127) and (15.128) are applicable only to linear systems for which the system operator \mathcal{H} can be approximated by a matrix, but they are easily modified to apply to any of the nonlinear systems discussed in Sec. 7.5. Let us write the noise-free mapping from object to image data as

$$\mathbf{g} = \mathcal{N}\{\mathbf{f}\} , \quad (15.129)$$

where \mathcal{N} is some nonlinear operator². For example, in electrical impedance tomography, \mathcal{N} represents the mapping by way of the Poisson equation from the object impedance to the voltages at a set of surface points for specified current sources.

If we use (15.7) to construct an approximate object representation, then the data-agreement functional can be chosen to enforce agreement between \mathbf{g} and the approximate data vector \mathbf{g}_a given by

$$\mathbf{g}_a = \mathcal{N}\{\mathbf{f}_a\} = \mathcal{N}\{\mathcal{D}_\phi^\dagger \boldsymbol{\theta}\} . \quad (15.130)$$

Thus (15.127) becomes

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta}}{\operatorname{argmin}} [Q_{data}(\mathbf{g}, \mathcal{N}\{\mathcal{D}_\phi^\dagger \boldsymbol{\theta}\}) + \eta Q_{reg}(\boldsymbol{\theta})] . \quad (15.131)$$

The same functional form for $Q_{data}(\mathbf{g}, \cdot)$ can be used for the linear and nonlinear cases, though it may be more work to compute it if the system is nonlinear. For example, a least-squares form is commonly used with nonlinear mappings, but computation of $\mathcal{N}\{\mathcal{D}_\phi^\dagger \boldsymbol{\theta}\}$ for a single $\boldsymbol{\theta}$ may require numerical solution of a differential equation.

Bayesian interpretation The estimate defined in (15.127) or (15.131) can be interpreted as a Bayesian MAP estimate as introduced in Sec. 13.3.3. We saw there that the MAP estimate maximizes the log posterior, or

²The boldface \mathcal{N} should not be confused with the symbol \mathcal{N} used to signify a normal distribution.

$$\hat{\boldsymbol{\theta}}_{MAP} = \underset{\boldsymbol{\theta}}{\operatorname{argmax}} \{ \ln[\operatorname{pr}(\mathbf{g}|\boldsymbol{\theta})] + \ln[\operatorname{pr}(\boldsymbol{\theta})] \} . \quad (15.132)$$

The first term agrees with (15.127) if we ignore issues of estimability and modeling error and write the likelihood as

$$\operatorname{pr}(\mathbf{g}|\boldsymbol{\theta}) = \frac{1}{Z_1} \exp[-Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta})] , \quad (15.133)$$

where Z_1 is a normalizing constant required to make $\operatorname{pr}(\mathbf{g}|\boldsymbol{\theta})$ a probability density function (or probability if \mathbf{g} is discrete). The log-likelihood can now be written as

$$\ln[\operatorname{pr}(\mathbf{g}|\boldsymbol{\theta})] = -Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) - \ln(Z_1) . \quad (15.134)$$

Note that $\boldsymbol{\theta}$ appears here only as $\mathbf{H}\boldsymbol{\theta}$ since $\boldsymbol{\theta}$ can influence the likelihood only through its effect on the data vector.

Similarly, we can write an arbitrary prior as

$$\operatorname{pr}(\boldsymbol{\theta}) = \frac{1}{Z_2} \exp[-\eta Q_{reg}(\boldsymbol{\theta})] , \quad (15.135)$$

so that

$$\ln[\operatorname{pr}(\boldsymbol{\theta})] = -\eta Q_{reg}(\boldsymbol{\theta}) - \ln(Z_2) . \quad (15.136)$$

The minus signs in (15.134) and (15.136) convert argmax to argmin , and the logs of the normalizing constants do not affect the argmin . Thus minimization of any functional of the form (15.127) or (15.131) can be interpreted as maximizing a log-posterior. This observation reinforces the Bayesian conceit that any reasonable estimation procedure can be interpreted as a Bayesian method with respect to some prior.

It is not possible, however, to interpret (15.135) in frequentist terms since it depends on the free parameter η , which is often called a *hyperparameter*. If $\operatorname{pr}(\boldsymbol{\theta})$ is to represent the frequency of occurrence of $\boldsymbol{\theta}$, its form and any parameters in it must be determined (according to the frequentist) by direct observations of the random vector $\boldsymbol{\theta}$. The parameter η , on the other hand, is set by the user of an inversion algorithm as a means of controlling noise, and its value can (and usually does) vary from image to image. A true frequentist prior distribution on the object would be independent of noise in any particular image. A true Bayesian would consider this point irrelevant and assert that one can choose any prior that reflects one's degree of belief, which may be influenced by noise, whim or any other factor. Key among these factors is often mathematical simplicity since the Bayesian, like the frequentist faced with the same inversion problem, must eventually find the minimum of a complicated functional. One believes in what one can compute.

To reiterate a point from Sec. 15.1.5, the authors of this book believe in objective, task-based assessment of image quality, so their prior is one that maximizes task performance. Instead of being established prior to data collection, the prior/regularizer in this pragmatist view is determined essentially by what one wants to do with the data after acquisition.

Bayesians and modeling In Sec. 15.3.2, we shall give specific mathematical forms for $\operatorname{pr}(\mathbf{g}|\boldsymbol{\theta})$, but in fact we rarely know this density. The difficulty is that the data statistics are not determined by $\boldsymbol{\theta}$ alone. As we emphasized in Chap. 7 and

reiterated in Sec. 15.1.2, the mean of \mathbf{g} is given by two terms, $\mathbf{H}\boldsymbol{\theta} + \mathcal{H}\delta\mathbf{f}$. In image reconstruction we often assume that we can ignore the second term, but it is worthwhile to try to articulate just what prior knowledge we are assuming when we do so.

Let $\mathbf{f} = \mathbf{f}_a + \mathbf{f}_\perp$, where \mathbf{f}_\perp is the component of \mathbf{f} in the (infinite-dimensional) orthogonal complement of representation space. Then

$$\Pr(\mathbf{g}|\boldsymbol{\theta}) = \Pr(\mathbf{g}|\mathbf{f}_a) = \int_{\mathbb{U}_\perp} d\mathbf{f}_\perp \Pr(\mathbf{g}|\mathbf{f}_a, \mathbf{f}_\perp) \text{pr}(\mathbf{f}_\perp). \quad (15.137)$$

Hence, setting $\Pr(\mathbf{g}|\boldsymbol{\theta}) = \Pr(\mathbf{g}|\mathbf{f})$ is equivalent to adopting the prior that \mathbf{f}_\perp is zero. With this assumption, $\bar{\mathbf{g}} = \mathbf{H}\boldsymbol{\theta}$, and simple forms for the density $\Pr(\mathbf{g}|\boldsymbol{\theta})$ follow.

As with many other Bayesian priors, this one should more accurately be called a prior desire rather than prior knowledge. We desire a solution where the modeling error can be neglected (since otherwise we cannot solve the problem). Again, the usefulness of this desire can be ascertained by task-based assessment methods.

15.3.2 Data-agreement functionals

In this section we survey a variety of data-agreement functionals that have been used in the literature and comment on how each is related to a likelihood model.

Agreement in the least-squares sense The simplest data-agreement functional is the \mathbb{L}_2 norm of the difference between \mathbf{g} and $\mathbf{H}\boldsymbol{\theta}$. As discussed in detail in Sec. 1.7, this choice leads to least-squares solutions of the set of linear equations $\mathbf{g} = \mathbf{H}\boldsymbol{\theta}$.

As a log-likelihood, the least-squares functional stems from an independent Gaussian noise model. Suppose we write

$$\mathbf{g} = \mathbf{H}\boldsymbol{\theta} + \boldsymbol{\epsilon} \quad (15.138)$$

and (ignoring modeling errors) assume that $\boldsymbol{\epsilon}$ is an $M \times 1$ multivariate normal random vector with zero mean and covariance matrix $\sigma^2\mathbf{I}$. Then the likelihood is given by

$$\text{pr}(\mathbf{g}|\boldsymbol{\theta}) = (2\pi\sigma^2)^{-\frac{1}{2}M} \exp\left[-\frac{1}{2\sigma^2} \sum_{m=1}^M [g_m - (\mathbf{H}\boldsymbol{\theta})_m]^2\right]. \quad (15.139)$$

The corresponding log-likelihood is

$$\ln[\text{pr}(\mathbf{g}|\boldsymbol{\theta})] = -\frac{1}{2}M \ln(2\pi\sigma^2) - \frac{1}{2\sigma^2} \sum_{m=1}^M [g_m - (\mathbf{H}\boldsymbol{\theta})_m]^2. \quad (15.140)$$

From (15.134), we have

$$Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) = \frac{1}{2\sigma^2} \sum_{m=1}^M [g_m - (\mathbf{H}\boldsymbol{\theta})_m]^2. \quad (15.141)$$

The multiplicative constant $1/(2\sigma^2)$ does not affect the position of the minimum as a function of $\boldsymbol{\theta}$, so we may as well write

$$Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) = \sum_{m=1}^M [g_m - (\mathbf{H}\boldsymbol{\theta})_m]^2 = \|\mathbf{g} - \mathbf{H}\boldsymbol{\theta}\|^2, \quad (15.142)$$

which is the usual least-squares form.

Weighted least-squares In least-squares problems we may know that some measurements are more reliable than others, so we weight them more heavily. For example, suppose the components of ϵ are independent normals with different variances. Then the covariance matrix of ϵ is given by

$$[\mathbf{K}_\epsilon]_{mm'} = \sigma_m^2 \delta_{mm'}, \quad (15.143)$$

and an argument similar to one just given shows that

$$Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) = \sum_{m=1}^M \frac{[g_m - (\mathbf{H}\boldsymbol{\theta})_m]^2}{\sigma_m^2}. \quad (15.144)$$

More generally, when ϵ is a real-valued normal random vector with covariance \mathbf{K}_ϵ , we find

$$Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) = (\mathbf{g} - \mathbf{H}\boldsymbol{\theta})^t \mathbf{K}_\epsilon^{-1} (\mathbf{g} - \mathbf{H}\boldsymbol{\theta}). \quad (15.145)$$

This is still an \mathbb{L}_2 norm, but now one defined with respect to the weight \mathbf{K}_ϵ^{-1} .

An interesting way to rewrite (15.145) is

$$Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) = \left[\mathbf{K}_\epsilon^{-\frac{1}{2}} (\mathbf{g} - \mathbf{H}\boldsymbol{\theta}) \right]^t \left[\mathbf{K}_\epsilon^{-\frac{1}{2}} (\mathbf{g} - \mathbf{H}\boldsymbol{\theta}) \right] = \|\mathbf{K}_\epsilon^{-\frac{1}{2}} (\mathbf{g} - \mathbf{H}\boldsymbol{\theta})\|^2, \quad (15.146)$$

where $\mathbf{K}_\epsilon^{-\frac{1}{2}}$ is the prewhitening matrix discussed in Secs. 8.1.6 and 13.2.8. Thus the data-agreement functional with any normal model for the noise is the \mathbb{L}_2 norm of the prewhitened residual vector.

Gaussian approximation to Poisson likelihood One important situation where (15.144) is used is when the data vector is Poisson but the mean number of counts per measurement is large, say greater than about 10. In that case, it is an excellent approximation to ignore the discrete nature of the data and consider each g_m to be a normal random variable with conditional mean $(\mathbf{H}\boldsymbol{\theta})_m$ (Barrett and Swindell, 1981, 1996). As we emphasized repeatedly in Chap. 11, Poisson random variables are inherently independent, so the covariance of (15.143) applies with $\sigma_m^2 = (\mathcal{H}\boldsymbol{\theta})_m \simeq (\mathbf{H}\boldsymbol{\theta})_m$, and (15.144) becomes

$$Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) = \sum_{m=1}^M \frac{[g_m - (\mathbf{H}\boldsymbol{\theta})_m]^2}{(\mathbf{H}\boldsymbol{\theta})_m}. \quad (15.147)$$

This functional is no longer quadratic in $\boldsymbol{\theta}$, so it does not, strictly speaking, correspond to a least-squares problem. However, to the same degree of approximation that allowed us to replace the Poisson with a Gaussian in the first place, we can replace $(\mathbf{H}\boldsymbol{\theta})_m$ with the observed g_m in the denominator, yielding

$$Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) = \sum_{m=1}^M \frac{[g_m - (\mathbf{H}\boldsymbol{\theta})_m]^2}{g_m}, \quad (15.148)$$

which is now quadratic in $\boldsymbol{\theta}$.

Even though g_m will only rarely go to zero if $(\mathbf{H}\boldsymbol{\theta})_m \gg 1$, as we assumed in deriving (15.148), it is nevertheless good programming practice to avoid division by zero, either by a conditional statement or by adding some small constant to the denominator.

Kullback-Leibler distance Of course, it is not necessary to approximate a Poisson by a Gaussian. For independent Poisson data, the log-likelihood is given exactly by

$$\begin{aligned} \ln[\text{pr}(\mathbf{g}|\boldsymbol{\theta})] &= \ln \prod_{m=1}^M \left\{ \exp[-(\mathbf{H}\boldsymbol{\theta})_m] \frac{[(\mathbf{H}\boldsymbol{\theta})_m]^{g_m}}{g_m!} \right\} \\ &= \sum_{m=1}^M \{ -(\mathbf{H}\boldsymbol{\theta})_m + g_m \ln[(\mathbf{H}\boldsymbol{\theta})_m] - \ln(g_m!) \}. \end{aligned} \quad (15.149)$$

Since $\ln(g_m!)$ is a constant that does not affect the minimization, we can write

$$Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) = \sum_{m=1}^M \{ (\mathbf{H}\boldsymbol{\theta})_m - g_m \ln[(\mathbf{H}\boldsymbol{\theta})_m] \}. \quad (15.150)$$

This form is closely related to the *Kullback-Leibler distance*, defined by³

$$D_{KL}(\mathbf{g}, \mathbf{g}_0) \equiv \sum_{m=1}^M \left\{ (g_{0m} - g_m + g_m \ln \left[\frac{g_m}{g_{0m}} \right]) \right\}. \quad (15.151)$$

Thus

$$Q_{data}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) = D_{KL}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta}) + \text{const}. \quad (15.152)$$

The Kullback-Leibler distance is also known as Csiszár's *I-divergence* or the *cross-entropy*. It is not truly a distance metric, as defined in Sec. 1.1.2, since $D_{KL}(\mathbf{g}, \mathbf{g}_0) \neq D_{KL}(\mathbf{g}_0, \mathbf{g})$. Instead, it is an example of a *generalized distance* or *Bregman distance*. The Kullback-Leibler distance will form the basis for the *expectation-maximization* algorithm to be discussed in Sec. 15.4.6.

15.3.3 Regularizing functionals

This section surveys some choices for the regularizing functional and discusses how each is related to a Bayesian prior.

Tikhonov regularization We encountered one example of a regularizing functional in Chap. 1, though we did not call it that. In Sec. 1.7.5 we introduced the minimum-norm, least-squares (MNLS) solution of $\mathbf{g} = \mathbf{H}\boldsymbol{\theta}$ as the unique least-squares solution with no null functions. Alternatively, we could have defined it as [cf. (1.191)]

$$\hat{\boldsymbol{\theta}}_{MNLS} = \lim_{\eta \rightarrow 0} \underset{\boldsymbol{\theta}}{\text{argmin}} \{ \|\mathbf{g} - \mathbf{H}\boldsymbol{\theta}\|^2 + \eta \|\boldsymbol{\theta}\|^2 \}. \quad (15.153)$$

As an exercise, the reader should show that

$$\hat{\boldsymbol{\theta}}_{MNLS} = \mathbf{H}^+ \mathbf{g}, \quad (15.154)$$

just as we found in Sec. 1.7.5.

³The sharp-eyed reader might note that a slightly different definition of the Kullback-Leibler distance was given in (8.258), but in that case it was a distance between two probability density functions. If we required g_m and g_{0m} to sum to unity, then (15.151) would reduce to (8.258).

We also showed in Sec. 1.7.5, however, that the MNLS solution is very noisy since we are forced, in the limit $\eta \rightarrow 0$, to divide by very small singular values. An interesting *ad hoc* solution to this problem is simply to forgo the limit and write

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta}}{\operatorname{argmin}} \{ \|\mathbf{g} - \mathbf{H}\boldsymbol{\theta}\|^2 + \eta\|\boldsymbol{\theta}\|^2 \} . \quad (15.155)$$

We have dropped the subscript MNLS here since this $\hat{\boldsymbol{\theta}}$ is not a least-squares solution. For nonzero η , the regularizing term $\eta\|\boldsymbol{\theta}\|^2$ drags the estimate away from the least-squares point, suppressing noise in the process.

In fact, we have already analyzed the noise in this problem. An extension of the discussion in Sec. 1.7.5 shows that (15.155) has the solution,

$$\hat{\boldsymbol{\theta}} = (\mathbf{H}^t\mathbf{H} + \eta\mathbf{I})^{-1}\mathbf{H}^t\mathbf{g} . \quad (15.156)$$

By using SVD relations derived in Chap. 1, we can show that this reconstruction operator is exactly the one stated in the SVD domain in (15.114). Thus the modification of the denominator in (15.114) to avoid division by zero is also accomplished implicitly by this regularizer.

The functional $\|\boldsymbol{\theta}\|^2$ is widely known as the *Tikhonov regularizer* since its properties have been studied in many contexts by A. N. Tikhonov. Tikhonov's original work was published in the Soviet Union during World War II (Tikhonov, 1943), but more recent accounts are given by Tikhonov and Arsenin (1979) and Morosov (1993).

Tikhonov and Bayes The Tikhonov regularizer can be interpreted as a Bayesian prior. From (15.135) we have

$$\operatorname{pr}(\boldsymbol{\theta}) = \frac{1}{Z_2} \exp[-\eta\|\boldsymbol{\theta}\|^2] , \quad (15.157)$$

which implies that the components of $\boldsymbol{\theta}$ are independent, zero mean normals, each with variance $1/(2\eta)$.

In frequentist terms, this result is quite puzzling. Suppose, for example, that the coefficients $\{\theta_n\}$ represent pixel values in a discrete object representation. There is no reason to expect *a priori* that these pixels would be normally distributed, and even if they were, they would hardly be zero-mean or uncorrelated. The zero mean implies that negative values are as probable as positive ones, even though in most situations θ_n is constrained to be nonnegative by its physical meaning. An *ad hoc* fix for this problem is to assume that (15.157) applies only when $\theta_n \geq 0$ for all n , with the probability of negative values being assigned zero prior probability.

This does not remove all of the objections to (15.157), however, since different components are still uncorrelated. Correlations between different points are what separate meaningful objects and images from snow on a television set tuned to an inactive channel, so an uncorrelated prior model is *a priori* wrong, at least in a frequentist sense. Nevertheless, the Tikhonov prior/regularizer can lead to quite useful reconstructed images, so it cannot be ruled out *a priori* by a pragmatist.

Entropy Another regularizer, for which many Bayesians show great fondness, is the entropy, defined by

$$Q_{reg}(\boldsymbol{\theta}) = \sum_{n=1}^N \theta_n \ln(\theta_n) . \quad (15.158)$$

The corresponding prior is

$$\text{pr}(\boldsymbol{\theta}) = \frac{1}{Z} \exp \left[-\eta \sum_{n=1}^N \theta_n \ln(\theta_n) \right], \quad \theta_n \geq 0, \quad (15.159)$$

where Z is a normalizing constant. Since this density is a product of factors that each involve only a single θ_n , the *a priori* assumption is again that the components are statistically independent. The density is defined only for positive values since the logarithm is imaginary if its argument is negative, but we shall see in Sec. 15.3.4 that this condition is satisfied almost automatically for any implicit estimate based on an entropy regularizer.

A more general form of entropy prior is

$$\text{pr}(\boldsymbol{\theta}) = \frac{1}{Z} \exp \left[-\eta \sum_{n=1}^N \theta_n \ln \left(\frac{\theta_n}{m_n} \right) \right], \quad (15.160)$$

where m_n is a component of a vector \mathbf{m} known as the *model*. The model is not the mean of the prior distribution, but instead is more closely related to the mode (most probable value). The reader may show that the peak of $\text{pr}(\boldsymbol{\theta})$ occurs when $\theta_n = m_n/e$ for all n . As $\eta \rightarrow \infty$, $\text{pr}(\boldsymbol{\theta}) \rightarrow \delta(\boldsymbol{\theta} - \mathbf{m}/e)$, so in this limit the mean equals the mode, but for finite η the density is skewed and there is no simple relationship between the model and the prior mean.

In practice, the most common model is a uniform field, $m_n = C$ for all n . This prior pulls the reconstruction towards the point where each $\theta_n = C/e$. If we really knew *a priori* that θ_n was likely to be close to some value θ_0 , we would therefore set $m_n = e\theta_0$, but usually the only purpose of the flat model is to smooth the image, so the actual value of C is of little import.

Why entropy? Many Bayesians argue fervently that the use of an entropy prior is virtually a moral imperative. For example, Gull and Skilling (1984) assert that “the maximum entropy method is ... the *only consistent way* of combining different data into a single positive image” [emphasis added]. Several different lines of argument are used to justify this fervor.

One common Bayesian argument postulates a set of axioms which, they say, any tenable prior must satisfy, and then they show that the axioms can be satisfied only by entropy (Shore and Johnson, 1990; Tikochinsky *et al.*, 1984; Skilling, 1988, Csiszár, 1991). Upon examination, however, the axioms themselves seem to be untenable since they require that the components of $\boldsymbol{\theta}$ be statistically independent *a priori*. As we noted above, statistically independent densities describe random noise fields, not meaningful objects and images. The Bayesian reply is that if we know something about correlations, we should construct the prior that has maximum entropy subject to the constraint of having a prescribed covariance matrix. This approach leads to correlated normal models and Wiener filters (see Sec. 13.3.7), topics that otherwise receive little attention in the Bayesian imaging literature.

The entropy distribution can also be derived on combinatorial grounds, as in statistical mechanics. If we suppose (for some reason) that all objects are constructed by randomly throwing indistinguishable elements of brightness called *grains* into pixels, then the most probable object is the one that can be constructed in the greatest number of ways.

Let ϵ be the grain size and suppose that pixel n contains k_n grains, so that $\theta_n = \epsilon k_n$. Let p_n be the probability that a grain thrown at random falls in pixel n , and let $K = \sum_n k_n$ be the total number of grains thrown. For fixed grain size, the probability law on $\boldsymbol{\theta}$ is the same as the probability law on the vector \mathbf{k} with components k_n . With the assumption that the grains are independent, that probability is the multinomial [cf. (C.164)],

$$\text{pr}(\mathbf{k}) = K! \prod_{n=1}^N \frac{p_n^{k_n}}{k_n!}. \quad (15.161)$$

If ϵ is small, then each of the k_n is large and we can use Stirling's approximation,

$$k! \approx \sqrt{2\pi k} k^k e^{-k}, \quad (15.162)$$

to show that

$$\begin{aligned} \ln[\text{pr}(\mathbf{k})] &= - \sum_{n=1}^N k_n \ln \left(\frac{k_n}{p_n} \right) + \text{const} \\ &= - \frac{1}{\epsilon} \sum_{n=1}^N \theta_n \ln \left(\frac{\theta_n}{m_n} \right) + \text{const}. \end{aligned} \quad (15.163)$$

This form agrees with (15.159) with η given by $1/\epsilon$ and the model components m_n given by p_n/ϵ . From this observation it is argued that $\text{pr}(\boldsymbol{\theta})$ must have the entropy form, even when $\boldsymbol{\theta}$ takes on a continuous range of values.

Finally, one way in which Bayesians attempt to appeal to the broader imaging community is to compare images reconstructed with an entropy prior to ones using, say, a Tikhonov regularizer; they then assert that the ones based on entropy are obviously superior on some subjective grounds. One problem with this comparison is that the Tikhonov images are almost always produced without a positivity constraint, while the maximum-entropy algorithms build in this physical reality. When constrained Tikhonov images are compared with maximum-entropy images, it is very hard even to tell them apart, much less to say which is subjectively superior. Moreover, when task performance is compared, even the unconstrained Tikhonov images seem to be as useful to a human observer as the entropy images (Gooley and Barrett, 1992).

Since none of these arguments for entropy says anything about its relation to task performance, they imply that the same prior and regularizing parameter should be used for all tasks and all observers. We have noted that the prior is irrelevant for an ideal observer and classification tasks, so it cannot be argued that entropy is in any sense optimal in that case. For the human observer, there is substantial psychophysical evidence that detection performance is optimized with different degrees of regularization for different background structures and signals, neither of which enter into the rationale for the entropy prior, so again it is difficult to argue that entropy is optimal. In short, since the entropy approach takes no account of task or observer, we fail to see why it should be accorded a privileged position in image-reconstruction problems; it is simply one more tool to be used and evaluated as any other method would be.

Nonlocal regularizers In practice, the Tikhonov and entropy regularizers usually produce smooth images, simply because they suppress the recovery of singular vectors that correspond to small singular values, which are the components that convey

the fine detail about an object. Even though the Bayesian priors are uncorrelated, they induce strong correlations in a reconstructed image. But if we know that adjacent points in an object are likely to be correlated, we can also build that knowledge directly into the regularizer or prior. Haynor (1997) argues that the most important function of a prior is to specify neighborhood relations since any decent imaging system will get the large-scale features correct without prior information.

There are many ways to build neighborhood information into a regularizer. For example, if we know that neighboring pixels are unlikely to have significantly different values, we can define the regularizer to penalize deviations between a pixel value and some average of its neighboring pixels. For real $\boldsymbol{\theta}$, one possible form is

$$Q_{reg}(\boldsymbol{\theta}) = \sum_{n=1}^N [\theta_n - (\mathbf{S}\boldsymbol{\theta})_n]^2, \quad (15.164)$$

where \mathbf{S} is a local smoothing operator and hence $(\mathbf{S}\boldsymbol{\theta})_n$ is a weighted average of θ_n and its neighbors. A common choice in 2D imaging is to average over a 3×3 or 5×5 neighborhood, with weights chosen such that $\theta_n - (\mathbf{S}\boldsymbol{\theta})_n = 0$ if the components of $\boldsymbol{\theta}$ are constant in the neighborhood. If the object is constant in this neighborhood, there is no penalty.

General quadratic regularizer The regularizer defined in (15.164) is a quadratic functional of $\boldsymbol{\theta}$. It can be rewritten as

$$Q_{reg}(\boldsymbol{\theta}) = \|(\mathbf{I} - \mathbf{S})\boldsymbol{\theta}\|^2 = \boldsymbol{\theta}^t (\mathbf{I} - \mathbf{S})^\dagger (\mathbf{I} - \mathbf{S}) \boldsymbol{\theta}. \quad (15.165)$$

The matrix $(\mathbf{I} - \mathbf{S})^\dagger (\mathbf{I} - \mathbf{S})$ is positive-semidefinite and Hermitian, as any matrix of the form $\mathbf{A}^\dagger \mathbf{A}$ is. This observation suggests that we define the general quadratic regularizer as

$$Q_{reg}(\boldsymbol{\theta}) = \boldsymbol{\theta}^t \mathbf{C} \boldsymbol{\theta}, \quad (15.166)$$

where \mathbf{C} is an arbitrary positive-semidefinite Hermitian matrix. We can define the square-root of \mathbf{C} as in Sec. A.8.3 and write

$$Q_{reg}(\boldsymbol{\theta}) = \|\mathbf{C}^{\frac{1}{2}} \boldsymbol{\theta}\|^2. \quad (15.167)$$

If we choose \mathbf{C} to be positive-definite rather than just positive-semidefinite, then the $\hat{\boldsymbol{\theta}}$ defined by (15.127) or (15.128) will be unique in spite of null functions in \mathbf{H} .

The Tikhonov regularizer is a special case of (15.167) with $\mathbf{C} = \mathbf{I}$. The entropy regularizer, however, does not fit this form since it is not quadratic in $\boldsymbol{\theta}$.

In Bayesian terms, the general quadratic regularizer amounts to choosing a zero-mean multivariate normal as the prior, with the inverse covariance matrix given by $\mathbf{K}_\theta^{-1} = 2\eta\mathbf{C}$. If we wanted to include a nonzero prior mean $\bar{\boldsymbol{\theta}}$, we would write

$$Q_{reg}(\boldsymbol{\theta}) = (\boldsymbol{\theta} - \bar{\boldsymbol{\theta}})^t \mathbf{C} (\boldsymbol{\theta} - \bar{\boldsymbol{\theta}}). \quad (15.168)$$

Gradient norms One common quadratic approach to regularization is to penalize large values of the image gradient. When dealing with digital images, the word gradient must be understood in a discrete sense, but it is easiest to explain the form of the regularizer in continuous terms and then worry about discretization later. Therefore, consider an object $f(\mathbf{r})$, where for definiteness $\mathbf{r} = (x, y)$ is a

2D vector. The object is scalar-valued, and its gradient is a 2D vector field with components

$$(\nabla f)_x = \frac{\partial f(\mathbf{r})}{\partial x}, \quad (\nabla f)_y = \frac{\partial f(\mathbf{r})}{\partial y}. \quad (15.169)$$

The norm of this vector field, defined in (7.7), is given by

$$\|\nabla f\|^2 = \int_{\mathbf{S}_f} d^2r \left\{ \left[\frac{\partial f(\mathbf{r})}{\partial x} \right]^2 + \left[\frac{\partial f(\mathbf{r})}{\partial y} \right]^2 \right\}. \quad (15.170)$$

Note that the norm here includes the sum of the squares of the components of the vector field at each position as well as an integral over position.

One might be tempted to compare $\|\nabla f\|^2$ with (15.167) and to identify $\mathbf{C}^{\frac{1}{2}}$ as a discrete gradient, but there are several problems with this approach. First, $\mathbf{C}^{\frac{1}{2}}$ acts on an $N \times 1$ vector and produces another $N \times 1$ vector, each such vector being the digital counterpart of a scalar field. The continuous gradient operator, on the other hand, acts on a scalar field and produces two scalar fields, $(\nabla f)_x$ and $(\nabla f)_y$. Moreover, the gradient operator is neither Hermitian nor positive-semidefinite, and both of these characteristics are required for \mathbf{C} if we are to define its square root.

To make (15.170) look like (15.167), we must identify \mathbf{C} not with the gradient but with the square root of the Laplacian operator. The Laplacian of $f(\mathbf{r})$ is defined by

$$\nabla^2 f(\mathbf{r}) = \frac{\partial^2 f(\mathbf{r})}{\partial x^2} + \frac{\partial^2 f(\mathbf{r})}{\partial y^2}. \quad (15.171)$$

The 2D Fourier transform of $\nabla^2 f(\mathbf{r})$ is given by (3.236) as

$$\mathcal{F}_2\{\nabla^2 f(\mathbf{r})\} = -4\pi^2 \rho^2 F(\boldsymbol{\rho}), \quad (15.172)$$

where $\boldsymbol{\rho} = (\xi, \eta)$ is the spatial frequency vector and hence $\rho^2 = \xi^2 + \eta^2$. From this form it can be shown that the CC operator $\mathbf{C} \equiv -\nabla^2$ is a positive-definite Hermitian operator. Then we can define $\mathbf{C}^{\frac{1}{2}}$ by

$$\mathcal{F}_2\{\mathbf{C}^{\frac{1}{2}} f(\mathbf{r})\} = 2\pi \rho F(\boldsymbol{\rho}), \quad (15.173)$$

and we find from Parseval's theorem that

$$\|(\nabla^2)^{\frac{1}{2}} f\|^2 = 4\pi^2 \int_{\infty} d^2\rho \rho^2 |F(\boldsymbol{\rho})|^2. \quad (15.174)$$

If we apply Parseval's theorem to (15.170), we get the same Fourier-domain integral, so $\|(\nabla^2)^{\frac{1}{2}} f\|^2 = \|\nabla f\|^2$.

In the frequency domain, this regularizer grows as ρ^2 and hence suppresses high spatial frequencies, giving smooth images. An even stronger bias against high frequencies would be obtained by use of $\|\nabla^2 f\|^2$ as the regularizer; in that case the penalty grows as ρ^4 .

Discretization of these continuous norms is straightforward. For example, a 2D discrete Laplacian can be realized by discrete convolution with a 3×3 kernel such as

$$\frac{1}{12} \begin{bmatrix} -1 & -2 & -1 \\ -2 & 12 & -2 \\ -1 & -2 & -1 \end{bmatrix}. \quad (15.175)$$

Nonquadratic regularizers A problem with quadratic regularizers is that they encourage smoothness even where the object itself may not be smooth, for example at a boundary between organs in medical imaging. We would like to smooth out small variations, which probably result from noise, but retain larger ones, which are more likely to be true edges.

One way to construct an edge-preserving regularizer is to use a nonlinear function of a scalar argument, $\Phi\{x\}$, and write

$$Q_{reg}(\boldsymbol{\theta}) = \sum_{n=1}^N \Phi\{[\mathbf{C}^{\frac{1}{2}}\boldsymbol{\theta}]_n\}, \tag{15.176}$$

where $\mathbf{C}^{\frac{1}{2}}$ is a positive-definite operator chosen, as above, to sense differences between a pixel's value and some average of its neighbors. If $\Phi\{x\} = x^2$, we are back to the general quadratic regularizer, but if we choose $\Phi\{x\}$ to grow less rapidly than x^2 for large x , then large variations will be penalized proportionally less than with the quadratic. For example, we can let $\Phi\{x\} = |x|^2$ for $|x| \leq 1$ and $\Phi\{x\} = 2|x| - 1$ for $|x| > 1$.

Another approach to edge-preserving, nonquadratic priors is *Markov random fields*, introduced in Sec. 8.4.4. In a pixel representation, the general form of the regularizer associated with a Markov random field is

$$Q_{reg}(\boldsymbol{\theta}) = \sum_{n=1}^N \sum_{j \in \mathcal{N}_n} U(\theta_n, \theta_j), \tag{15.177}$$

where \mathcal{N}_n is a set of pixels in some suitably defined neighborhood of pixel n , and $U(\theta_n, \theta_j)$ is called the *potential*.

One commonly used potential has the form

$$U(\theta_n, \theta_j) = |\theta_n - \theta_j|^p, \tag{15.178}$$

where p is usually chosen to be in the range $1 < p \leq 2$. The corresponding prior density is then

$$\text{pr}(\boldsymbol{\theta}) \propto \prod_{n=1}^N \prod_{j \in \mathcal{N}_n} \exp[-\eta|\theta_n - \theta_j|^p]. \tag{15.179}$$

Densities of this form have a cusp at the origin and high kurtosis (long tails) compared to a Gaussian. We saw in Sec. 8.4.3 that a similar behavior was often observed experimentally and could be explained very broadly in terms of Gaussian mixtures. Thus the prior of (15.179) has some frequentist justification, in that it exhibits characteristics seen empirically in collections of images.

Data-dependent and space-variant regularizers We have denoted the regularizing functional as $Q_{reg}(\boldsymbol{\theta})$, but there is no reason why it cannot depend on \mathbf{g} also. One might object that it can then no longer be interpreted as a prior, but we lost that feature anyway when we allowed the regularizing parameter η to be determined from the data. In a sense, it is mandatory for the regularizing term to depend on the data since the two terms in (15.126) are defined in different spaces. The data agreement term is a norm or some other distance measure in data space while the regularizing term is defined in the reconstruction space. If we scale the matrix \mathbf{H}

by a constant, such that $\mathbf{H}' = C\mathbf{H}$ and $\mathbf{g}' = C\mathbf{g}$, then we change the ratio of the two terms and hence the degree of regularization. To compensate for this effect, a user of a regularizing functional would adjust η in accordance with the scaling of \mathbf{H} .

This global adjustment alone may not achieve the desired result, however, if the system sensitivity [defined in (7.232) or (15.36)] is a strong function of position. The value of η that achieves a desired balance between data agreement and smoothness at one point will lead to either oversmoothing or undersmoothing at other points in the reconstruction. With pixels or other local representations, it is straightforward to make η a function of position, thereby achieving a nonlocal regularization.

An alternative approach suggested by Fessler (1994) is to make the regularizing functional depend on the data \mathbf{g} as well as the reconstruction $\boldsymbol{\theta}$. Fessler has demonstrated that this approach can yield a spatial resolution independent of position even when the system sensitivity varies with position. (See also Fessler and Rogers, 1996, and Stayman and Fessler, 2000).

15.3.4 Effects of positivity

If there are no constraints on the value of $\boldsymbol{\theta}$, and if we assume that $Q(\boldsymbol{\theta}, \mathbf{g})$ is everywhere differentiable with respect to its first argument, then the implicit estimate must satisfy

$$\frac{\partial}{\partial \theta_n} Q(\boldsymbol{\theta}, \mathbf{g}) = 0, \quad (15.180)$$

for all n at $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$. If we allow only nonnegative solutions, however, the minimum may not occur at a point of zero derivative; it can also occur when one or more of the components θ_n are zero, so long as the derivative is positive at this point (see Fig. 15.2). We can allow for this possibility by requiring that

$$\theta_n \frac{\partial}{\partial \theta_n} Q(\boldsymbol{\theta}, \mathbf{g}) = 0 \quad \text{and} \quad \frac{\partial}{\partial \theta_n} Q(\boldsymbol{\theta}, \mathbf{g}) \geq 0, \quad (15.181)$$

for all n at $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$. The first condition says that the solution can occur when either θ_n or the derivative is zero, and the second requires that the derivative be nonnegative if the solution occurs at $\theta_n = 0$, since otherwise there would be a smaller value with $\theta_n > 0$.

Fig. 15.2 Illustration of the Karush-Kuhn-Tucker conditions.

These conditions are often ascribed to Kuhn and Tucker⁴ (1951), but in the simple form given here they were published earlier in a master's thesis by Karush (1939), so we shall refer to (15.181) as the *Karush-Kuhn-Tucker* or *KKT* conditions. More general Kuhn-Tucker conditions, some of which do not require the existence of the derivative, are discussed in detail in Mangasarian (1994).

Tikhonov and KKT To illustrate the effects of the KKT conditions, consider a least-squares data-agreement term and a Tikhonov regularizer. The derivative we need was discussed in Sec. 1.7.4, where we showed that

$$\begin{aligned} \frac{\partial}{\partial \theta_n} Q(\boldsymbol{\theta}, \mathbf{g}) &= \frac{\partial}{\partial \theta_n} [\|\mathbf{g} - \mathbf{H}\boldsymbol{\theta}\|^2 + \eta \|\boldsymbol{\theta}\|^2] \\ &= -2[\mathbf{H}^t(\mathbf{g} - \mathbf{H}\boldsymbol{\theta})]_n + 2\eta\theta_n. \end{aligned} \tag{15.182}$$

Since $\eta > 0$, the KKT conditions require that

$$\hat{\theta}_n [\mathbf{H}^t(\mathbf{g} - \mathbf{H}\hat{\boldsymbol{\theta}})]_n - \eta\hat{\theta}_n = 0 \quad \text{and} \quad \hat{\theta}_n \geq \eta^{-1} [\mathbf{H}^t(\mathbf{g} - \mathbf{H}\hat{\boldsymbol{\theta}})]_n. \tag{15.183}$$

If we define a vector $\hat{\mathbf{a}}$ in data space by

$$\hat{\mathbf{a}} = \frac{1}{\eta}(\mathbf{g} - \mathbf{H}\hat{\boldsymbol{\theta}}), \tag{15.184}$$

then (15.183) can be rewritten as

$$\hat{\theta}_n [(\mathbf{H}^t\hat{\mathbf{a}})_n - \hat{\theta}_n] = 0 \quad \text{and} \quad \hat{\theta}_n \geq (\mathbf{H}^t\hat{\mathbf{a}})_n. \tag{15.185}$$

It is useful to define a nonlinear operator \mathbf{P}_+ that has the effect of clipping off all negative values. Applied to a vector \mathbf{b} , \mathbf{P}_+ is defined by

$$[\mathbf{P}_+\mathbf{b}]_m = b_m \text{step}(b_m) = \begin{cases} b_m & \text{if } b_m \geq 0 \\ 0 & \text{if } b_m < 0 \end{cases}. \tag{15.186}$$

With this operator, (15.185) is formally solved by

$$\hat{\boldsymbol{\theta}} = \mathbf{P}_+\mathbf{H}^t\hat{\mathbf{a}}, \tag{15.187}$$

where $\hat{\mathbf{a}}$ must satisfy

$$\mathbf{H}\mathbf{P}_+\mathbf{H}^t\hat{\mathbf{a}} + \eta\hat{\mathbf{a}} = \mathbf{g}. \tag{15.188}$$

Of course (15.187) is not really a solution to our problem since it depends on the vector $\hat{\mathbf{a}}$, which must be found by solving (15.188) by some iterative algorithm. It does show, however, that the solution must have the form of the clipped backprojection of some vector in data space.

⁴It was something of an accident that the topologist Albert W. Tucker (1905–1955) got into mathematical programming. He happened to be free to give George Dantzig a ride to the Princeton train station after Dantzig had made an unsuccessful trip to Princeton to try to interest John von Neumann in the new field, and Dantzig ended up recruiting Tucker rather than von Neumann (S. B. Maurer, *SIAM News*, July 1995).

Relation to the unconstrained Tikhonov problem It is interesting to relate (15.187) and (15.188) back to the corresponding equations for the same problem without the positivity constraint. If we simply delete the clipping operator, (15.188) becomes

$$[\mathbf{H}\mathbf{H}^t + \eta\mathbf{I}] \hat{\mathbf{a}} = \mathbf{g}. \quad (15.189)$$

Since $\eta > 0$, $\mathbf{H}\mathbf{H}^t + \eta\mathbf{I}$ is a positive-definite (hence invertible) operator, and we can write

$$\hat{\mathbf{a}} = [\mathbf{H}\mathbf{H}^t + \eta\mathbf{I}]^{-1} \mathbf{g}. \quad (15.190)$$

Thus (15.187) becomes

$$\hat{\boldsymbol{\theta}} = \mathbf{H}^t [\mathbf{H}\mathbf{H}^t + \eta\mathbf{I}]^{-1} \mathbf{g} = [\mathbf{H}^t\mathbf{H} + \eta\mathbf{I}]^{-1} \mathbf{H}^t \mathbf{g}, \quad (15.191)$$

where the equivalence of these two forms can be demonstrated with SVD expressions derived in Chap. 1. The second form agrees with (15.156).

Entropy and KKT The positivity constraint enters in a somewhat different way with the entropy regularizer. Consider the implicit estimate defined by

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta} \geq \mathbf{0}}{\operatorname{argmin}} \left[\|\mathbf{g} - \mathbf{H}\boldsymbol{\theta}\|^2 + \eta \sum_{n=1}^N \theta_n \ln \left(\frac{\theta_n}{m_n} \right) \right]. \quad (15.192)$$

Now the required derivative is [cf. (15.182)]

$$\frac{\partial}{\partial \theta_n} Q(\boldsymbol{\theta}, \mathbf{g}) = -2 [\mathbf{H}^t(\mathbf{g} - \mathbf{H}\boldsymbol{\theta})]_n + \eta \ln \left(\frac{\theta_n}{m_n} \right) + \eta. \quad (15.193)$$

This derivative vanishes if

$$\theta_n = \frac{m_n}{e} \exp \left(\frac{2}{\eta} [\mathbf{H}^t(\mathbf{g} - \mathbf{H}\boldsymbol{\theta})]_n \right), \quad (15.194)$$

so this equation must be satisfied at the minimum if that minimum does not occur when $\theta_n = 0$. Note that $\theta_n \rightarrow m_n/e$ as $\eta \rightarrow \infty$, in which case the prior dominates the data-agreement term. For small η , on the other hand, the solution must have g_m close to $(\mathbf{H}\boldsymbol{\theta})_m$, emphasizing the data-agreement term.

In fact, the solution cannot be at $\theta_n = 0$ since the derivative approaches $-\infty$ at this point and the second KKT condition cannot be satisfied there. Since entropy is a convex regularizer, there must be at least one minimum, and it must occur where (15.194) is satisfied. Moreover, (15.194) is automatically consistent with the positivity constraint (if $m_n > 0$) since the exponential lies between 0 and infinity, never reaching either extreme for finite argument. We do not need to include a clipping operator like \mathbf{P}_+ since there are never any negative values to clip.

Some in the Bayesian community regard the inability to get a zero value as a virtue. Csiszár (1991) notes that “use of an entropy regularizer/prior ensures that a nonnegative quantity is never inferred to be 0 when the available information *permits* it to be positive, which is generally considered to be desirable” [emphasis added]. Even from a Bayesian perspective, this feature seems to be at odds with any reasonable prior. We often have the prior knowledge that many pixels in the object representation will be zero. For example, a point outside the patient’s body in medical imaging must be zero, though we do not know beforehand where these points are located in the scene. A Bayesian could take this obvious fact into account by including a delta function at the origin in the prior density, but we know of no case where this has been done.

15.3.5 Reconstruction without discretization

So far in this section we have discussed minimization of a functional involving the vector $\boldsymbol{\theta}$ of coefficients in an approximate discrete object representation. As we shall show in this section, however, it is also possible to formulate the implicit reconstruction problem in continuous terms without ever adopting a discrete representation. The results will be analogous to what we obtained with the Backus-Gilbert method in Sec. 15.2.2, but with an implicit formulation and a positivity constraint. The treatment here owes a great deal to the authors' interactions with Eric Clarkson.

If we denote a continuous estimate as $\hat{f}(\mathbf{r})$, with the corresponding vector in an infinite-dimensional Hilbert space denoted by $\hat{\mathbf{f}}$, then we can define the estimate by [cf. (15.128)]

$$\hat{\mathbf{f}} = \underset{\mathbf{f} \geq 0}{\operatorname{argmin}} [Q_{data}(\mathbf{g}, \mathcal{H}\mathbf{f}) + \eta Q_{reg}(\mathbf{f})] . \quad (15.195)$$

Here, the constraint $\mathbf{f} \geq 0$ means $f(\mathbf{r}) \geq 0$ for all \mathbf{r} in \mathbf{S}_f , and \mathcal{H} is a CD operator.

To find the minimum of this functional, we introduce the concept of a *Fréchet derivative* (Stakgold, 1979). An ordinary gradient of a scalar-valued function with a vector argument is a vector of the same dimensionality as the argument. The same is true of the Fréchet derivative of a scalar-valued functional, even though the argument is infinite-dimensional. The definition is also familiar; if the vector \mathbf{f} is perturbed to $\mathbf{f} + \epsilon \mathbf{u}$, where \mathbf{u} is some vector in the Hilbert space, then we can define the Fréchet derivative $\delta_f \psi$ of the scalar functional $\psi(\mathbf{f})$ via

$$\lim_{\epsilon \rightarrow 0} \frac{\psi(\mathbf{f} + \epsilon \mathbf{u}) - \psi(\mathbf{f})}{\epsilon} = (\delta_f \psi, \mathbf{u}) . \quad (15.196)$$

If \mathbf{u} is a basis vector in the space, the right-hand side can be viewed as a component of the vector $\delta_f \psi$. With only a slight loss of generality, we can restrict attention to reproducing-kernel Hilbert spaces where functions can be evaluated pointwise (see Sec. 1.8). Then if we let \mathbf{u} correspond to the evaluation function for the Hilbert space [analogous to $\delta(\mathbf{r} - \mathbf{r}_0)$], the scalar product on the right in (15.196) is the function $[\delta_f \psi](\mathbf{r})$ evaluated at $\mathbf{r} = \mathbf{r}_0$. The Fréchet derivative of a scalar functional is thus a function.

Two examples of (15.196) will prove useful. For the continuous Tikhonov regularizer,

$$\psi(\mathbf{f}) = \int_{\mathbf{S}_f} d^2r [f(\mathbf{r})]^2 , \quad (15.197)$$

we can write the Fréchet derivative as a vector in Hilbert space,

$$\delta_f \psi = 2\mathbf{f} , \quad (15.198)$$

or equivalently as a function,

$$[\delta_f \psi](\mathbf{r}) = 2f(\mathbf{r}) . \quad (15.199)$$

Similarly, for the continuous entropy regularizer,

$$\psi(\mathbf{f}) = \int_{\mathbf{S}_f} d^2r f(\mathbf{r}) \ln[f(\mathbf{r})] , \quad (15.200)$$

we find

$$[\delta_f \psi](\mathbf{r}) = \ln f(\mathbf{r}) + 1 . \quad (15.201)$$

In both of these examples we have assumed that $f(\mathbf{r})$ is real.

A somewhat more complicated example comes from a least-squares data-agreement term. If we consider

$$\psi(\mathbf{f}) = \|\mathbf{g} - \mathcal{H}\mathbf{f}\|^2 = \sum_{m=1}^M \left[g_m - \int_{\mathbf{S}_r} d^2r' h_m(\mathbf{r}') f(\mathbf{r}') \right]^2, \quad (15.202)$$

with all quantities being real, then we can show that

$$[\delta_f \psi](\mathbf{r}) = -2 \sum_{m=1}^M h_m(\mathbf{r}) \left[g_m - \int_{\mathbf{S}_r} d^2r' h_m(\mathbf{r}') f(\mathbf{r}') \right]. \quad (15.203)$$

To get a more abstract operator form, we can use the definition of the adjoint of a CD operator from (7.237) and write

$$\delta_f \psi = -2\mathcal{H}^\dagger[\mathbf{g} - \mathcal{H}\mathbf{f}]. \quad (15.204)$$

Continuous Tikhonov reconstruction Consider the regularized least-squares problem with the data-agreement functional (15.202) and the continuous Tikhonov regularizer (15.197). From results above, we see that the Fréchet derivative is a modest generalization of (15.182):

$$\delta_f Q(\mathbf{f}, \mathbf{g}) = -2[\mathcal{H}^\dagger(\mathbf{g} - \mathcal{H}\mathbf{f})] + 2\eta\mathbf{f}. \quad (15.205)$$

Similarly, (15.183) becomes

$$\hat{f}(\mathbf{r})[\mathcal{H}^\dagger(\mathbf{g} - \mathcal{H}\hat{\mathbf{f}})](\mathbf{r}) - \eta\hat{f}(\mathbf{r}) = 0; \quad \hat{f}(\mathbf{r}) \geq \eta^{-1}[\mathcal{H}^\dagger(\mathbf{g} - \mathcal{H}\hat{\mathbf{f}})](\mathbf{r}). \quad (15.206)$$

Just as (15.183) had to hold for all n at the solution point, so too must these continuous conditions hold for all \mathbf{r} . They thus comprise a set of infinite-dimensional KKT conditions.⁵

From this point it is just a matter of notational changes to get a set of equations for the continuous estimate. Specifically, (15.187) becomes

$$\hat{f}(\mathbf{r}) = [\mathbf{P}_+ \mathcal{H}^\dagger \hat{\mathbf{a}}](\mathbf{r}), \quad (15.207)$$

where $\hat{\mathbf{a}}$ is still a finite-dimensional vector in data space and satisfies [cf. (15.188)]

$$\mathcal{H}\mathbf{P}_+ \mathcal{H}^\dagger \hat{\mathbf{a}} + \eta\hat{\mathbf{a}} = \mathbf{g}. \quad (15.208)$$

From (15.207) we see that $\hat{f}(\mathbf{r})$ is simply a clipped backprojection of $\hat{\mathbf{a}}$, or equivalently a clipped superposition of natural pixels with weights $\{a_m\}$. Thus the reconstruction problem boils down to finding the M components of $\hat{\mathbf{a}}$ by solving (15.208). One approach would be a fixed-point iteration (see Sec. 15.4.4). In practice, the nonlinear operator $\mathcal{H}\mathbf{P}_+ \mathcal{H}^\dagger$ could be implemented by replacing the integral over object space by a finely sampled sum, but this sampling would not imply that a discrete object representation had been adopted.

⁵These conditions were originally derived by Eric Clarkson but have not been published elsewhere at this writing.

Other regularized reconstructions By arguments parallel to those leading to (15.194), we can show that the continuous maximum-entropy solution must satisfy

$$\hat{f}(\mathbf{r}) = \frac{m(\mathbf{r})}{e} \exp \left\{ \frac{2}{\eta} [\mathcal{H}^\dagger(\mathbf{g} - \mathcal{H}\mathbf{f})](\mathbf{r}) \right\}. \quad (15.209)$$

As in the discrete case, any solution to this equation automatically satisfies the positivity constraint.

From (15.207) and (15.209), we see that the solution must have the form of a nonlinear point operator acting on a superposition of natural pixels, at least for least-squares problems with the Tikhonov or entropy regularizers. The same is true for a wide variety of other continuous implicit estimates.⁶

Night skies The purpose of regularization in any inverse problem is to reduce noise variance, but with implicit estimation of functions, a completely new class of solutions arises if we do not regularize. In particular, we can have solutions that consist of a finite number of delta functions:

$$\hat{f}(\mathbf{r}) = \sum_{k=1}^K \alpha_k \delta(\mathbf{r} - \mathbf{r}_k), \quad \alpha_k > 0, \quad K \leq M. \quad (15.210)$$

Since this set of delta functions might represent stars in the sky, solutions of this form can be called *night-sky reconstructions*. Needless to say, a night-sky reconstruction will usually not resemble the actual object, so solutions like (15.210) are infinitely biased with respect to almost any real object, and they have infinite variance. Nevertheless, they can always occur if we do not regularize or discretize.

To understand the existence of night-sky reconstructions, consider the moment cone, introduced in Sec. 15.1.4, and suppose first that \mathbf{g} lies in its interior. Then we can express \mathbf{g} as a positive linear combination of points on the boundary of the moment cone. Each of these points is the image of a unit delta function in object space, so it is always possible to find an $\hat{\mathbf{f}}$ in the form of (15.210) that will give $\mathcal{H}\hat{\mathbf{f}} \equiv \mathbf{g}$. Any distance measure $Q_{data}(\mathbf{g}, \mathcal{H}\mathbf{f})$ will be minimized when $\mathcal{H}\mathbf{f} = \mathbf{g}$, so the night-sky estimate will necessarily minimize the distance. Since \mathcal{H} has null functions, it is also possible that there will be other objects \mathbf{f} such that $\mathcal{H}\mathbf{f} \equiv \mathbf{g}$, yielding the same value of zero for the data-agreement functional. Some or all of these objects may not be night skies; which object is found depends on the specific minimization algorithm and its initial estimate.

Because of noise, \mathbf{g} may not lie in the moment cone. In fact, in many cases it is overwhelmingly likely that \mathbf{g} will not lie in the moment cone, because the moment cone is a lower-dimensional manifold in the data space. If the DC operator \mathcal{H}^\dagger has null functions, then as we saw in Sec. 15.2.5 there are consistency conditions in data space, and different components of noise-free data are not linearly independent. If there are K consistency conditions and M components to the data vector, then consistency space is an $(M - K)$ -dimensional manifold in data space. Since the moment cone is a subset of consistency space, it also has just $M - K$ dimensions. A noisy data vector, on the other hand, does not have the linear dependence, so it will lie at a general point in data space, with a vanishingly small probability of hitting the cone.

⁶Unpublished results of Eric Clarkson.

If a noisy \mathbf{g} lies outside in the moment cone, and if the data-agreement functional is strictly convex, then there must be a unique point \mathbf{g}_0 on the surface of the moment cone such that $Q_{data}(\mathbf{g}, \mathcal{H}\mathbf{f})$ is minimized (though not zero). Since \mathbf{g}_0 is on the surface of the moment cone, it is either the image of a single point object or a positive combination of at most M point objects. Thus the equation $\mathcal{H}\mathbf{f} = \mathbf{g}_0$ can always be solved exactly by a night-sky object.

Moreover, if \mathbf{g} is outside the moment cone, the night-sky object will be unique in the absence of exact consistency conditions. Consider a CD imaging system with three detectors viewing a 1D object function $f(x)$. As shown in Fig. 15.3, moving a delta function along the x -axis in object space traces out a curve C in data space, and the moment cone is formed by taking the convex hull and drawing a line from the origin through each point in the hull to infinity. As the figure is drawn, the cone is a 3D manifold, so there are no consistency conditions. Nevertheless, two examples of data vectors, \mathbf{g} and \mathbf{g}' , outside the cone are shown. The point on the cone nearest to \mathbf{g} is \mathbf{g}_0 and the one nearest to \mathbf{g}' is \mathbf{g}'_0 . As shown, \mathbf{g}'_0 lies on the original curve C , so it is uniquely the image of a single delta function. By contrast, \mathbf{g}_0 lies on a flat (two-dimensional) face created when the convex hull was formed. This face touches C at just two points, each of which is the image of a delta function, so \mathbf{g}_0 is uniquely the image of an object consisting of two delta functions. The only way in which a smooth object could produce \mathbf{g}_0 would be if the curve C itself had a face, which would be the image of delta functions $\delta(\mathbf{r} - \mathbf{r}_0)$ for a continuous range of \mathbf{r}_0 ; then any point in the face could be the image of an integral superposition of these delta functions, not just a finite sum.

Fig. 15.3 The moment cone for a linear system with three detectors viewing a 1D object $f(x)$.

In summary, there is always a nonnegative night-sky object that will minimize the unregularized data-agreement functional. If there are consistency conditions, the data vector \mathbf{g} will usually lie outside the moment cone, and the night sky object will usually be unique. Thus night skies are almost inevitable in unregularized positive reconstruction without discretization. Similar features occur in DD problems, as discussed by Byrne (1993, 1995).

15.3.6 Resolution and noise in implicit estimates

Sometimes the minimum of an objective function $Q(\boldsymbol{\theta}, \mathbf{g})$ occurs at a point where it is differentiable with respect to both its arguments. This is the case, for example, with the least-squares data-agreement term and any popular regularizer if there are no constraints on the solution, and even a positivity constraint may not spoil the differentiability, as we saw in the case of the entropy regularizer in Sec. 15.3.4. In this section we shall explore some properties of the argmin estimate when $Q(\boldsymbol{\theta}, \mathbf{g})$ is differentiable at the minimum with respect to both arguments.

Implicit derivatives If x and y are real scalars, the equation $f(x, y) = 0$ defines y as an implicit function of x . The total differential of f is

$$df = \frac{\partial f}{\partial x} dx + \frac{\partial f}{\partial y} dy = 0, \tag{15.211}$$

from which we see that

$$\frac{dy}{dx} = -\frac{\partial f / \partial x}{\partial f / \partial y}. \tag{15.212}$$

Now suppose \mathbf{x} is a real $M \times 1$ column vector and \mathbf{y} is a real $N \times 1$ column vector. To define \mathbf{y} as an implicit function of \mathbf{x} , we need N linearly independent equations of the form $f_n(\mathbf{x}, \mathbf{y}) = 0$. Then, by the chain rule,

$$df_n = \frac{\partial f_n}{\partial \mathbf{x}^t} d\mathbf{x} + \frac{\partial f_n}{\partial \mathbf{y}^t} d\mathbf{y} = 0, \tag{15.213}$$

where $\partial f_n / \partial \mathbf{x}^t$ is a row vector of partial derivatives. (For more discussion of the vector notation used here, see Sec. A.9.2.) If we consider a vector $d\mathbf{x}$ where all components except dx_j are zero, we see that

$$\frac{\partial f_n}{\partial x_j} = -\sum_k \frac{\partial f_n}{\partial y_k} \frac{\partial y_k}{\partial x_j}. \tag{15.214}$$

This result can be written in matrix-vector form by defining a matrix $\partial \mathbf{y} / \partial \mathbf{x}^t$ with jk^{th} component given by $\partial y_k / \partial x_j$, so that

$$\frac{\partial f_n}{\partial \mathbf{x}} = -\frac{\partial \mathbf{y}}{\partial \mathbf{x}^t} \frac{\partial f_n}{\partial \mathbf{y}}. \tag{15.215}$$

Application to implicit estimates Suppose that the minimum of $Q(\boldsymbol{\theta}, \mathbf{g})$ occurs at a point $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}(\mathbf{g})$ where $\partial Q(\boldsymbol{\theta}, \mathbf{g}) / \partial \theta_n = 0$ for $n = 1, \dots, N$. Then we can apply (15.215) with $f_n = \partial Q(\hat{\boldsymbol{\theta}}, \mathbf{g}) / \partial \theta_n$, $\mathbf{y} = \hat{\boldsymbol{\theta}}$ and $\mathbf{x} = \mathbf{g}$, yielding

$$\frac{\partial}{\partial \mathbf{g}} \left[\frac{\partial Q(\hat{\boldsymbol{\theta}}, \mathbf{g})}{\partial \hat{\theta}_n} \right] = -\frac{\partial \hat{\boldsymbol{\theta}}}{\partial \mathbf{g}^t} \frac{\partial}{\partial \hat{\boldsymbol{\theta}}} \left[\frac{\partial Q(\hat{\boldsymbol{\theta}}, \mathbf{g})}{\partial \hat{\theta}_n} \right], \tag{15.216}$$

or, in full matrix form,

$$\frac{\partial^2 Q(\hat{\boldsymbol{\theta}}, \mathbf{g})}{\partial \mathbf{g} \partial \hat{\boldsymbol{\theta}}^t} = -\frac{\partial \hat{\boldsymbol{\theta}}}{\partial \mathbf{g}^t} \frac{\partial^2 Q(\hat{\boldsymbol{\theta}}, \mathbf{g})}{\partial \hat{\boldsymbol{\theta}} \partial \hat{\boldsymbol{\theta}}^t}. \tag{15.217}$$

The second derivative on the right is the Hessian matrix (see Sec. A.9.2), which will be invertible whenever the objective function has a unique minimum. Multiplying (15.217) from the right with the inverse Hessian and taking a transpose yields the multivariate counterpart of (15.212):

$$\frac{\partial \hat{\boldsymbol{\theta}}}{\partial \mathbf{g}} = - \left[\frac{\partial^2 Q(\hat{\boldsymbol{\theta}}, \mathbf{g})}{\partial \hat{\boldsymbol{\theta}} \partial \hat{\boldsymbol{\theta}}^t} \right]^{-1} \frac{\partial^2 Q(\hat{\boldsymbol{\theta}}, \mathbf{g})}{\partial \hat{\boldsymbol{\theta}} \partial \mathbf{g}^t}. \quad (15.218)$$

We can rewrite (15.218) as

$$d\hat{\boldsymbol{\theta}} = [\mathbf{A}(\hat{\boldsymbol{\theta}}(\mathbf{g}), \mathbf{g})] d\mathbf{g}, \quad (15.219)$$

where $\mathbf{A}(\hat{\boldsymbol{\theta}}, \mathbf{g})$ is the $N \times M$ matrix defined by the right-hand side of (15.218):

$$\mathbf{A}(\hat{\boldsymbol{\theta}}, \mathbf{g}) = - \left[\frac{\partial^2 Q(\hat{\boldsymbol{\theta}}, \mathbf{g})}{\partial \hat{\boldsymbol{\theta}} \partial \hat{\boldsymbol{\theta}}^t} \right]^{-1} \frac{\partial^2 Q(\hat{\boldsymbol{\theta}}, \mathbf{g})}{\partial \hat{\boldsymbol{\theta}} \partial \mathbf{g}^t}. \quad (15.220)$$

As it stands, (15.219) is a nonlinear mapping since $\mathbf{A}(\hat{\boldsymbol{\theta}}, \mathbf{g})$ depends on $\hat{\boldsymbol{\theta}}$. To linearize it, let $\bar{\mathbf{g}}$ be the mean data vector and let $\hat{\boldsymbol{\theta}}(\bar{\mathbf{g}})$ be the argmin estimate obtained when $\mathbf{g} = \bar{\mathbf{g}} \equiv \mathcal{H}\mathbf{f}$. [Note that $\hat{\boldsymbol{\theta}}(\bar{\mathbf{g}})$ is not necessarily the mean of $\hat{\boldsymbol{\theta}}$.] For small deviations of the data vector from its mean, we can write

$$\Delta \hat{\boldsymbol{\theta}} = [\mathbf{A}(\hat{\boldsymbol{\theta}}(\mathcal{H}\mathbf{f}), \mathcal{H}\mathbf{f})] \Delta \mathbf{g}. \quad (15.221)$$

This formula, derived by Fessler (1996), is now a linearized mapping from $\Delta \mathbf{g}$ to $\Delta \hat{\boldsymbol{\theta}}$, though the mapping operator depends on the actual object \mathbf{f} . A change in \mathbf{g} can result from either a change in the object or from noise, so the formula can be used to discuss the resolution and noise properties of implicit estimates.

Resolution Now suppose $\Delta \mathbf{g}$ results from adding a weak delta function $\epsilon \delta(\mathbf{r} - \mathbf{r}_0)$ to the object, where ϵ is small enough that $\Delta g_m \ll g_m$ for all m . For our usual CD model, $\Delta g_m = \epsilon h_m(\mathbf{r}_0)$. The point response function for the overall system (CD operator plus implicit estimator) is the $N \times 1$ vector $\mathbf{p}(\mathbf{r}_0)$ defined as the image of this point object divided by ϵ ; it is given by

$$\mathbf{p}(\mathbf{r}_0) = [\mathbf{A}(\hat{\boldsymbol{\theta}}(\mathcal{H}\mathbf{f}), \mathcal{H}\mathbf{f})] \mathbf{h}(\mathbf{r}_0), \quad (15.222)$$

where $\mathbf{h}(\mathbf{r}_0)$ is a vector in data space with m^{th} component given by $h_m(\mathbf{r}_0)$.

In practice, this PRF might be evaluated with the aid of a DD model for the imaging system. If we neglect null functions and modeling errors, then $\mathcal{H}\mathbf{f} \simeq \mathbf{H}\boldsymbol{\theta}$. If $\boldsymbol{\theta}$ is perturbed by adding $\epsilon \delta_{nn_0}$, representing a change of ϵ in the element $n = n_0$, then the PRF in $\hat{\boldsymbol{\theta}}$ is

$$\mathbf{p}(n_0) = [\mathbf{A}(\hat{\boldsymbol{\theta}}(\mathbf{H}\boldsymbol{\theta}), \mathbf{H}\boldsymbol{\theta})] \mathbf{h}(n_0), \quad (15.223)$$

where $\mathbf{h}(n_0)$ is an $M \times 1$ vector with the m^{th} element given by H_{mn_0} . If $\mathbf{h}(n_0)$ is a good approximation to $\mathbf{h}(\mathbf{r}_0)$, then the PRF of (15.223) could accurately represent (15.222), but the assumptions should be checked in particular cases. An additional possible simplification is that the noise-free reconstruction $\hat{\boldsymbol{\theta}}(\mathbf{g})$ accurately reproduces $\boldsymbol{\theta}$, in which case $\mathbf{A}(\hat{\boldsymbol{\theta}}(\mathbf{H}\boldsymbol{\theta}), \mathbf{H}\boldsymbol{\theta}) \simeq \mathbf{A}(\boldsymbol{\theta}, \mathbf{H}\boldsymbol{\theta})$, but again this step should be taken with caution.

Variance and covariance in the estimate The linearized mapping of (15.221) allows us to use the formalism of Sec. 15.2.6 to discuss the statistical properties of $\hat{\boldsymbol{\theta}}$. From (15.107) and (15.221), the conditional covariance matrix for the reconstruction, given a specified object, is

$$\mathbf{K}_{\hat{\boldsymbol{\theta}}|\mathbf{f}} = \mathbf{A}\mathbf{K}_g\mathbf{A}^\dagger, \quad (15.224)$$

where $\mathbf{A} = \mathbf{A}(\hat{\boldsymbol{\theta}}(\mathcal{H}\mathbf{f}), \mathcal{H}\mathbf{f})$, but it might be approximated as in (15.223) if a DD model is used.

As discussed in Secs. 12.2 and 15.2.6, it is frequently a good model to assume that $\mathbf{g} \sim \mathcal{N}(\mathcal{H}\mathbf{f}, \sigma^2\mathbf{I})$, and in that case the conditional covariance matrix, in component form, is given by

$$\left[\mathbf{K}_{\hat{\boldsymbol{\theta}}|\mathbf{f}}\right]_{nn'} = \sigma^2 \sum_{m=1}^M A_{nm}A_{n'm}^*, \quad (15.225)$$

and the corresponding conditional variance is

$$\text{Var}\{\hat{\theta}_n|\mathbf{f}\} = \sigma^2 \left[\mathbf{A}\mathbf{A}^\dagger\right]_{nn} = \sigma^2 \sum_{m=1}^M |A_{nm}|^2. \quad (15.226)$$

These expressions are very similar to (15.108) and (15.109), respectively, but there is a key difference. Since \mathbf{A} is a function of \mathbf{f} (or approximately, $\boldsymbol{\theta}$), the noise in the reconstruction depends on the object and hence on position in the image.

The term *signal-dependent noise* is often encountered in the literature, and it can be applied here if the signal is construed to be the object itself. By the terminology introduced in Chap. 8, however, *signal* refers to a part of the object that we might be interested in detecting. If the signal in this sense is a small perturbation to the object, then it may have little influence on the statistics of $\hat{\boldsymbol{\theta}}$, so we would say that the noise is object-dependent but signal-independent.

This same argument applies even in the case of Poisson noise, which is often called signal-dependent. In that case the conditional covariance and variance of $\hat{\boldsymbol{\theta}}$ are given by (15.120) and (15.121) (with \mathbf{O} replaced by \mathbf{A}). Then the noise depends on position in the image for two reasons: the data covariance depends on the object, and the implicit reconstruction procedure also introduces an object dependence. Nevertheless, if we think of a signal as a small perturbation to an object, then the noise in the reconstruction is signal-independent but object-dependent.

Example 1: Tikhonov regularization and least-squares Within the linearized approximation, computation of resolution and noise in the reconstruction requires only that we be able to compute the $N \times M$ matrix \mathbf{A} defined in (15.220). We shall now show how to do that for two special cases.

First, consider a least-squares data-agreement term and a Tikhonov regularizer. The first derivative of the objective function with respect to $\boldsymbol{\theta}$ is given by (15.182), and the Hessian matrix is obtained by differentiating (15.182) again; the result is

$$\frac{\partial^2}{\partial\theta_n\partial\theta_m}Q(\boldsymbol{\theta}, \mathbf{g}) = 2 \left[\mathbf{H}^t\mathbf{H}\right]_{nm} + 2\eta\delta_{nm}. \quad (15.227)$$

The requisite cross-derivative is

$$\frac{\partial^2}{\partial\theta_n\partial g_m}Q(\boldsymbol{\theta}, \mathbf{g}) = 2H_{mn}. \quad (15.228)$$

Thus (15.220) takes the familiar form,

$$\mathbf{A}(\hat{\boldsymbol{\theta}}, \mathbf{g}) = [\mathbf{H}^t \mathbf{H} + \eta \mathbf{I}]^{-1} \mathbf{H}^t, \quad (15.229)$$

which is identical to the regularized least-squares operator derived in Sec. 1.7.5 and reproduced in (15.156). Since this operator is independent of $\hat{\boldsymbol{\theta}}$ and \mathbf{g} , the linearization is exact in this case.

Example 2: Entropy regularization For a least-squares data-agreement functional and the entropy regularizer of (15.158), the Hessian is

$$\frac{\partial^2}{\partial \theta_n \partial \theta_m} Q(\boldsymbol{\theta}, \mathbf{g}) = 2 [\mathbf{H}^t \mathbf{H}]_{nm} + 2 \left(\frac{\eta}{\theta_n} \right) \delta_{nm}. \quad (15.230)$$

The cross-derivative is still given by (15.228), so

$$\mathbf{A}(\hat{\boldsymbol{\theta}}, \mathbf{g}) = [\mathbf{H}^t \mathbf{H} + \eta \mathbf{D}(\hat{\boldsymbol{\theta}})]^{-1} \mathbf{H}^t, \quad (15.231)$$

where

$$[\mathbf{D}(\hat{\boldsymbol{\theta}})]_{nn'} = \frac{1}{\hat{\theta}_n} \delta_{nn'}. \quad (15.232)$$

Now the matrix \mathbf{A} depends on $\hat{\boldsymbol{\theta}}$, so different mappings apply at different points in the image. Since the regularizing parameter is divided by $\hat{\theta}_n$, the qualitative effect is to reduce the variance in regions of the image where $\hat{\theta}_n$ is small.

15.4 ITERATIVE ALGORITHMS

Once we have chosen an objective functional to minimize, we next need an algorithm to find the minimum. In one sense, this choice is more a matter of computer science than image science. If the functional is strictly convex, then the minimum is unique and all algorithms should obtain the same image if run to convergence. The only issues are which algorithm will find the minimum most efficiently and with the least computing resources, and those questions are peripheral to the goal of this book.

In practice, however, iterative algorithms may not be run to convergence. In that case, the resulting image depends on the algorithm, the initial estimate and the stopping rule (as well as the data and the model, of course). One focus in this section, therefore, will be on the properties of images produced by iterative algorithms as a function of iteration number.

We shall distinguish linear from nonlinear algorithms, depending on whether the update rule gives the next estimate as a linear (or at least affine) functional of the previous estimate. Linear algorithms are, of course, easier to analyze, but nonlinear algorithms may offer considerable advantages. For example, imposition of a positivity constraint at each iteration requires nonlinearity, but it may be effective in controlling noise and artifacts in the image.

We begin in Sec. 15.4.1 with a survey of linear iterative algorithms, building on the discussion of iteration computation of the pseudoinverse in Sec. 1.7.6. Noise properties of linear iterative algorithms are derived in Sec. 15.4.2.

In Sec. 15.4.3 we give a rapid survey of optimization methods. Some emphasis is placed on conjugate-gradient methods, but mainly for pedagogical purposes; as

we shall see, conjugate gradients are closely related to two main themes of this book, pseudoinverses and prewhitening.

In Sec. 15.4.4, we shall see how to introduce nonlinear constraints into iterative algorithms, and we shall revisit the KKT conditions in the context of a specific class of nonlinear algorithms, fixed-point iterations. Another important general class of algorithms is projections onto convex sets, surveyed briefly in Sec. 15.4.5.

The popular expectation-maximization (EM) algorithm is introduced in Sec. 15.4.6, and its relation to Poisson likelihood is discussed, and in Sec. 15.4.7, we discuss noise propagation in nonlinear iterative algorithms, using the EM algorithm as an example.

Finally, in Sec. 15.4.8 we consider iterative algorithms in which the update step is random. Starting with an algorithm called *simulated annealing*, we discuss a general class of algorithms called *Markov-chain Monte Carlo*. Applications of this algorithm to image-quality assessment have already been mentioned in Sec. 14.3.3 and 14.3.4.

15.4.1 Linear iterative algorithms

In Sec. 1.7.6 we introduced several iterative methods for minimizing a quadratic data-agreement functional; included there were the Landweber, Gauss-Seidel and Jacobi methods. For these algorithms and many others, the iteration rule has the general form [cf. (1.236)]

$$\hat{\boldsymbol{\theta}}^{(k+1)} = \hat{\boldsymbol{\theta}}^{(k)} + \mathbf{B} \left[\mathbf{g} - \mathbf{H}\hat{\boldsymbol{\theta}}^{(k)} \right], \quad (15.233)$$

where \mathbf{B} is an $N \times M$ matrix. Since the correction term is added to the previous estimate, (15.233) is often referred to as an *additive algorithm*. It is also called a *linear algorithm* since only linear operations are performed on the k^{th} estimate to obtain the correction term; the relation between $\hat{\boldsymbol{\theta}}^{(k+1)}$ and $\hat{\boldsymbol{\theta}}^{(k)}$ is, however, affine rather than strictly linear.

The choices to be made in using this kind of algorithm are the matrix \mathbf{B} , the starting estimate $\hat{\boldsymbol{\theta}}^{(0)}$ and the number of iterations K . For example, a modified Landweber algorithm can be defined by taking $\mathbf{B} = \alpha \mathbf{H}^t$, where α is called an *acceleration parameter* since it controls the rate of convergence. Common choices for $\hat{\boldsymbol{\theta}}^{(0)}$ are $\mathbf{H}^t \mathbf{g}$ or a uniform field (*i.e.*, $\hat{\theta}_n^{(0)} = c$ for all n).

Conditions under which algorithms like (15.233) converge were discussed in Sec. 1.7.6. For present purposes, let us simply assume that the algorithm converges and see what it gives when it does. Convergence means that $\hat{\boldsymbol{\theta}}^{(k+1)} - \hat{\boldsymbol{\theta}}^{(k)} \rightarrow 0$, or $\mathbf{B}[\mathbf{g} - \mathbf{H}\hat{\boldsymbol{\theta}}^{(k)}] \rightarrow 0$. If the rank of \mathbf{B} is the data dimension M , then \mathbf{B} has no null functions in data space, so convergence can occur only if $\mathbf{g} = \mathbf{H}\hat{\boldsymbol{\theta}}^{(k)}$. Thus the algorithm attempts to enforce agreement between the actual noisy data \mathbf{g} and the estimated data $\mathbf{H}\hat{\boldsymbol{\theta}}$; as we have seen several times, strict agreement with noisy data results in a very noisy image, so this algorithm is almost never run to convergence.

A more general linear algorithm has the form

$$\hat{\boldsymbol{\theta}}^{(k+1)} = \hat{\boldsymbol{\theta}}^{(k)} - \eta \mathbf{C} \hat{\boldsymbol{\theta}}^{(k)} + \mathbf{B} \left[\mathbf{g} - \mathbf{H}\hat{\boldsymbol{\theta}}^{(k)} \right], \quad (15.234)$$

where \mathbf{C} is an $N \times N$ matrix. Now the algorithm no longer forces $\mathbf{g} = \mathbf{H}\hat{\boldsymbol{\theta}}^{(k)}$ but instead converges (if it does so at all) to a $\hat{\boldsymbol{\theta}}^{(k)}$ such that

$$\eta \mathbf{C} \hat{\boldsymbol{\theta}}^{(k)} = \mathbf{B} \left[\mathbf{g} - \mathbf{H} \hat{\boldsymbol{\theta}}^{(k)} \right]. \quad (15.235)$$

Equivalently, the algorithm converges to

$$\hat{\boldsymbol{\theta}}^{(k)} = (\mathbf{B}\mathbf{H} + \eta\mathbf{C})^{-1} \mathbf{B}\mathbf{g}, \quad (15.236)$$

provided the indicated inverse exists. If $\mathbf{C} = \mathbf{I}$ and $\mathbf{B} = \mathbf{H}^t$, then we are back to the regularized least-squares solution of (15.156). In any case, \mathbf{C} controls the form of the regularization and η controls the amount.

The algorithm of (15.234) can be written as

$$\hat{\boldsymbol{\theta}}^{(k+1)} = \boldsymbol{\Omega} \hat{\boldsymbol{\theta}}^{(k)} + \mathbf{B}\mathbf{g}, \quad (15.237)$$

where

$$\boldsymbol{\Omega} = \mathbf{I} - \eta\mathbf{C} - \mathbf{B}\mathbf{H}. \quad (15.238)$$

Since (15.237) has the form of a general linear (more precisely, affine) mapping, any linear iterative algorithm with a fixed update rule can be put in this form with proper choice of $\boldsymbol{\Omega}$ and \mathbf{B} .

The only possible remaining generalization is to let the update rule vary with iteration number. For example, the regularizing constant η or the accelerating parameter α could vary with k . The general form of the algorithm then becomes

$$\hat{\boldsymbol{\theta}}^{(k+1)} = \boldsymbol{\Omega}^{(k)} \hat{\boldsymbol{\theta}}^{(k)} + \mathbf{B}^{(k)} \mathbf{g}. \quad (15.239)$$

This form can encompass algorithms, called *row-action methods*, that use only a subset of the data at each iteration. We have already encountered one important row-action method in Chap. 1, where we introduced the Gauss-Seidel or ART method in the context of pseudoinverse calculations. For a detailed survey of row-action methods, see Censor (1981).

15.4.2 Noise propagation in linear algorithms

Since (15.239) describes the most general linear algorithm, we shall now use this equation to discuss the evolution of the covariance matrix with iteration number, a process sometimes referred to as *noise propagation*.

The first step is to find an expression for the evolution of the mean vector. If we take a conditional average of both sides of (15.239) for a fixed object \mathbf{f} , the result is

$$\langle \hat{\boldsymbol{\theta}}^{(k+1)} \rangle_{\mathbf{g}|\mathbf{f}} = \boldsymbol{\Omega}^{(k)} \langle \hat{\boldsymbol{\theta}}^{(k)} \rangle_{\mathbf{g}|\mathbf{f}} + \mathbf{B}^{(k)} \boldsymbol{\mathcal{H}}\mathbf{f}, \quad (15.240)$$

where, as discussed in Sec. 15.2.6, $\langle \mathbf{g} \rangle_{\mathbf{g}|\mathbf{f}} = \boldsymbol{\mathcal{H}}\mathbf{f}$. In practice (or at least in simulation studies), this mean vector can be found as a function of k simply by running the iterative algorithm on a noise-free data set.

Subtraction of (15.240) from (15.239) yields

$$\Delta \hat{\boldsymbol{\theta}}^{(k+1)} = \boldsymbol{\Omega}^{(k)} \Delta \hat{\boldsymbol{\theta}}^{(k)} + \mathbf{B}^{(k)} \mathbf{n}, \quad (15.241)$$

where $\mathbf{n} \equiv \mathbf{g} - \boldsymbol{\mathcal{H}}\mathbf{f}$, and $\Delta \hat{\boldsymbol{\theta}}^{(k)}$ indicates the deviation of the estimate from its mean.

If the initial estimate $\hat{\boldsymbol{\theta}}^{(0)}$ is nonrandom, the deviation after the first iteration is

$$\Delta \hat{\boldsymbol{\theta}}^{(1)} = \boldsymbol{\Omega}^{(0)} \Delta \hat{\boldsymbol{\theta}}^{(0)} + \mathbf{B}^{(0)} \mathbf{n} = \mathbf{B}^{(0)} \mathbf{n}. \quad (15.242)$$

The next two iterations yield

$$\Delta \hat{\boldsymbol{\theta}}^{(2)} = \boldsymbol{\Omega}^{(1)} \Delta \hat{\boldsymbol{\theta}}^{(1)} + \mathbf{B}^{(1)} \mathbf{n} = \boldsymbol{\Omega}^{(1)} \mathbf{B}^{(0)} \mathbf{n} + \mathbf{B}^{(1)} \mathbf{n}. \quad (15.243)$$

$$\Delta \hat{\boldsymbol{\theta}}^{(3)} = \boldsymbol{\Omega}^{(2)} \Delta \hat{\boldsymbol{\theta}}^{(2)} + \mathbf{B}^{(2)} \mathbf{n} = \boldsymbol{\Omega}^{(2)} \mathbf{B}^{(1)} \mathbf{n} + \boldsymbol{\Omega}^{(2)} \boldsymbol{\Omega}^{(1)} \mathbf{B}^{(0)} \mathbf{n} + \mathbf{B}^{(2)} \mathbf{n}. \quad (15.244)$$

By extension (or induction), the general form is

$$\Delta \hat{\boldsymbol{\theta}}^{(k)} = \mathbf{U}^{(k)} \mathbf{n}, \quad (15.245)$$

where

$$\mathbf{U}^{(k+1)} = \mathbf{B}^{(k)} + \boldsymbol{\Omega}^{(k)} \mathbf{U}^{(k)}. \quad (15.246)$$

With the initial condition $\mathbf{U}^{(1)} = \mathbf{B}^{(0)}$, (15.246) constitutes an iterative algorithm for the matrix $\mathbf{U}^{(k)}$ that relates the deviation $\Delta \hat{\boldsymbol{\theta}}^{(k)}$ back to the noise vector \mathbf{n} . Even with large images, the algorithm is feasible in practice since it requires only a single matrix-matrix multiply and a matrix addition at each step.

If we have computed $\mathbf{U}^{(k)}$ by (15.246), we can immediately determine the conditional covariance matrix for $\hat{\boldsymbol{\theta}}^{(k)}$. From (8.50) we know how to transform a covariance matrix through a linear transformation, so we have

$$\mathbf{K}_{\hat{\boldsymbol{\theta}}^{(k)}|\mathbf{f}} = \mathbf{U}^{(k)} \mathbf{K}_{\mathbf{n}} \mathbf{U}^{(k)\dagger}. \quad (15.247)$$

For i.i.d. noise, [cf. (15.107)], we have

$$\mathbf{K}_{\hat{\boldsymbol{\theta}}^{(k)}|\mathbf{f}} = \sigma^2 \mathbf{U}^{(k)} \mathbf{U}^{(k)\dagger}. \quad (15.248)$$

The covariance expression (15.248) must be modified if the data noise is Poisson. By comparison to (15.120), we see that

$$\left[\mathbf{K}_{\hat{\boldsymbol{\theta}}^{(k)}|\mathbf{f}} \right]_{nn'} = \sum_{m=1}^M [\mathcal{H}\mathbf{f}]_m U_{nm}^{(k)} \left[U_{n'm}^{(k)} \right]^*. \quad (15.249)$$

Conditional PDFs and optimization of algorithms If the noise in the data is normally distributed, then any linear transformation leaves it normal, so (15.240) and (15.247) are sufficient to specify fully the statistics of the linear reconstruction at each iteration. For Poisson noise, the reconstruction is not exactly normal, but as we argued in Sec. 15.2.6, the normal law will often be an excellent approximation. Thus in either case we have good knowledge of the conditional statistics for any linear algorithm and number of iterations. This statistical description can be used in conjunction with any of the task-based figures of merit developed in Chap. 14 to optimize the number of iterations and other free parameters of the algorithm.

15.4.3 Search algorithms for functional minimization

As we saw in Sec. 15.3, image reconstruction is often formulated as minimization of some functional $Q(\boldsymbol{\theta}, \mathbf{g})$. A host of methods for performing this minimization can be found in the literature on optimization, and only a brief overview will be given here. For more details, see Golub and van Loan (1989), Scales (1985), Pierre (1986) or Gill *et al.* (1981).

A general approach to functional minimization is to choose a search direction in the reconstruction space, take a step in that direction, and then repeat the process iteratively. The iteration rule for algorithms in this class is thus

$$\hat{\boldsymbol{\theta}}^{(k+1)} = \hat{\boldsymbol{\theta}}^{(k)} + h^{(k)} \mathbf{s}^{(k)}, \quad (15.250)$$

where the vector $\mathbf{s}^{(k)}$ specifies the search direction for the k^{th} iteration, and $h^{(k)}$ is the corresponding step size. Each algorithm is specified by the initial estimate, a procedure for setting the sequence of directions $\{\mathbf{s}^{(k)}\}$ and a rule for determining the step sizes $\{h^{(k)}\}$.

The most common initial estimates are a uniform field (all components equal) and the discrete backprojection $\mathbf{H}^t \mathbf{g}$. If enough iterations are used and $Q(\boldsymbol{\theta}, \mathbf{g})$ has a unique minimum, the final solution does not depend on the initialization, but with a finite number of iterations the solution is biased towards the initial estimate, which can thus be regarded as a kind of regularization or prior knowledge.

Common choices for $\{\mathbf{s}^{(k)}\}$ lead to algorithms known as *iterative coordinate descent*, *steepest descent* and *conjugate gradient*, all of which will be summarized below, but first we look at ways of choosing the step size.

One-dimensional minimization algorithms Since the objective of the search is to find a minimum of $Q(\boldsymbol{\theta}, \mathbf{g})$, it is usual (though not mandatory) to choose $h^{(k)}$ at each step so that $Q(\hat{\boldsymbol{\theta}}^{(k+1)}, \mathbf{g}) \leq Q(\hat{\boldsymbol{\theta}}^{(k)}, \mathbf{g})$. Colloquially, the step is in a downhill direction. For example, we could choose a step size h_0 and take each $h^{(k)}$ to be either h_0 or $-h_0$, depending on which direction is downhill. If neither h_0 nor $-h_0$ results in a reduction in the functional, no change is made. If few changes are made in the course of many iterations, we can change h_0 , for example by halving it, and repeat the process.

Rather than just moving in the direction of the minimum, one can also attempt to come as close as possible to the minimum along each search direction before moving on to a new direction. Many methods for finding this minimum are available. The brute-force method is just to take many small steps in the downhill direction until you start uphill again. More sophisticated methods such as the *golden-section search* (Pierre, 1986) vary the step size in an attempt to bracket the minimum.

Other methods such as *Newton-Raphson* (Pierre, 1986; Scales, 1985) attempt to estimate the location of the minimum from the gradient and/or Hessian (curvature) of the functional. All of these methods approximate the functional at its current estimate by means of a multivariate Taylor series as discussed in Sec. A.10.2. From (15.250) and (A.181), we can write

$$Q(\hat{\boldsymbol{\theta}}^{(k+1)}, \mathbf{g}) = Q(\hat{\boldsymbol{\theta}}^{(k)}, \mathbf{g}) + h^{(k)} \mathbf{s}^{(k)t} \nabla Q^{(k)} + \frac{1}{2} [h^{(k)}]^2 \mathbf{s}^{(k)t} \mathbf{A}^{(k)} \mathbf{s}^{(k)} + \dots, \quad (15.251)$$

where $\nabla Q^{(k)}$ and $\mathbf{A}^{(k)}$ are, respectively, the gradient vector and Hessian matrix evaluated at $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}^{(k)}$; in the notation of App. A,

$$\nabla Q^{(k)} = \left[\frac{\partial}{\partial \boldsymbol{\theta}} Q(\boldsymbol{\theta}, \mathbf{g}) \right]_{\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}^{(k)}}, \quad \mathbf{A}^{(k)} = \left[\frac{\partial^2}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}^t} Q(\boldsymbol{\theta}, \mathbf{g}) \right]_{\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}^{(k)}}. \quad (15.252)$$

If we truncate the Taylor series at the quadratic term, the minimum of $Q(\hat{\boldsymbol{\theta}}^{(k+1)}, \mathbf{g})$ in direction $\mathbf{s}^{(k)}$ occurs when

$$h^{(k)} = -\frac{\mathbf{s}^{(k)t} \nabla Q^{(k)}}{\mathbf{s}^{(k)t} \mathbf{A}^{(k)} \mathbf{s}^{(k)}}. \quad (15.253)$$

This is the univariate Newton-Raphson formula, and in the local quadratic approximation to the functional it provides a way to reach the minimum in direction $\mathbf{s}^{(k)}$ in a single step. If the functional is not locally quadratic, then (15.253) may still be a reasonable choice when the gradient and Hessian can be computed. It is easy to compute the gradient and Hessian for some functionals, such as the Tikhonov-regularized least-squares one, but difficult or impossible for others, so (15.253) and its variants are not universally applicable.

Iterative coordinate descent When we adopt an approximate object representation $f_a(\mathbf{r})$ in the form of (15.6), the functions $\phi_n(\mathbf{r})$ are the basis vectors in the representation space, and the coefficients θ_n specify the components of the vector \mathbf{f}_a in this basis. Thus, if we vary one coefficient at a time, we are sequentially moving along the different coordinate axes in representation space. Algorithms that use the coordinate axes as the search directions and that reduce the functional at each step are known generically as *iterative coordinate descent*. Their advantage is that no computation is needed to determine the search directions, and in particular no knowledge of the gradient or Hessian is required for this purpose.

If iteration k varies the component n_k of the estimate, then the update has the form

$$[\hat{\boldsymbol{\theta}}^{(k+1)}]_{n_k} = [\hat{\boldsymbol{\theta}}^{(k)}]_{n_k} + h^{(k)}, \quad (15.254)$$

and all other components are left unchanged at this iteration. If the estimate has N components, the index n_k should cycle through all N of them in the course of N iterations. The sequence of components $\{n_k\}$ is called the *control sequence*. It can be some natural order such as lexicographic ordering of pixels, or it can assure that adjacent pixels are not altered in immediate succession, or the order can even be chosen randomly.

Any of the one-dimensional minimization techniques mentioned above can be used to determine the step size $h^{(k)}$. For example, the step can be fixed at each iteration as $\pm h_0$, whichever is downhill. Alternatively, we can make a fixed fractional change in the component at each step, so that

$$[\hat{\boldsymbol{\theta}}^{(k+1)}]_{n_k} = (1 \pm \alpha^{(k)}) [\hat{\boldsymbol{\theta}}^{(k)}]_{n_k}, \quad (15.255)$$

with $0 < \alpha^{(k)} < 1$ and the sign chosen so that the step is downhill. Again, if neither sign results in a downhill step, then no change is made, and the size of $\alpha^{(k)}$ can be reduced when this happens for many components. Both of these coordinate-descent algorithms are conceptually simple and easy to code, requiring only the ability to compute the functional rather than its gradient or Hessian; both will find the minimum if it is unique and computational time is not a limitation.

If we actually find the minimum in one coordinate direction (for example by Newton-Raphson) before moving on to the next direction, the algorithm is called *iterative conditional modes*. This term arises from the interpretation of $Q(\boldsymbol{\theta}, \mathbf{g})$ as the negative logarithm of a posterior (see Sec. 15.3.1), so that minimizing it is equivalent to maximizing the probability density, $\text{pr}(\boldsymbol{\theta}|\mathbf{g})$. Similarly, minimizing $Q(\boldsymbol{\theta}, \mathbf{g})$ along the n^{th} coordinate axis is the same as maximizing $\text{pr}(\theta_n|\mathbf{g}, \{\theta_j, j \neq n\})$. Since the peak of a probability density function is called its *mode*, all coordinate-descent methods that minimize the functional individually for each direction iteratively determine this conditional mode.

Steepest descent The coordinate-descent algorithms are usually slow since most directions chosen do not point very close to the minimum. Another general approach is try to choose the direction optimally at each iteration. For example, one might choose to go downhill as steeply as possible. Since the direction in which a scalar functional changes most rapidly is the direction of its gradient, the new search direction in this approach is taken as the negative of the local gradient. This method is called *steepest descent* or *gradient descent*. Typically it is combined with one of the search methods mentioned above so the actual minimum in the gradient direction is found or estimated.

Steepest descent is particularly simple when it is applied to a functional that is either exactly or approximately quadratic. Dropping the dependence on \mathbf{g} for notational convenience, we consider a general quadratic functional of the form

$$Q(\boldsymbol{\theta}) = \frac{1}{2}\boldsymbol{\theta}^t \mathbf{A}\boldsymbol{\theta} - \mathbf{b}^t \boldsymbol{\theta}. \quad (15.256)$$

This form could represent a least-squares problem with a quadratic regularizer, or it could be the local quadratic approximation to a more general functional as in (15.251).

The gradient of $Q(\boldsymbol{\theta})$ is given, from (A.126) and (A.127), as

$$\nabla Q(\boldsymbol{\theta}) = \mathbf{A}\boldsymbol{\theta} - \mathbf{b}. \quad (15.257)$$

Finding the minimum of $Q(\boldsymbol{\theta})$ requires setting the gradient to zero, which we see is equivalent to solving the set of linear equations $\mathbf{A}\boldsymbol{\theta} = \mathbf{b}$. If \mathbf{A} is positive-definite (hence nonsingular), then $Q(\boldsymbol{\theta})$ has a unique minimum at $\boldsymbol{\theta} = \mathbf{A}^{-1}\mathbf{b}$, but in large problems it is not feasible to compute this inverse even though it exists. In nonsingular quadratic problems, therefore, steepest-descent is a way of finding $\mathbf{A}^{-1}\mathbf{b}$ without knowing \mathbf{A}^{-1} .

If we have a current estimate $\hat{\boldsymbol{\theta}}^{(k)}$, the next search direction is parallel to $-\nabla Q(\hat{\boldsymbol{\theta}}^{(k)})$, which we called $-\nabla Q^{(k)}$ earlier. Thus

$$\nabla Q^{(k)} = \mathbf{A}\hat{\boldsymbol{\theta}}^{(k)} - \mathbf{b}, \quad (15.258)$$

which is just the residual vector $\mathbf{r}^{(k)}$ specifying the difference between $\mathbf{A}\boldsymbol{\theta}$ and \mathbf{b} at the current estimate. The descent direction is the negative of the residual, and finding the overall minimum of $Q(\boldsymbol{\theta})$ is equivalent to driving the residual to zero.

Conjugacy Though steepest descent sounds appealing, it may converge slowly when the functional has long regions (canyons) where it varies slowly in one direction but rapidly in another (see Fig. 15.4). An alternative approach which may converge more rapidly is the *conjugate-gradient* method, described below.

Fig. 15.4 (a) Illustration of a situation where steepest descent converges very slowly. (b) Convergence of the conjugate-gradient algorithm for the same situation.

To explain the conjugate-gradient method, we must first explain the concept of *conjugacy*. Let \mathbf{A} be a real $N \times N$ Hermitian matrix of rank R . Two real $N \times 1$ vectors \mathbf{p}_j and \mathbf{p}_k are said to be \mathbf{A} -conjugate (or conjugate with respect to \mathbf{A}) if

$$\mathbf{p}_j^t \mathbf{A} \mathbf{p}_k = d_j \delta_{jk}. \quad (15.259)$$

One possible choice for the set $\{\mathbf{p}_j, j = 1, \dots, R\}$ is the set of eigenvectors of \mathbf{A} , but there are many other possibilities. As shown in Sec. 1.4.4, the eigenvectors are mutually orthogonal (or can be chosen to be via Gram-Schmidt if there are degeneracies). Conjugate vectors can be shown to be linearly independent (Scales, 1985), but they are not necessarily orthogonal.

Conjugacy is formally related to the idea of prewhitening, introduced in a statistical context in Sec. 8.1.6. Here we do not need any particular statistical interpretation; we simply define⁷

$$\tilde{\mathbf{p}}_j = \mathbf{A}^{\frac{1}{2}} \mathbf{p}_j, \quad (15.260)$$

where $\mathbf{A}^{\frac{1}{2}}$ is the square root of the Hermitian matrix \mathbf{A} (see Sec. A.8.3). With this transformation and the definition of the adjoint in (1.39), the conjugacy condition (15.259) can be written as

$$\mathbf{p}_j^t \mathbf{A} \mathbf{p}_k = (\mathbf{A}^{\frac{1}{2}} \mathbf{p}_j)^t (\mathbf{A}^{\frac{1}{2}} \mathbf{p}_k) = \tilde{\mathbf{p}}_j^t \tilde{\mathbf{p}}_k = d_j \delta_{jk}. \quad (15.261)$$

Thus the prewhitened vectors $\{\mathbf{A}^{\frac{1}{2}} \mathbf{p}_j, j = 1, \dots, R\}$ form an orthogonal set, and they can be normalized to yield the orthonormal set, $\{d_j^{-\frac{1}{2}} \mathbf{A}^{\frac{1}{2}} \mathbf{p}_j, j = 1, \dots, R\}$.

Conjugate vectors and minimization of a quadratic Let us return to the quadratic problem of (15.256) and assume for simplicity that \mathbf{A} is Hermitian and positive-definite. As applied to this problem, conjugate-gradient algorithms all have the general iteration rule

$$\hat{\boldsymbol{\theta}}^{(k+1)} = \hat{\boldsymbol{\theta}}^{(k)} + h^{(k)} \mathbf{p}_k, \quad (15.262)$$

where each \mathbf{p}_k is conjugate (with respect to \mathbf{A}) to all previous $\mathbf{p}_j, j < k$. For an exact linear search, $h^{(k)}$ is chosen by (15.253) to minimize $Q(\hat{\boldsymbol{\theta}}^{(k+1)})$:

$$h^{(k)} = -\frac{\mathbf{p}_k^t \nabla Q^{(k)}}{d_k}. \quad (15.263)$$

The advantage of choosing conjugate vectors to define the search directions can be seen by applying the prewhitening transformation $\mathbf{A}^{\frac{1}{2}}$ as in (15.260). If we define

$$\tilde{\boldsymbol{\theta}} = \mathbf{A}^{\frac{1}{2}} \boldsymbol{\theta} \quad \text{and} \quad \tilde{\mathbf{b}} = \mathbf{A}^{-\frac{1}{2}} \mathbf{b}, \quad (15.264)$$

then the functional to be minimized becomes

$$\tilde{Q}(\tilde{\boldsymbol{\theta}}) = \tilde{\mathbf{b}}^t \tilde{\boldsymbol{\theta}} + \frac{1}{2} \tilde{\boldsymbol{\theta}}^t \tilde{\boldsymbol{\theta}}. \quad (15.265)$$

⁷When $Q(\boldsymbol{\theta}, \mathbf{g})$ is the negative of a multivariate Gaussian log-likelihood, then $\mathbf{A} = \mathbf{K}^{-1}$, where \mathbf{K} is the covariance matrix. In that case, (15.249) is identical to what we called prewhitening in Sec. 8.1.6 and 13.2.18.

Thus the transformation converts the isocontours of the functional into N -dimensional spheres in the prewhitened space. It follows from (15.261) that any algorithm of the form (15.262) will make a succession of minimizations along mutually orthogonal directions in the prewhitened space if the vectors $\{\mathbf{p}_k\}$ satisfy the conjugacy condition (15.259). This search will reach the overall minimum in at most N steps; zig-zagging along the canyon as in Fig. 15.4 does not occur after prewhitening. Of course, a steepest-descent algorithm would reach the minimum in one step after prewhitening, but we would need to know the operator $\mathbf{A}^{\frac{1}{2}}$ in order to find the steepest-descent direction. For large problems we must assume that $\mathbf{A}^{\frac{1}{2}}$ and \mathbf{A}^{-1} are not accessible.

Generating conjugate vectors To generate a sequence of conjugate vectors, we can in principle generate a sequence of orthogonal vectors in the prewhitened space and then apply the operator $\mathbf{A}^{-\frac{1}{2}}$; fortunately, as we shall see, we can do this without actually knowing $\mathbf{A}^{-\frac{1}{2}}$.

To set notation, let $\tilde{\mathbb{U}}^{(k)}$ be the k D space spanned by $\{\tilde{\mathbf{p}}_j, 0 \leq j \leq k-1\}$, and let $\mathbb{U}^{(k)}$ be the k D space spanned by $\{\mathbf{p}_j, 0 \leq j \leq k-1\}$. Since $\mathbf{A}^{\frac{1}{2}}$ is square and nonsingular, there is a 1:1 correspondence between these two spaces.

If we know the vectors $\{\tilde{\mathbf{p}}_j, 0 \leq j \leq k-1\}$, we can generate a new vector $\tilde{\mathbf{p}}_k$ orthogonal to all of them by choosing a vector $\tilde{\mathbf{q}}_k$, which is arbitrary except that it cannot lie entirely in $\tilde{\mathbb{U}}^{(k)}$, and projecting it onto the orthogonal complement of $\tilde{\mathbb{U}}^{(k)}$, denoted $\tilde{\mathbb{U}}_{\perp}^{(k)}$. Since the set $\{d_j^{-\frac{1}{2}} \mathbf{A}^{\frac{1}{2}} \mathbf{p}_j, 0 \leq j \leq k-1\}$ is an orthonormal basis for $\tilde{\mathbb{U}}^{(k)}$, the projector onto $\tilde{\mathbb{U}}_{\perp}^{(k)}$ has the form [cf. (1.60)]

$$\begin{aligned} \tilde{\mathbf{p}}_k &\equiv \tilde{\mathcal{P}}_{\perp}^{(k)} \tilde{\mathbf{q}}_k = \left[\mathbf{I} - \sum_{j=0}^{k-1} \frac{1}{d_j} \tilde{\mathbf{p}}_j \tilde{\mathbf{p}}_j^t \right] \tilde{\mathbf{q}}_k \\ &= \tilde{\mathbf{q}}_k - \sum_{j=0}^{k-1} \frac{1}{d_j} (\mathbf{A}^{\frac{1}{2}} \mathbf{p}_j) (\mathbf{A}^{\frac{1}{2}} \mathbf{p}_j)^t \tilde{\mathbf{q}}_k. \end{aligned} \tag{15.266}$$

Letting $\mathbf{q}_k = \mathbf{A}^{-\frac{1}{2}} \tilde{\mathbf{q}}_k$ and multiplying (15.266) by $\mathbf{A}^{-\frac{1}{2}}$, we find

$$\mathbf{p}_k = \mathbf{q}_k - \sum_{j=0}^{k-1} \frac{\mathbf{p}_j^t \mathbf{A} \mathbf{q}_k}{d_j} \mathbf{p}_j. \tag{15.267}$$

Note that $\mathbf{A}^{\frac{1}{2}}$ no longer appears in this expression.

To show explicitly that this \mathbf{p}_k is conjugate to the previous $\mathbf{p}_i (i < k)$, we take the scalar product of \mathbf{p}_k with $\mathbf{A} \mathbf{p}_i$, yielding

$$(\mathbf{p}_k, \mathbf{A} \mathbf{p}_i) = \mathbf{q}_k^t \mathbf{A} \mathbf{p}_i - \sum_{j=0}^{k-1} \frac{\mathbf{p}_j^t \mathbf{A} \mathbf{q}_k}{d_j} (\mathbf{p}_j^t \mathbf{A} \mathbf{p}_i) = \mathbf{q}_k^t \mathbf{A} \mathbf{p}_i - \mathbf{q}_k^t \mathbf{A} \mathbf{p}_i = 0, \tag{15.268}$$

where we have used the conjugacy condition to set $\mathbf{p}_j^t \mathbf{A} \mathbf{p}_i$ to zero for $j \neq i$ and $i, j \leq k-1$. Thus, with any choice of \mathbf{q}_k , \mathbf{p}_k as defined by (15.267) can be used as the next conjugate vector, provided only that \mathbf{p}_k is nonzero.

Figure 15.5 provides a geometrical interpretation of (15.267). Since each \mathbf{p}_k is built from \mathbf{q}_k and the previous \mathbf{p}_i , the space $\mathbb{U}^{(k)}$ is spanned either by

$\{\mathbf{p}_j, 0 \leq j \leq k-1\}$ or by $\{\mathbf{q}_j, 0 \leq j \leq k-1\}$. The figure is drawn for $N = 3$ and $k = 2$, so $\mathbb{U}^{(k)}$ is an ordinary 2D plane, but in general it is a hyperplane. The vector \mathbf{p}_k is conjugate (not orthogonal) to this hyperplane.

Fig. 15.5 Illustration of the conjugate-gradient algorithm in 3D.

When the sequence of vectors $\{\mathbf{p}_k\}$ is used with the exact linear search algorithm of (15.262) and (15.263), the residual $\mathbf{r}^{(k)}$ is systematically reduced. Recalling that the residual $\mathbf{r}^{(k)}$ is the same thing as the gradient $\nabla Q^{(k)}$, we see from (15.258) and (15.262) that

$$\mathbf{r}^{(k+1)} = \mathbf{r}^{(k)} + h^{(k)} \mathbf{A} \mathbf{p}_k. \quad (15.269)$$

In fact, $\mathbf{r}^{(k+1)}$ turns out to be orthogonal to $\mathbb{U}^{(k)}$. We know that $\mathbf{A} \mathbf{p}_k$ is orthogonal to all previous \mathbf{p}_j and hence orthogonal to the subspace $\mathbb{U}^{(k)}$, and a proof by induction can be used to show that $\mathbf{r}^{(k)}$ is orthogonal to $\mathbb{U}^{(k)}$ (see Scales, 1985).

Hestenes-Stiefel algorithm The algorithm implied by (15.267) is not an efficient way of generating conjugate vectors since each term in the sum requires a matrix-vector multiplication, and the number of terms increases with k . Hestenes and Stiefel (1952) realized that a recursive algorithm requiring only one matrix-vector multiplication for each new conjugate vector could be obtained by choosing \mathbf{q}_k to be specifically the steepest-descent direction:

$$\mathbf{q}_k = -\nabla Q^{(k)} = -\mathbf{r}^{(k)}. \quad (15.270)$$

The algorithm is initialized by performing the initial search in the steepest-descent direction:

$$\mathbf{p}_0 = -\mathbf{r}^{(0)}. \quad (15.271)$$

With these choices and (15.267), the k^{th} conjugate vector is given by

$$\mathbf{p}_k = - \left[\mathbf{I} - \sum_{j=0}^{k-1} \frac{1}{d_j} \mathbf{p}_j (\mathbf{A} \mathbf{p}_j)^t \right] \mathbf{r}^{(k)} = -\mathbf{r}^{(k)} + \sum_{j=0}^{k-1} \frac{(\mathbf{A} \mathbf{p}_j)^t \mathbf{r}^{(k)}}{d_j} \mathbf{p}_j. \quad (15.272)$$

The key observation in the Hestenes-Stiefel approach is that

$$(\mathbf{A}\mathbf{p}_j)^t \mathbf{r}^{(k)} = 0 \quad \text{if } j < k - 1, \quad (15.273)$$

which follows from (15.269) since $\mathbf{A}\mathbf{p}_j \propto \mathbf{r}^{(j)} - \mathbf{r}^{(j-1)}$, a vector in $\mathbb{U}^{(j)}$, and we have already noted that successive residuals are orthogonal. Thus only one term in the sum in (15.272) survives, and we have

$$\mathbf{p}_k = -\mathbf{r}^{(k)} + \beta_k \mathbf{p}_{k-1}, \quad (15.274)$$

where

$$\beta_k = \frac{(\mathbf{A}\mathbf{p}_{k-1})^t \mathbf{r}^{(k)}}{d_{k-1}}. \quad (15.275)$$

Hence computation of \mathbf{p}_k requires knowledge of only the current residual and the immediately preceding conjugate vector, \mathbf{p}_{k-1} .

Quadratic termination An often-cited advantage of conjugate-gradient algorithms is their *quadratic-termination property*: If the functional is strictly quadratic, the true minimum will be reached in at most N steps. This property follows from (15.269); the residual is reduced component-by-component at each iteration and must be zero after N iterations.

As applied to image reconstruction, however, where N can be of order 10^5 or 10^6 , this property is not very useful. We can virtually never afford the computing resources to run this many iterations of any algorithm. Typically, reconstruction algorithms are run for only 10–100 iterations.

Conjugacy and pseudoinverses Conjugate vectors are also related to pseudoinverses of \mathbf{A} (Hestenes, 1975). Suppose \mathbf{A} is an $N \times N$ matrix of rank R . If we have a set of conjugate vectors, we can form the pseudoinverse of \mathbf{A} via

$$\mathbf{A}^+ = \sum_{j=1}^R \frac{1}{d_j} \mathbf{p}_j \mathbf{p}_j^t. \quad (15.276)$$

It follows from (15.259) that \mathbf{A}^+ constructed this way is a (1,2)-pseudoinverse (as defined in Sec. 1.6.1), and Hestenes shows that it is a Moore-Penrose pseudoinverse if and only if all of the \mathbf{p}_j are orthogonal to the null space of \mathbf{A} . Thus any algorithm for generating a sequence of conjugate vectors also generates a pseudoinverse of \mathbf{A} .

Moreover, if we have an arbitrary $N \times K$ matrix \mathbf{M} of rank R and wish to generate its pseudoinverse, we can simply form the $K \times K$ square matrix $\mathbf{A} = \mathbf{M}^t \mathbf{M}$ and generate the \mathbf{A} -conjugate $K \times 1$ vectors $\{\mathbf{p}_j, j = 1, \dots, R\}$. The pseudoinverse of \mathbf{M} is then given by (Hestenes, 1975)

$$\mathbf{M}^+ = \sum_{j=1}^R \frac{1}{d_j} \mathbf{p}_j (\mathbf{M}\mathbf{p}_j)^t. \quad (15.277)$$

This result can be compared to (1.131); the structure is the same but we do not need to find the singular vectors and singular values in order to use (15.277).

15.4.4 Nonlinear constraints and fixed-point iterations

Linear algorithms or search methods can always be used to minimize the functional $Q(\boldsymbol{\theta}, \mathbf{g})$ if there are no constraints on the solution, but often we want to impose some nonlinear constraints, the most important of which is that the solution cannot go negative. In this section we first discuss some simple modifications of linear algorithms to incorporate such constraints. Then we introduce a broad class of algorithms that will often converge to a solution satisfying the constraints.

Modified linear algorithms As a starting point, consider the form of linear algorithm given in (15.233), which is general enough to encompass the Jacobi, Gauss-Seidel and Landweber algorithms, among others. As we discussed in Sec. 15.4.1, when this algorithm converges it ensures that $\mathbf{g} = \mathbf{H}\hat{\boldsymbol{\theta}}^{(k)}$, but it places no other constraints on the solution. It can be very useful to modify the algorithm so as to enforce prior knowledge such as positivity or finite support.

One way to enforce a positivity constraint is to clip off negative values at each iteration. Then (15.233) is modified to

$$\hat{\boldsymbol{\theta}}^{(k+1)} = \mathbf{P}_+ \{ \hat{\boldsymbol{\theta}}^{(k)} + \mathbf{B}[\mathbf{g} - \mathbf{H}\hat{\boldsymbol{\theta}}^{(k)}] \}, \quad (15.278)$$

where \mathbf{P}_+ is the positivity operator defined in (15.186). At each iteration the estimate is nonnegative, so if the algorithm converges it must do so by finding a nonnegative solution such that $\mathbf{B}[\mathbf{g} - \mathbf{H}\hat{\boldsymbol{\theta}}^{(k)}] = 0$. If \mathbf{B} has no null functions in data space, that means that $\mathbf{g} = \mathbf{H}\hat{\boldsymbol{\theta}}^{(k)}$.

Other constraint operators can be used in addition to or in place of the operator \mathbf{P}_+ in (15.278). For example, if we are working in a pixel representation and we know that the object is zero outside a support region \mathbf{S} , we can use an operator $\mathbf{P}_{\mathbf{S}}$ that sets pixel values to zero outside this region.

A general framework for successively enforcing constraints such as positivity and support is the method of projections onto convex sets, to be discussed in Sec. 15.4.5.

Fixed-point iterations As we saw in Sec. 15.3.4, it is often possible to work from the KKT conditions to an implicit equation that must be satisfied when the functional $Q(\boldsymbol{\theta}, \mathbf{g})$ is minimized; an example is given in (15.194). The general form of this implicit equation is

$$\hat{\boldsymbol{\theta}} = \mathbf{T}\{\hat{\boldsymbol{\theta}}, \mathbf{g}\}, \quad (15.279)$$

where $\mathbf{T}\{\hat{\boldsymbol{\theta}}, \mathbf{g}\}$ is some vector-valued (and usually nonlinear) functional of its arguments.

To convert (15.279) to an iterative algorithm, we can define a sequence of estimates $\hat{\boldsymbol{\theta}}^{(k)}$ by a *fixed-point iteration* of the form

$$\hat{\boldsymbol{\theta}}^{(k+1)} = \mathbf{T}\{\hat{\boldsymbol{\theta}}^{(k)}, \mathbf{g}\}. \quad (15.280)$$

It is not obvious that this sequence will converge, but if it does the convergent point must satisfy (15.279); this point is called the fixed point of the nonlinear equation.

A sufficient condition for the convergence of a fixed-point iteration is provided by the *contraction-mapping theorem* generally attributed to Banach (see Stakgold, 1979; Kreysig, 1978). For fixed \mathbf{g} , the mapping $\mathbf{T}\{\boldsymbol{\theta}, \mathbf{g}\}$ is called a *contraction* if

$$\|\mathbf{T}\{\boldsymbol{\theta}_1, \mathbf{g}\} - \mathbf{T}\{\boldsymbol{\theta}_2, \mathbf{g}\}\|^2 < \|\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2\|^2, \quad (15.281)$$

for any vectors θ_1 and θ_2 . That is, the effect of the mapping is to bring two arbitrary points closer together. The contraction-mapping theorem states that the algorithm (15.280) will converge to the fixed point for all starting points if $\mathbf{T}\{\theta, \mathbf{g}\}$ is a contraction. A graphical way of understanding this theorem is given in Fig. 15.6. Weaker versions of the theorem that require the operator to be a contraction only within some local region are given by Kreysig (1978).

An example of a fixed-point iteration is (15.278). For the special case where $\mathbf{B} = \mathbf{H}^\dagger$, it can be shown (details are left to the reader) that the mapping in that algorithm is a contraction provided $\mu_1 < 2$, where μ_1 is the largest eigenvalue of $\mathbf{H}^\dagger \mathbf{H}$. This is precisely the condition derived in Sec. 1.7.6 for the convergence of the linear Landweber algorithm, and now we see that it is sufficient for the nonlinear version as well.

Fig. 15.6 Illustration of a fixed-point algorithm in 1D.

15.4.5 Projections onto convex sets

As we have seen, image reconstruction often seeks to find an image that satisfies certain constraints such as positivity, support, smoothness or agreement with the data. Many of these constraints can be formulated as convex sets (defined more precisely below), and a satisfactory image can be regarded as one that satisfies all of the constraints and hence lies in the intersection of these sets. The *method of projections* (MOP) and more specifically *projections onto convex sets* (POCS) is a very general tool for finding such a satisfactory image.

MOP was originated by John von Neumann (1950) who considered projections onto closed linear manifolds. The extension to convex sets was made by Bregman (1965), and the potential of POCS for signal processing was enunciated by Youla (1978). Applications to imaging were discussed by Youla and Webb (1982). Levi and Stark (1987) extended MOP to nonconvex projections, yielding the *method of generalized projections*. Excellent reviews are given by Sezan (1992), Combettes (1993) and Stark and Sezan (1994).

Convexity A convex set is defined as follows: If θ and θ' are members of the set, so is $\alpha\theta + (1 - \alpha)\theta'$ for $0 \leq \alpha \leq 1$. The geometric interpretation of this condition is that all points along the line joining θ and θ' are members of the set if θ and θ' are members (see Fig. 15.7). The set of all nonnegative objects is a convex set, as is the set of all objects with a specified support region.

The operators \mathbf{P}_+ and \mathbf{P}_S defined in Sec. 15.4.4 are projectors onto convex sets. Acting on a θ that is not a member of the set, they produce the member of the set

that is nearest to $\boldsymbol{\theta}$ in the sense of minimizing the \mathbb{L}_2 norm $\|\mathbf{P}\boldsymbol{\theta} - \boldsymbol{\theta}\|$. Projectors onto convex sets are not necessarily projectors onto subspaces as discussed in Sec. 1.3.6. The set of vectors with nonnegative components, for example, is not a linear vector space.

Fig. 15.7 Examples of convex and nonconvex sets.

Besides positivity and support, many other convex sets have been proposed in the imaging literature (Stark and Sezan, 1994). For example, if the object is defined as a transmittance, it can take on values only between 0 and 1, and the upper limit as well as the lower limit defines a convex set. Smoothness can be enforced by setting an upper bound to the norm of some derivative of the image.

Data agreement Agreement with the data also defines a convex set. Strict agreement implies the set of all $\boldsymbol{\theta}$ such that $\mathbf{H}\boldsymbol{\theta} \equiv \mathbf{g}$, so members of the set differ by null functions. Since linear combinations of null functions are null functions, it follows readily that this set is convex.

To discover the form for the projector onto this set, recall from (1.188) that the general exact solution to $\mathbf{H}\boldsymbol{\theta} = \mathbf{g}$ is

$$\boldsymbol{\theta} = \mathbf{H}^+ \mathbf{g} + [\mathbf{I}_N - \mathbf{H}^+ \mathbf{H}] \mathbf{y}, \quad (15.282)$$

where \mathbf{y} is an arbitrary $N \times 1$ vector and $[\mathbf{I}_N - \mathbf{H}^+ \mathbf{H}] \mathbf{y}$ is the component of \mathbf{y} in the null space (if any) of the $M \times N$ matrix \mathbf{H} . Projection of an arbitrary $\hat{\boldsymbol{\theta}}$ onto the set of functions of this form is accomplished by replacing the measurement component of $\hat{\boldsymbol{\theta}}$ with $\mathbf{H}^+ \mathbf{g}$ and leaving the null component unchanged; in this way we find the vector in the convex set that is closest (in a Euclidean sense) to the original $\hat{\boldsymbol{\theta}}$. Explicitly, if we denote the projector onto the set defined by $\mathbf{H}\boldsymbol{\theta} = \mathbf{g}$ as $\mathbf{P}_{\mathbf{g}}$, then

$$\mathbf{P}_{\mathbf{g}}\{\hat{\boldsymbol{\theta}}\} = \mathbf{H}^+ \mathbf{g} + [\mathbf{I}_N - \mathbf{H}^+ \mathbf{H}] \hat{\boldsymbol{\theta}}. \quad (15.283)$$

We shall illustrate the use of this equation below when we discuss the Gerchberg-Papoulis algorithm.

We can also define the set of all $\boldsymbol{\theta}$ such that $\|\mathbf{g} - \mathbf{H}\boldsymbol{\theta}\| \leq \epsilon$. To see that this set is convex, note that

$$\begin{aligned} \|\mathbf{g} - \alpha \mathbf{H}\boldsymbol{\theta} - (1 - \alpha) \mathbf{H}\boldsymbol{\theta}'\| &= \|\alpha(\mathbf{g} - \mathbf{H}\boldsymbol{\theta}) - (1 - \alpha)(\mathbf{g} - \mathbf{H}\boldsymbol{\theta}')\| \\ &\leq \alpha \|\mathbf{g} - \mathbf{H}\boldsymbol{\theta}\| + (1 - \alpha) \|\mathbf{g} - \mathbf{H}\boldsymbol{\theta}'\| \leq \alpha \epsilon + (1 - \alpha) \epsilon = \epsilon, \end{aligned} \quad (15.284)$$

where we have used some properties of the norm, including the triangle inequality (see Sec. 1.1.2).

Another convex set related to data agreement is the set of all θ such that $(\mathbf{H}\theta)_m = g_m$ for a particular m . Derivation of the projectors for these latter two sets will be left as an exercise.

Fundamental theorem of POCS Suppose we have J different convex sets $\mathbf{C}_j, j = 1, \dots, J$, with corresponding projectors $\mathbf{P}_j, j = 1, \dots, J$. Suppose also that the intersection of these sets is not empty. If we apply each of the projectors sequentially (in any order), so that the update rule is

$$\hat{\theta}^{(k+1)} = \mathbf{P}_J \mathbf{P}_{J-1} \dots \mathbf{P}_2 \mathbf{P}_1 \hat{\theta}^{(k)}, \tag{15.285}$$

then the iteration will converge, regardless of the initialization, to a point in the intersection of the sets (Youla, 1978). This result is illustrated geometrically in Fig. 15.8.

Fig. 15.8 Illustration of successive projections onto convex sets.

Corresponding to the projector \mathbf{P}_j , there is a *relaxed* projector defined by

$$\mathbf{P}_j^\lambda = \mathbf{I} + \lambda_j (\mathbf{P}_j - \mathbf{I}), \tag{15.286}$$

where $\lambda_j \geq 0$ and \mathbf{I} is the identity operator. The iteration rule for the relaxed projectors is

$$\hat{\theta}^{(k+1)} = \mathbf{P}_J^\lambda \mathbf{P}_{J-1}^\lambda \dots \mathbf{P}_2^\lambda \mathbf{P}_1^\lambda \hat{\theta}^{(k)}, \tag{15.287}$$

and this iteration can be shown (Youla, 1978) to converge to a point in the intersection of the sets provided $0 < \lambda_j < 2$ for all j .

Example of POCS: Gerchberg-Papoulis algorithm Suppose we have acquired image data with a diffraction-limited lens and a discrete detector array such as a CCD (charge-coupled device). We know from the discussion in Sec. 9.7 that this system is approximately shift-invariant and bandlimited, and we know how to compute its presampling transfer function $P(\rho)$. If the detector array samples finely enough, simple inverse filtering will allow us to estimate accurately the object Fourier components for $\rho < \rho_c$, where ρ_c is the cutoff frequency and $\rho = |\boldsymbol{\rho}|$. Can we also recover components with $\rho > \rho_c$, which lie in the null space of the imaging system? Doing so is often referred to as *superresolution*.

One approach that has had a modicum of success in achieving superresolution is a form of POCS known as the *Gerchberg-Papoulis algorithm* (Gerchberg, 1974;

Papoulis, 1975). It successively enforces data agreement and positivity and support constraints in the hope that the prior information infused by the latter two constraints will help to fill in the null space.

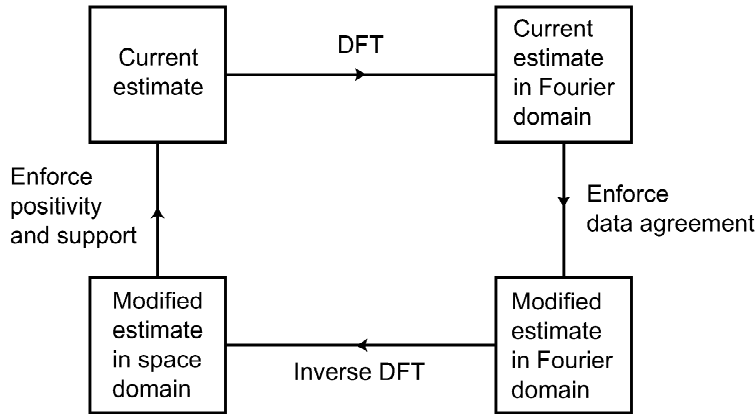

Fig. 15.9 Illustration of the Gerchberg-Papoulis algorithm.

In practice, the Gerchberg-Papoulis algorithm uses a DFT (discrete Fourier transform) of θ and assumes that the components are known (after inverse filtering) within the system passband. The algorithm, illustrated in Fig. 15.9, is specified by

$$\hat{\theta}^{(k+1)} = \mathbf{P}_g \mathbf{P}_+ \mathbf{P}_s \hat{\theta}^{(k)}, \quad (15.288)$$

where the three projection operators have been defined above. Agreement with the data is enforced in the discrete Fourier domain by replacing the Fourier components within the band with their known values but retaining the current estimates for out-of-band components. Roughly speaking, out-of-band Fourier components are identified with null functions, and Fourier-domain inverse filtering is essentially the pseudoinverse for shift-invariant systems, so this projection operation is an implementation of (15.283). Then the estimate is transformed back to the (discrete) space domain so that the positivity and support constraints can easily be enforced. The algorithm will converge to a $\hat{\theta}$ satisfying all three constraints if such a solution exists.

Gerchberg-Papoulis and Fourier crosstalk The discussion above glossed over the CD nature of the imaging system and the distinctions between continuous and discrete Fourier transforms. It was also based implicitly on a finite-dimensional object representation with coefficients specified by the $N \times 1$ vector θ . We shall now sketch a treatment based on the infinite-dimensional Fourier-series representation of the object and the Fourier crosstalk matrix. Essential background information will be found in Sec. 7.3.3.

Consider a spacelimited object but a bandlimited imaging system consisting again of a lens and a detector array, and assume that the system is linear and shift-invariant (LSIV) before sampling. The system thus maps a 2D object $f(\mathbf{r})$ into a 2D irradiance distribution on the detector plane.

If the noise is negligible (as it must be for superresolution to work), then the data can be expressed as [cf. (7.260)]

$$g_m = \sum_{\mathbf{k}} \psi_{m\mathbf{k}} F_{\mathbf{k}}, \quad (15.289)$$

where $F_{\mathbf{k}}$ is the doubly infinite vector of object Fourier coefficients. In vector form, (15.289) is $\mathbf{g} = \Psi \mathbf{F}$. We know from (7.274) that

$$\psi_{m\mathbf{k}} = \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}_{dm}) P(\boldsymbol{\rho}_{\mathbf{k}}), \quad (15.290)$$

where \mathbf{r}_{dm} is the location of the m^{th} detector element and $P(\boldsymbol{\rho})$ is the presampling transfer function of the overall LSIV system (including the finite size of the detector elements). Since the system is bandlimited, $P(\boldsymbol{\rho}) = 0$ if $\boldsymbol{\rho}$ is greater than some cutoff frequency ρ_c .

It often happens that a useful first step in an inverse problem is to apply an adjoint operator to get back to the object domain. If the object is specified by its Fourier coefficients, the relevant adjoint is Ψ^\dagger ; applying Ψ^\dagger to \mathbf{g} yields

$$\Psi^\dagger \mathbf{g} = \Psi^\dagger \Psi \mathbf{F} = \mathbf{B} \mathbf{F}, \quad (15.291)$$

where \mathbf{B} is the Fourier crosstalk matrix. As discussed in Sec. 7.3, \mathbf{B} is an infinite matrix, but in the present problem all of its elements are zero except within a finite-dimensional submatrix. Moreover, if the pitch of the detector array satisfies the Nyquist condition⁸ for sampling the irradiance pattern incident on the detector, this submatrix is strictly diagonal, and its elements are known from (7.276) to be

$$\beta_{\mathbf{k}\mathbf{k}} = M |P(\boldsymbol{\rho}_{\mathbf{k}})|^2, \quad (15.292)$$

where M is the total number of detector elements.

With these assumptions, the pseudoinverse of Ψ consists of division by the nonzero diagonal elements. If we assume that $P(\boldsymbol{\rho}_{\mathbf{k}})$ is not exactly zero at any in-band sampling frequency $\boldsymbol{\rho}_{\mathbf{k}}$, the in-band Fourier coefficients are given by

$$F_{\mathbf{k}} = \Psi^+ \mathbf{g} = \frac{[\Psi^\dagger \mathbf{g}]_{\mathbf{k}}}{\beta_{\mathbf{k}\mathbf{k}}} = \frac{P^*(\boldsymbol{\rho}_{\mathbf{k}}) \sum_m g_m \exp(-2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}_{dm})}{M |P(\boldsymbol{\rho}_{\mathbf{k}})|^2}, \quad |\boldsymbol{\rho}_{\mathbf{k}}| < \rho_c. \quad (15.293)$$

To get an infinite-dimensional form of Gerchberg-Papoulis, the projector $\mathbf{P}_{\mathbf{g}}$ defined in (15.283) is replaced by the infinite-dimensional operator $\mathcal{P}_{\mathbf{g}}$ that projects a function $\hat{\mathbf{f}}$ onto the subset of \mathbb{U} for which $\mathcal{H}\mathbf{f} = \mathbf{g}$ or equivalently, $\Psi \mathbf{F} = \mathbf{g}$. By analogy to (15.283), this operator is formally

$$\mathcal{P}_{\mathbf{g}}\{\hat{\mathbf{F}}\} = \Psi^+ \mathbf{g} + [\mathcal{I} - \Psi^+ \Psi] \hat{\mathbf{F}}. \quad (15.294)$$

Operationally, this projector can be implemented at each POCS iteration by replacing in-band Fourier coefficients with the known values from (15.293) and leaving

⁸There are two distinct Nyquist conditions in this problem, one for the object and one for the system, and both can be exactly satisfied simultaneously. The finite spatial support of the object sets the required sampling in the Fourier domain (see Sec. 3.5.4), and the finite bandwidth of the system before sampling sets the required pitch of the CCD to avoid aliasing. We do not need to assume that the object is bandlimited or that the irradiance pattern on the CCD plane is spatially limited.

the out-of-band ones alone.

Positivity and support constraints cannot be implemented readily on Fourier coefficients, so transformation back to the space domain is still required. The exact transformation rule is

$$\hat{f}(\mathbf{r}) = \sum_{\mathbf{k}} \hat{F}_{\mathbf{k}} \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}), \quad (15.295)$$

where the sum is, in principle, infinite in two dimensions. In practice, of course, a finite sum must be used, with the range determined by the amount of superresolution desired. To transform back to Fourier coefficients, the exact equation is

$$\hat{F}_{\mathbf{k}} = \frac{1}{L^2} \int_{\mathbf{S}_f} d^2r \hat{f}(\mathbf{r}) \exp(-2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}), \quad (15.296)$$

where the object support \mathbf{S}_f is assumed to be a square of side L . In practice the integral would be implemented as a sum, most likely as a DFT (though one with many more than M elements).

15.4.6 MLEM algorithm

An important iterative technique is the *maximum-likelihood expectation-maximization* or *MLEM* algorithm, so called because it can be derived by alternating expectation (E) and maximization (M) steps, and because it maximizes the likelihood for a Poisson data model. MLEM has been rediscovered several times. To the authors' knowledge, the earliest paper to present the algorithm was by Metz and Pizer (1971) at the second international conference on Information Processing in Medical Imaging (IPMI). Unfortunately, the untimely death of the conference organizer, Eberhard Jahns, led to the promised Proceedings of IPMI II never appearing and thus the Metz and Pizer paper never being published.

In the optics literature, the MLEM algorithm was presented independently by Richardson (1972) and Lucy (1974), and it is still referred to often as the Richardson-Lucy algorithm. The paper that ignited widespread interest for tomographic applications was by Shepp and Vardi (1982). Another important early contribution to the tomographic literature was Lange and Carson (1984).

MLEM is but one example of a broad class of algorithms that alternate expectation and maximization steps. A rigorous treatment of these more general EM algorithms was given in an important paper by Dempster, Laird and Rubin (1977), and an excellent monograph on the subject is McLachlan and Krishnan (1997). In this section, however, we consider only the MLEM algorithm.

MLEM as a multiplicative algorithm The iteration rule for the basic MLEM algorithm is

$$\hat{\theta}_n^{(k+1)} = \hat{\theta}_n^{(k)} \frac{1}{s_n} \sum_{m=0}^M \frac{g_m}{(\mathbf{H}\hat{\theta}^{(k)})_m} H_{mn}, \quad (15.297)$$

where s_n is the n^{th} component of the point sensitivity vector, defined in (7.312) as

$$s_n = \sum_{m=0}^M H_{mn}. \quad (15.298)$$

To interpret s_n , consider the usual voxel description of a source where θ_n is the mean number of photons emitted from the n^{th} voxel and H_{mn} is the probability that a

photon from voxel n is detected in detector m . Then $s_n \theta_n$ is the mean number of photons from that voxel detected by all detectors, and s_n is the probability that a photon emitted from voxel n is detected somewhere. We need not worry about dividing by zero in (15.297) since voxels with $s_n = 0$ have zero probability of ever contributing to the data and should not be included in the representation in the first place.

Unlike the linear algorithms discussed in Sec. 15.4.1 and the modified linear algorithms discussed in Sec. 15.4.4, MLEM is a *multiplicative algorithm* where an estimate is modified by multiplying it by a correction factor rather than adding a correction term. Other important examples of multiplicative algorithms include multiplicative ART or MART (Gordon *et al.*, 1970) and its variants (Byrne, 1993; 1995) and the SAGE (space-alternating generalized EM) algorithms (Fessler and Hero, 1994), but we shall not discuss any of these methods further.

The MLEM algorithm preserves positivity; that is, if the initial estimate $\hat{\boldsymbol{\theta}}^{(0)}$ is nonnegative, and if all elements of \mathbf{g} and \mathbf{H} are nonnegative, then all subsequent iterations remain nonnegative since we always multiply by a nonnegative factor. By the same token, however, a component of the estimate will seldom be driven exactly to zero; if H_{mn} is nonzero for *any* m for which g_m is nonzero, then the correction factor for $\hat{\theta}_n^{(k)}$ will not be zero. In this respect, the MLEM algorithm is like maximum entropy in that it tends to drive the estimate towards zero but never quite gets there. The exception would be if $g_m = 0$ for all detectors for which $H_{mn} \neq 0$ for a given n ; in that case $\hat{\theta}_n^{(k)}$ would be immediately set to zero.

If we know the support of the object *a priori*, on the other hand, we can set the elements of the estimate (in a voxel representation) outside the support to zero in the initial estimate and they will remain zero for all subsequent iterations.

Finally, note that the algorithm strives for agreement between the actual data and the image of the estimate. If $(\mathbf{H}\hat{\boldsymbol{\theta}}^{(k)})_m = g_m$ for all m , then the correction factor is unity and no further change in the estimate occurs. Of course, it may not be possible to find an estimate such that $(\mathbf{H}\hat{\boldsymbol{\theta}}^{(k)})_m = g_m$ for all m , and in that case it turns out (as we shall see below) that the algorithm converges to an estimate that minimizes the Kullback-Leibler distance (see Sec. 15.3.2) $D_{\text{KL}}(\mathbf{g}, \mathbf{H}\hat{\boldsymbol{\theta}})$ between the data and the image of the estimate.

Poisson likelihood As presented so far, the MLEM algorithm is just a convenient way of finding an estimate that agrees as well as possible (in the Kullback-Leibler sense) with the data. It has no particular relation to the statistics of the data and in fact will work with many different kinds of data. We know from Sec. 15.3.2, however, that the Kullback-Leibler distance is closely related to the log-likelihood for Poisson data, and we shall now explore this relation further.

If we consider an *MD* Poisson random vector \mathbf{g} with mean $\mathbf{H}\boldsymbol{\theta}$, then

$$\Pr(\mathbf{g}|\boldsymbol{\theta}) = \prod_{m=1}^M \exp[-(\mathbf{H}\boldsymbol{\theta})_m] \frac{[(\mathbf{H}\boldsymbol{\theta})_m]^{g_m}}{g_m!}, \quad (15.299)$$

and $\Pr(\mathbf{g}|\boldsymbol{\theta})$ is the likelihood of $\boldsymbol{\theta}$ for a given \mathbf{g} . One must view this equation with caution, however, since we are free to choose any representation we like for the object, with any number of components N . It is only when the finite object representation is an adequate representation of the data, in the sense that $\mathbf{H}\boldsymbol{\theta}$ is a good approximation to $\boldsymbol{\mathcal{H}}\mathbf{f}$, that $\Pr(\mathbf{g}|\boldsymbol{\theta})$ is really the likelihood of $\boldsymbol{\theta}$. [See (15.137)

and the associated discussion.]

With this caveat, the logarithm of the likelihood is given by (15.149), repeated here for convenience:

$$\ln[\Pr(\mathbf{g}|\boldsymbol{\theta})] = \sum_{m=1}^M \{- (\mathbf{H}\boldsymbol{\theta})_m + g_m \ln[(\mathbf{H}\boldsymbol{\theta})_m] - \ln(g_m!)\}. \quad (15.300)$$

An extremum of this function occurs at a point where the derivative with respect to all components vanishes:

$$\frac{\partial}{\partial \theta_j} \ln[\Pr(\mathbf{g}|\boldsymbol{\theta})] = \sum_{m=0}^M \left\{ -H_{mj} + \frac{g_m}{(\mathbf{H}\boldsymbol{\theta})_m} H_{mj} \right\} = 0, \quad j = 1, \dots, N. \quad (15.301)$$

To see whether the extremum is a minimum or a maximum, we take another derivative:

$$\frac{\partial^2}{\partial \theta_j \partial \theta_k} \ln[\Pr(\mathbf{g}|\boldsymbol{\theta})] = \sum_{m=0}^M \left\{ -\frac{g_m}{[(\mathbf{H}\boldsymbol{\theta})_m]^2} H_{mj} H_{mk} \right\}. \quad (15.302)$$

All components of \mathbf{g} and $\mathbf{H}\boldsymbol{\theta}$ must be nonnegative for the Poisson law to be applicable; a negative number of counts makes no sense. Moreover, all elements of \mathbf{H} must be nonnegative, since otherwise a negative component of $\mathbf{H}\boldsymbol{\theta}$ could occur for some nonnegative $\boldsymbol{\theta}$. Thus the second derivative is negative everywhere (*i.e.*, the log-likelihood is concave), and any extremum must be a maximum. Maximizing the likelihood is thus equivalent to solving the implicit equation (15.301) for $\boldsymbol{\theta}$. Moreover, from the discussion in Sec. 15.3.2, it is also equivalent to minimizing the Kullback-Leibler distance $D_{\text{KL}}(\mathbf{g}, \mathbf{H}\boldsymbol{\theta})$.

MLEM as a fixed-point iteration We can rewrite (15.301) (with the dummy index j changed to n) as

$$\frac{1}{s_n} \sum_{m=0}^M \frac{g_m}{(\mathbf{H}\boldsymbol{\theta})_m} H_{mn} = 1, \quad (15.303)$$

where s_n is defined in (15.298). We now multiply both sides of (15.303) by θ_n , yielding

$$\theta_n = \theta_n \frac{1}{s_n} \sum_{m=0}^M \frac{g_m}{(\mathbf{H}\boldsymbol{\theta})_m} H_{mn}. \quad (15.304)$$

To get an iterative algorithm, we replace $\boldsymbol{\theta}$ by a succession of estimates $\hat{\boldsymbol{\theta}}^{(k)}$ and use the fixed-point iteration procedure introduced in Sec. 15.4.4; the result is the MLEM algorithm:

$$\hat{\theta}_n^{(k+1)} = \hat{\theta}_n^{(k)} \frac{1}{s_n} \sum_{m=0}^M \frac{g_m}{(\mathbf{H}\hat{\boldsymbol{\theta}}^{(k)})_m} H_{mn}. \quad (15.305)$$

If this algorithm converges, it must find a maximum of the log-likelihood (and hence of the likelihood itself).

Convergence and stopping rules The mapping defined by (15.305) is not a contraction and hence does not necessarily converge to a fixed point independent of the initial estimate. It can, however, be shown to converge in the sense that the likelihood increases monotonically at each step (Dempster *et al.*, 1977). Of course, just

because the algorithm approaches a specified likelihood (the maximum value) does not mean it approaches a specified image. The likelihood is a function of $\mathbf{H}\boldsymbol{\theta}$, not $\boldsymbol{\theta}$ alone. If \mathbf{H} has null functions, many different $\boldsymbol{\theta}$ can give the same $\mathbf{H}\boldsymbol{\theta}$ and hence the same likelihood; which one is obtained by the algorithm depends on the null components of the initial estimate.

Moreover, maximum likelihood is seldom a desirable end point in image reconstruction. As we have stressed repeatedly, forcing agreement with noisy data (in any sense) results in noisy images. In practice, running the MLEM algorithm for a large number of iterations usually results in a virtually useless image, often one consisting of a few bright pixels like the night-sky reconstructions discussed in Sec. 15.3.5. (For an example, see Fig. 17.9.)

The most common way of avoiding these problems is just to stop the algorithm before it gives a poor image in some sense. In this case, the image is not a maximum-likelihood estimate, and it depends on the number of iterations and the initial estimate. The choice of stopping point is usually made purely subjectively, though various statistical stopping rules have been proposed (see, for example, Llacer and Veklerov, 1989) as a means of avoiding excessive noise amplification. The stopping point should ideally be chosen to optimize some objective measure of image quality, such as the ability of a human observer to detect an abnormality (see Sec. 14.2), but in practice it is usually done without regard to task.

15.4.7 Noise propagation in nonlinear algorithms

We have already discussed the noise properties of reconstructed images in several cases in this chapter. In Sec. 15.2.6 we treated the effect of a linear reconstruction operator on noise in the data, and in Sec. 15.3.6 we considered implicit estimates and found that we could get useful analytical forms for the covariance without specifying the algorithm for actually finding the estimate. Then, in Sec. 15.4.2 we studied noise propagation through linear iterative algorithms. Now we shall show how that analysis needs to be modified for nonlinear iterative algorithms. The main difference will turn out to be that constant matrices are replaced by ones that depend on the current estimate.

Differentiable update rules All of the iterative algorithms considered in this chapter have the general form,

$$\hat{\boldsymbol{\theta}}^{(k+1)} = \mathbf{D}^{(k)}\{\hat{\boldsymbol{\theta}}^{(k)}, \mathbf{g}\}, \quad (15.306)$$

where $\mathbf{D}^{(k)}\{\cdot, \cdot\}$ is a vector-valued functional of its two arguments. The fixed-point iteration of (15.280) is immediately in this form, and POCS, MLEM and conjugate-gradient fit as well.

It will be very useful to assume that $\mathbf{D}^{(k)}\{\cdot, \cdot\}$ is differentiable with respect to both arguments. That assumption is justified by inspection for MLEM, conjugate-gradient and many other algorithms, but it may not hold for POCS or other algorithms that employ a clipping operator such as \mathbf{P}_+ as defined in (15.186). To get around this difficulty, we can redefine $\mathbf{P}_+\{x\}$ as the limit of a differentiable functional, for example,

$$\mathbf{P}_+\{x\} = x \operatorname{step}(x) = \lim_{\beta \rightarrow \infty} \frac{x}{1 - \exp(-\beta x)}. \quad (15.307)$$

Basic propagation equations Assuming the update operator $\mathbf{D}^{(k)}\{\hat{\boldsymbol{\theta}}^{(k)}, \mathbf{g}\}$ is differentiable, we want to expand it in a Taylor series and retain only terms linear in small perturbations of both arguments. For the perturbation of the second argument, we have two options: we can write either $\mathbf{g} = \mathbf{H}\boldsymbol{\theta} + \boldsymbol{\epsilon}$ or $\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}$, and therefore we can consider either $\boldsymbol{\epsilon}$ or \mathbf{n} to be the perturbation. As we did in earlier noise analysis in this chapter, we shall choose \mathbf{n} because we know a great deal more about its statistics: it has zero mean by definition, and its covariance can usually be determined from the physics of the imaging process.

Similarly, we have some options about how we expand the first argument. A natural choice would seem to be to consider small perturbations about the true $\boldsymbol{\theta}$, but that runs afoul of what we have learned in this chapter about estimability. We know that many different objects can give the same data and hence the same sequence of estimates $\{\hat{\boldsymbol{\theta}}^{(k)}\}$, yet they may have quite different true $\boldsymbol{\theta}$; a small perturbation about one of them might be a large perturbation with respect to another. Another option would be to expand about the final estimate, $\hat{\boldsymbol{\theta}}^{(\infty)}$ or some approximation to it, but this is not wise either; the algorithm may not converge at all (which is precisely why we need to know the statistics as a function of iteration number), or it may converge to a solution that is substantially different from $\hat{\boldsymbol{\theta}}^{(k)}$ at earlier iterations, so $\hat{\boldsymbol{\theta}}^{(\infty)}$ is a poor choice for the center of expansion.

A better choice is to expand $\hat{\boldsymbol{\theta}}^{(k)}$ about its mean *at each iteration* (Barrett *et al.*, 1994). We thus use a different Taylor series for each k , and so long as \mathbf{n} is small enough compared to $\mathcal{H}\mathbf{f}$, we can be confident that truncation of the series with linear terms is valid.

To simplify the notation, we denote the conditional mean of $\hat{\boldsymbol{\theta}}^{(k)}$ (for specified \mathbf{f}) as $\mathbf{a}^{(k)}$ and write

$$\hat{\boldsymbol{\theta}}^{(k)} = \mathbf{a}^{(k)} + \Delta\hat{\boldsymbol{\theta}}^{(k)}. \quad (15.308)$$

The linearized Taylor expansion is then

$$\hat{\boldsymbol{\theta}}^{(k+1)} = \mathbf{D}^{(k)}\{\hat{\boldsymbol{\theta}}^{(k)}, \mathbf{g}\} \simeq \mathbf{D}^{(k)}\{\hat{\mathbf{a}}^{(k)}, \mathcal{H}\mathbf{f}\} + \boldsymbol{\Omega}^{(k)}\Delta\hat{\boldsymbol{\theta}}^{(k)} + \mathbf{B}^{(k)}\mathbf{n}, \quad (15.309)$$

where $\boldsymbol{\Omega}^{(k)}$ is an $N \times N$ matrix with components

$$[\boldsymbol{\Omega}^{(k)}]_{nn'} = \frac{\partial}{\partial \hat{\theta}_{n'}} D_n^{(k)}\{\hat{\boldsymbol{\theta}}^{(k)}, \mathcal{H}\mathbf{f}\}, \quad (15.310)$$

and $\mathbf{B}^{(k)}$ is an $N \times M$ matrix with components

$$[\mathbf{B}^{(k)}]_{nm} = \left[\frac{\partial}{\partial g_m} D_n^{(k)}\{\hat{\boldsymbol{\theta}}^{(k)}, \mathbf{g}\} \right]_{\mathbf{g}=\mathcal{H}\mathbf{f}}. \quad (15.311)$$

Within this linearized formulation, therefore, the mean estimate evolves as

$$\hat{\mathbf{a}}^{(k+1)} = \mathbf{D}^{(k)}\{\hat{\mathbf{a}}^{(k)}, \mathcal{H}\mathbf{f}\} \quad (15.312)$$

and the deviation from the mean evolves as

$$\Delta\hat{\boldsymbol{\theta}}^{(k+1)} = \boldsymbol{\Omega}^{(k)}\Delta\hat{\boldsymbol{\theta}}^{(k)} + \mathbf{B}^{(k)}\mathbf{n}. \quad (15.313)$$

These results should be compared to (15.240) and (15.241), which were derived for linear iterative algorithms. Like (15.240), (15.312) shows that the sequence of mean

values $\{\hat{\mathbf{a}}^{(k)}\}$ can be generated by running the algorithm on noise-free data, $\mathbf{g} = \mathcal{H}\mathbf{f}$, which can be simulated or obtained experimentally by frame-averaging or by using a long exposure time (in the case of Poisson noise).

The equations for propagation of the deviations through linear and nonlinear algorithms, (15.241) and (15.313) respectively, have identical forms, but the matrices $\mathbf{\Omega}^{(k)}$ and $\mathbf{B}^{(k)}$ have somewhat different meanings. They are independent of \mathbf{g} and $\boldsymbol{\theta}^{(k)}$ in the linear case, and they are also independent of k unless the update rule itself varies with iteration number. In the nonlinear case, by contrast, the matrices depend on the current estimate $\boldsymbol{\theta}^{(k)}$, so they must vary with k .

Since (15.241) and (15.313) have the same form, the remainder of the derivation in Sec. 15.4.2 still holds, and in particular the expressions (15.247)–(15.249) for the covariance matrix are still valid. As noted in Sec. 15.4.2, computation of the covariance requires running a recursive algorithm based on (15.246) to compute $\mathbf{U}^{(k)}$, but this turns out to be computationally feasible even for large images and nonlinear algorithms.

Application to the MLEM algorithm Wilson *et al.* (1994) applied a recursive scheme analogous to (15.246) to the MLEM algorithm, (15.305). Because MLEM is a multiplicative algorithm, they took the logarithm of both sides of (15.305) and obtained an update rule for $\hat{y}_n^{(k)} \equiv \ln \hat{\theta}_n^{(k)}$; they then recursively computed the matrix $\mathbf{U}^{(k)}$ relevant to the covariance matrix for $\hat{\mathbf{y}}^{(k)}$.

Because the update rule for $\hat{\mathbf{y}}^{(k)}$ was nearly linear, it could be argued from the central-limit theorem that $\hat{\mathbf{y}}^{(k)}$ should be a multivariate-normal random vector, so its mean and covariance as computed by the recursion should fully specify its statistics. Moreover, if $\hat{\mathbf{y}}^{(k)}$ is normal, it implies that $\hat{\boldsymbol{\theta}}^{(k)}$ is multivariate log-normal. As a consequence, the univariate PDF on each pixel value is also a log-normal, exhibiting the characteristic long tails of that density. Finally, it was predicted that a map of the pixel variance would resemble the mean image, with low variance in regions of low object brightness. These predictions were borne out to high accuracy in a detailed Monte Carlo study performed by Wilson and in later studies by Wang and Gindi (1997) and Soares *et al.* (1998).

15.4.8 Stochastic algorithms

All of the iterative algorithms discussed so far will converge to the minimum of the functional if there is only one such minimum. Sometimes, however, we are interested in functionals with multiple local minima, such that small changes in any direction about a local minimum will increase the value, yet there may be a distant point with a lower value. If an iterative algorithm is initialized with an estimate that is near one of the local minima, straightforward minimization (say by gradient descent or conjugate gradient) may draw it towards this point even if a distant minimum would result in a lower value.

In image reconstruction, multiple minima can occur with Bayesian priors based on *mixture models*, where it is assumed that the object can be drawn from one of two or more classes, with each class having its own prior density. Thus we write

$$\text{pr}(\boldsymbol{\theta}) = \sum_{j=1}^J \text{pr}(\boldsymbol{\theta}|C_j) \text{Pr}(C_j), \quad (15.314)$$

where $\text{pr}(\boldsymbol{\theta}|C_j)$ is the density associated with class C_j , and $\text{Pr}(C_j)$ is the prior probability that the object came from that class. A mixture prior is often multimodal (exhibiting multiple maxima), and the posterior can also be multimodal if the likelihood is not too sharply peaked. Since the objective functional $Q(\boldsymbol{\theta}, \mathbf{g})$ can be interpreted as the negative logarithm of the posterior (see Sec. 15.3.1), it can have multiple local minima.

Another way in which local minima can occur is with parametric object descriptions (see Sec. 7.1.6) where the mean data vector is a nonlinear functional of the parameters. For example, if we describe an astronomical object as a set of N stars at locations $\{\mathbf{r}_n, n = 1, \dots, N\}$ and brightnesses $\{b_n, n = 1, \dots, N\}$, we may want to estimate the N locations and brightnesses as well as N itself; for one choice of N , there is a minimum of the objective functional with respect to the locations and brightnesses, but a different N might give a lower minimum.

Yet another way in which local minima can arise is when the gray levels are quantized. In the extreme where only black or white pixels are allowed, it often happens that an estimate will be reached where changing the state of any one pixel will increase the objective functional, but some entirely new configuration may have a lower value.

This section describes several methods for dealing with local minima, with emphasis on the *simulated-annealing* algorithm. Simulated annealing was developed initially by Metropolis *et al.* (1953) in the context of statistical mechanics, but its general applicability to optimization problems was later recognized by Kirkpatrick *et al.* (1983, 1984). Following quickly after Kirkpatrick, the method was applied to imaging by W. E. Smith *et al.* (1983), Geman and Geman (1984) and Geman and McClure (1985). For a detailed treatment of simulated annealing in a variety of problems, see van Laarhoven and Aarts (1987).

As we shall see, simulated annealing is a special case of a very powerful technique known as *Markov-chain Monte Carlo* or *MCMC*. We have already alluded to MCMC in Chap. 14 as a tool for computing averages needed in observer-performance studies, and more detail on this use is also given in this section. Excellent books on MCMC include Robert and Casella (1999) and Gilks *et al.* (1996).

The approach taken here will be first to provide some background on statistical mechanics, then specifically describe the simulated-annealing algorithm and its use in both statistical mechanics and image reconstruction. Finally, we shall describe the more general construct of MCMC and briefly mention some of its applications in imaging.

Basic results from statistical mechanics Consider a gas of N particles, where the state of the n^{th} particle is described by its 3D position \mathbf{r}_n and 3D velocity \mathbf{v}_n . The complete state of the system is thus described by $6N$ coordinates, and the system can be represented as a point in a $6N$ -dimensional phase space. The total energy of the system can thus be written as $\mathcal{E}(\{\mathbf{r}_n\}, \{\mathbf{v}_n\})$ (where the brackets denote sets with N members). Since the positions and velocities are random, the energy fluctuates about some mean $\bar{\mathcal{E}}$; we assume that the system is coupled to a heat bath that fixes the temperature, so the mean energy is a constant.

For bookkeeping purposes, we sample the phase space on a regular $6N$ -dimensional grid,⁹ so the system has a finite (but immense) number of possible states. In the j^{th} state, $\mathbf{r}_n = \mathbf{r}_{nj}$, $\mathbf{v}_n = \mathbf{v}_{nj}$ and $\mathcal{E}_j = \mathcal{E}(\{\mathbf{r}_{nj}\}, \{\mathbf{v}_{nj}\})$. A fundamental result of statistical mechanics (Reif, 1965) is that the probability of occurrence of this state in thermal equilibrium is given by

$$\Pr(j) = \frac{1}{Z} \exp\left(-\frac{\mathcal{E}_j}{k_B T}\right) = \frac{1}{Z} \exp(-\beta \mathcal{E}_j), \quad (15.315)$$

where T is the absolute temperature, k_B is Boltzmann's constant, and

$$\beta \equiv \frac{1}{k_B T}. \quad (15.316)$$

The normalizing constant Z , called the *partition function*, is given by

$$Z = \sum_j \exp(-\beta \mathcal{E}_j), \quad (15.317)$$

where the sum is over all possible states of the system.

All important thermodynamic quantities can be expressed in terms of derivatives of the partition function with respect to β . For example, as the reader may show, the mean energy is given by

$$\bar{\mathcal{E}} = -\frac{1}{Z} \frac{\partial Z}{\partial \beta} = -\frac{\partial \ln Z}{\partial \beta}, \quad (15.318)$$

and the thermodynamic entropy (the quantity that appears in the second law of thermodynamics) is given by

$$S \equiv -k_B \sum_j \Pr(j) \ln \Pr(j) = k_B \ln Z + \frac{\bar{\mathcal{E}}}{T}. \quad (15.319)$$

We know from Sec. 15.3.3 that $-\sum_j \Pr(j) \ln \Pr(j)$ is (within constants) the logarithm of the number of ways¹⁰ that the state can be constructed from indistinguishable molecules [*cf.* (15.163)]; the mythical grains used to justify entropy priors in image reconstruction correspond to actual molecules in statistical mechanics.

The equation of state is the relationship between mean pressure \bar{p} , volume V and temperature T . In terms of the partition function,

$$\bar{p} = \frac{1}{\beta} \frac{\partial \ln Z}{\partial V}. \quad (15.320)$$

⁹In classical statistical mechanics, the phase-space sampling interval is arbitrary and can eventually be allowed to go to zero, so that sums become integrals. In quantum statistical mechanics, on the other hand, there is a natural interval set by the uncertainty principle. For more discussion, see Reif (1965).

¹⁰The number of ways the state can be constructed is frequently denoted W , and the equation $S = k \log W$ appears on Ludwig Boltzmann's gravestone. For a photograph, see Cercignani (1998).

Metropolis algorithm in statistical mechanics Since the partition function is very difficult to calculate for complex systems, Metropolis *et al.* (1953) proposed estimation of the equation of state by Monte Carlo sampling. If we can generate many random samples of the configurations $\{\mathbf{r}_n, \mathbf{v}_n, n = 1, \dots, N\}$, then properties of the system can be estimated by replacing ensemble averages by sample averages. In Sec. 10.4.5, we discussed ways of producing the samples by generating and tracing individual particles, but this method does not correspond to thermal equilibrium where the probability of occurrence of different states must obey (15.315). The problem addressed by the Metropolis paper was to generate configurations $\{\mathbf{r}_n, \mathbf{v}_n\}$ from this probability law.

The Metropolis algorithm starts with a system in some initial state i with particle configuration $\{\mathbf{r}_{ni}, \mathbf{v}_{ni}\}$ and energy \mathcal{E}_i . It then proposes a change to the configuration by altering one or more \mathbf{r}_n or \mathbf{v}_n , so the proposed new state j has configuration $\{\mathbf{r}_{nj}, \mathbf{v}_{nj}\}$ and energy \mathcal{E}_j . If $\mathcal{E}_j < \mathcal{E}_i$, the proposed change is accepted and the system makes a transition to the new configuration. If $\mathcal{E}_j > \mathcal{E}_i$, however, the change is not necessarily rejected; instead it is accepted with a probability

$$\Pr(i \rightarrow j) = \exp[-\beta(\mathcal{E}_j - \mathcal{E}_i)], \quad \mathcal{E}_j > \mathcal{E}_i. \quad (15.321)$$

In practice, the decision to accept or reject the proposed change is made by drawing a random number t uniformly distributed on $(0, 1)$ and accepting the change if $\exp[-\beta(\mathcal{E}_j - \mathcal{E}_i)] > t$. Since $\beta > 0$, this condition is always satisfied for any t on $(0, 1)$ if $\mathcal{E}_j < \mathcal{E}_i$, so we can write

$$\Pr(i \rightarrow j) = \min\{1, \exp[-\beta(\mathcal{E}_j - \mathcal{E}_i)]\}. \quad (15.322)$$

This process is then repeated iteratively, generating many successive configurations. Though we won't attempt to prove it, eventually an equilibrium is reached. Equilibrium means that any two states i and j satisfy the condition of *detailed balance*, so that

$$\Pr(i) \Pr(i \rightarrow j) = \Pr(j) \Pr(j \rightarrow i). \quad (15.323)$$

A more verbose way to state this condition is in terms of joint probabilities:

$$\begin{aligned} & \Pr(\text{state } i \text{ at iteration } k, \text{ state } j \text{ at iteration } k + 1) \\ &= \Pr(\text{state } j \text{ at iteration } k, \text{ state } i \text{ at iteration } k + 1). \end{aligned} \quad (15.324)$$

Were this condition not satisfied, the relative probabilities of the two states would change with iteration number and the system would not be in equilibrium. (Note that one cycle through the process described above is counted as one iteration, whether or not the proposed change is accepted; thus iteration number is discretized time, and equilibrium means that all probabilities are independent of time.)

The beauty of the Metropolis algorithm is that the basic relation of statistical mechanics, (15.315), is satisfied at equilibrium. To see this, consider two states i and j for which $\mathcal{E}_j > \mathcal{E}_i$. Then (15.323) and (15.322) require that

$$\Pr(i) \exp[-\beta(\mathcal{E}_j - \mathcal{E}_i)] = \Pr(j) \cdot 1, \quad (15.325)$$

in accord with (15.315).

Simulated annealing in optimization problems As described so far, the Metropolis algorithm is concerned with systems in thermal equilibrium (in spite of its origins in the Manhattan project). It is also possible, however, to gradually reduce the temperature T (increase β) so that the system evolves through a series of near-equilibrium states. In this fashion properties such as specific heat and thermal expansion can be studied.

In materials science, a gradual reduction in temperature is called *annealing*; its opposite, an abrupt reduction in temperature, is called *quenching*. Suppose, for example, that one wants to make a sample of silicon for use in manufacturing semiconductor devices. Basic solid-state physics tells us that the lowest-energy configuration of silicon atoms at $T = 0$ is a perfect crystal with discrete translational symmetry. At room temperature the equilibrium configuration involves small fluctuations (phonons) around the ideal lattice, but it is nevertheless a good approximation to consider silicon in thermal equilibrium to be nearly a regular crystal lattice with a high degree of translational order. If excess electrons or holes are somehow produced in such a crystal, they exhibit very high mobility (see Sec. 12.1.2) and lead to excellent device properties.

On the other hand, the equilibrium state of silicon at very high temperature is a liquid with little translational order and poor electrical properties. When the liquid is cooled below the melting point, the silicon atoms are not initially arranged into a regular lattice, but instead inherit the disorder of the liquid. If the solid is held at a temperature just below the melting point, the atoms gradually approach an equilibrium where the atoms fluctuate around the ideal lattice points, and if the temperature is gradually reduced, so too are the fluctuations. If the temperature reduction is too rapid, however, the atoms get frozen into non-equilibrium positions, and the deviations from ideal translational symmetry degrade the electrical properties at room temperature. Thus physical annealing is a way of assuring that the material finds its way to its lowest-energy state.

Kirkpatrick *et al.* (1983, 1984) proposed using the Metropolis algorithm as a way of simulating the physical annealing process in problems having nothing to do with thermodynamics. Specifically, he was interested in the design of integrated circuits consisting of many electrical gates and a complex system of interconnections. The locations of the gates on the silicon crystal were the main design variables, and he defined a cost function involving both performance and actual cost of manufacture. The objective was to choose the gate location so as to minimize the cost. Thus the analogy to thermodynamics: gate locations correspond to coordinates in a gas, and the cost function corresponds to an energy.

Kirkpatrick began with some initial configuration of gates, just as Metropolis began with an initial configuration of gas molecules, and he proposed a change in the configuration at each step. The change was accepted or rejected according to (15.322) with the cost function in place of the physical energy. Since the probability of accepting a transition to a higher-cost design depends on β (or equivalently T), choice of this free parameter is critical. If β is large (T small), then there is very little chance of getting out of a local minimum, and if β is small there are large fluctuations around a minimum and the algorithm explores many high-cost designs. The solution is to increase β gradually, always remaining near equilibrium. Then, as illustrated qualitatively in Fig. 15.10, the equilibrium probability density function approaches a delta function centered on the true optimal configuration.

Fig. 15.10 Illustration of a cost function in 1D and the corresponding equilibrium probability density function at three different temperatures.

The art of simulated annealing Many questions arise in actually implementing simulated annealing for optimization problems, and many relevant theorems have been derived. In practice, however, simulated annealing remains more art than science.

The first concern is how rapidly the temperature should be reduced. The true minimum will be attained so long as the temperature is proportional to the reciprocal of the logarithm of the iteration number, but this is an extraordinarily slow approach to the optimum, and to the authors' knowledge never used. Instead, various *ad hoc* annealing schedules are used in an effort to trade off computational time and final cost (another optimization problem). One useful technique is to monitor the cost function and change the temperature when it seems to be fluctuating about some constant value.

Another open question is how the proposed changes to the system should be chosen. In one sense, this choice doesn't matter; so long as all possible states of the system can eventually be reached, the equilibrium distribution will be (15.315). Practically, however, the approach to equilibrium following a temperature change can be slow if only small changes are proposed.

Simulated annealing in image reconstruction Since we have presented image reconstruction as an optimization problem, it is natural to consider simulated annealing whenever there might be multiple minima. In image reconstruction, the state of the system is specified by the estimated coefficient vector $\hat{\theta}$. At the k^{th} iteration, a change to the state is proposed in which one or more pixel values are altered in some way, so that the proposed new configuration is given by

$$\hat{\theta}^{(k+1)} = \hat{\theta}^{(k)} + \mathbf{h}^{(k)}. \quad (15.326)$$

By analogy to (15.322), this proposed change is accepted with probability

$$\Pr(\text{acc}) = \min \left\{ 1, \exp \left[-\beta \left(Q \left(\hat{\theta}^{(k+1)} \right) - Q \left(\hat{\theta}^{(k)} \right) \right) \right] \right\}. \quad (15.327)$$

As in the Kirkpatrick application, the temperature can be gradually lowered in order to entice the reconstruction into the true minimum of $Q(\hat{\theta})$.

As with any other image-reconstruction algorithm, there are free parameters to set and choices to be made. The strategy for choosing the proposed changes $\mathbf{h}^{(k)}$ must be specified, the annealing schedule must be chosen, and of course the cost function itself must be selected. In principle, all of these choices should be made in such a way as to optimize observer performance, though in practice this nested optimization would be very difficult to carry out.

Metropolis-Hastings algorithms Hastings (1970) proposed a generalization of the Metropolis algorithm. In a general notation, let us assume that the goal is to generate a sequence of samples of a parameter $\boldsymbol{\theta}$ from a density $\pi(\boldsymbol{\theta})$ and that the current value of the parameter is $\boldsymbol{\theta}^{(k)}$. A new trial parameter $\boldsymbol{\theta}'$ is generated from a density $q(\boldsymbol{\theta}'|\boldsymbol{\theta}^{(k)})$, which can depend on the current state. The probability of accepting this proposed change is¹¹

$$\Pr(acc) = \min \left\{ 1, \frac{\pi(\boldsymbol{\theta}') q(\boldsymbol{\theta}^{(k)}|\boldsymbol{\theta}')}{\pi(\boldsymbol{\theta}^{(k)}) q(\boldsymbol{\theta}'|\boldsymbol{\theta}^{(k)})} \right\}. \quad (15.328)$$

If the change is accepted, we set $\boldsymbol{\theta}^{(k+1)} = \boldsymbol{\theta}'$; otherwise $\boldsymbol{\theta}^{(k+1)} = \boldsymbol{\theta}^{(k)}$. By a detailed-balance argument similar to the one used in (15.323), the equilibrium distribution is indeed $\pi(\boldsymbol{\theta})$; details are left as an exercise.

Comparison of (15.328) and (15.323) shows that the original Metropolis algorithm is a Hastings algorithm with a symmetric proposal density, $q(\boldsymbol{\theta}'|\boldsymbol{\theta}) = q(\boldsymbol{\theta}|\boldsymbol{\theta}')$. In terms of proposed changes $\mathbf{h}^{(k)}$ as in (15.326), the proposal density is symmetric if $+\mathbf{h}^{(k)}$ and $-\mathbf{h}^{(k)}$ are equally likely. When this condition is satisfied, (15.328) becomes

$$\Pr(acc) = \min \left\{ 1, \frac{\pi(\boldsymbol{\theta}')}{\pi(\boldsymbol{\theta}^{(k)})} \right\}, \quad (15.329)$$

which is the general form of a Metropolis algorithm. The specific form (15.322) is recovered by choosing $\pi(\boldsymbol{\theta}) \propto \exp[-\beta\mathcal{E}(\boldsymbol{\theta})]$ as in (15.315). Note that the partition function Z is not required since it cancels out in (15.328) and (15.329); Metropolis and Metropolis-Hastings algorithms can be used for drawing samples from densities that we cannot normalize.

Another special case of interest is the *single-component Metropolis-Hastings algorithm* in which only a single component of the vector is altered at a time. In an imaging context, for example, the candidate image differs from the current image at only a single pixel.

To describe the single-component algorithm, we need some additional notation. Let θ_n denote the n^{th} component of the $N \times 1$ vector $\boldsymbol{\theta}$, and let $\boldsymbol{\theta}_{-n}$ be the $(N-1) \times 1$ vector obtained by deleting θ_n from $\boldsymbol{\theta}$. Thus the set $\{\theta_n, \boldsymbol{\theta}_{-n}\}$ is the same thing as $\boldsymbol{\theta}$.

With this notation, proposal of a new vector $\boldsymbol{\theta}'$ is equivalent to proposing a new value for θ_n , and we write the proposal density as $q_n(\theta'_n, |\boldsymbol{\theta})$, where the subscript on q_n indicates that different proposal densities can be used for different components.

¹¹We use $\pi(\boldsymbol{\theta})$ and $q(\boldsymbol{\theta}'|\boldsymbol{\theta}^{(k)})$ here instead of our usual notations, $\text{pr}(\boldsymbol{\theta})$ and $\text{pr}(\boldsymbol{\theta}'|\boldsymbol{\theta}^{(k)})$, respectively, since we mean specific functional forms, not generic densities. To see what would happen without this notational distinction between $\pi(\cdot)$ and $q(\cdot)$, see the discussion below of the Gibbs sampler.

Thus (15.328) becomes

$$\Pr(acc) = \min \left\{ 1, \frac{\pi(\boldsymbol{\theta}') q_n(\boldsymbol{\theta}_n^{(k)} | \boldsymbol{\theta}')}{\pi(\boldsymbol{\theta}^{(k)}) q_n(\boldsymbol{\theta}'_n | \boldsymbol{\theta}^{(k)})} \right\}. \quad (15.330)$$

An advantage of this algorithm is that the samples are drawn from a univariate density, so any of the methods discussed in Sec. C.7 can be used.

A succinct tutorial on Metropolis-Hastings algorithms is given by Chib and Greenberg (1995), and a collection of practical papers on the subject is found in Gilks *et al.* (1996).

Gibbs sampler In a general Metropolis-Hastings algorithm, the proposal density $q(\boldsymbol{\theta}' | \boldsymbol{\theta})$ need not have anything to do with the density $\pi(\boldsymbol{\theta})$ from which we wish to draw samples. All that is required is that it be possible to generate any $\boldsymbol{\theta}$ in the sample space by a sequence of proposals. In a *Gibbs sampler*, on the other hand, the proposal density is a conditional density derived from $\pi(\boldsymbol{\theta})$. Specifically,

$$q_n(\boldsymbol{\theta}'_n | \boldsymbol{\theta}) = \pi(\boldsymbol{\theta}'_n | \boldsymbol{\theta}_{-n}), \quad (15.331)$$

where $\pi(\boldsymbol{\theta}_n | \boldsymbol{\theta}_{-n})$ is the *full conditional*, defined by [cf. (C.76)]

$$\pi(\boldsymbol{\theta}_n | \boldsymbol{\theta}_{-n}) = \frac{\pi(\boldsymbol{\theta})}{\int d\boldsymbol{\theta}_n \pi(\boldsymbol{\theta})}. \quad (15.332)$$

Note carefully that the quantity that appears on the right in (15.331), namely $\pi(\boldsymbol{\theta}'_n | \boldsymbol{\theta}_{-n})$, is simply $\pi(\boldsymbol{\theta}_n | \boldsymbol{\theta}_{-n})$ evaluated at $\boldsymbol{\theta}_n = \boldsymbol{\theta}'_n$; this substitution causes no notational problems since $\pi(\cdot)$, unlike $\text{pr}(\cdot)$, denotes a specific functional form.

If we use (15.331) and (15.332), the ratio that appears in (15.330) becomes

$$\frac{\pi(\boldsymbol{\theta}') q_n(\boldsymbol{\theta}_n^{(k)} | \boldsymbol{\theta}')}{\pi(\boldsymbol{\theta}^{(k)}) q_n(\boldsymbol{\theta}'_n | \boldsymbol{\theta}^{(k)})} = \frac{\pi(\boldsymbol{\theta}') \pi(\boldsymbol{\theta}^{(k)}) / \int d\boldsymbol{\theta}_n^{(k)} \pi(\boldsymbol{\theta}^{(k)})}{\pi(\boldsymbol{\theta}^{(k)}) \pi(\boldsymbol{\theta}') / \int d\boldsymbol{\theta}'_n \pi(\boldsymbol{\theta}')} = 1, \quad (15.333)$$

where the integrals cancel since $\boldsymbol{\theta}'$ and $\boldsymbol{\theta}^{(k)}$ are identical except for the n^{th} component, which is integrated out. Thus the probability of acceptance is given by

$$\Pr(acc) = \min\{1, 1\} = 1, \quad (15.334)$$

and no proposal is ever rejected in a Gibbs sampler.

In summary, Gibbs samplers always draw univariate samples from the full conditionals. They are very efficient since no proposal is ever rejected, but they require that the conditionals be known. For a survey of methods of drawing the samples, see Gilks *et al.* (1996), Chap. 5. For a tutorial on Gibbs samplers, see Casella and George (1992).

Markov chains A *Markov chain* is a sequence of random vectors $\{\boldsymbol{\theta}^{(k)}\}$ in which the probability of occurrence of one value depends only on the immediate previous value in the chain, *i.e.*, $\text{pr}(\boldsymbol{\theta}^{(k+1)} | \boldsymbol{\theta}^{(k)}, \boldsymbol{\theta}^{(k-1)}, \boldsymbol{\theta}^{(k-2)}, \dots) = \text{pr}(\boldsymbol{\theta}^{(k+1)} | \boldsymbol{\theta}^{(k)})$. All of the stochastic algorithms described above generate Markov chains, and the general term for these methods is *Markov-chain Monte Carlo*. If the proposal density and acceptance rule are independent of iteration number k , the Markov chain is *stationary*. Thus the basic Metropolis-Hastings and Gibbs algorithms generate stationary chains, but simulated annealing is at best quasistationary since the temperature parameter changes as the iteration proceeds.

Bayesian applications MCMC methods can in principle be used for drawing samples from any PDF, but for Bayesian applications the important PDF is the posterior. Indeed, a good working definition of a Bayesian is that it is someone who draws inferences only from posteriors.

In the context of Bayesian image analysis, we can identify four distinct uses of MCMC. The first is to find a MAP estimate where the posterior $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$ is maximized with respect to $\boldsymbol{\theta}$. As noted above, this is an optimization problem that can be solved by simulated annealing or a more general Metropolis-Hastings algorithm in the limit as $T \rightarrow 0$.

The second use of MCMC is to derive other point estimates from the posterior. For example, we noted in Sec. 13.3.3 that a posterior-mean estimator minimizes a quadratic loss function. Except for the case of Gaussian noise and a Gaussian object model, where the posterior mean leads to the Wiener filter, this estimator is rarely used in image analysis, largely because of computational difficulties. MCMC offers a potential way of overcoming these difficulties.

The third Bayesian application of MCMC is to study uncertainties in estimates. Uncertainties in the Bayesian world are based on the posterior, so posterior variance and covariance are regarded as measures of accuracy of estimates. It must be noted, however, that Bayesian priors reflect belief rather than any sampling properties of real-world objects, so posterior variance can be reduced arbitrarily just by adopting a stringent prior—if the prior is sharply peaked, so too is the posterior. Many Bayesians avoid this trap by using neutral or noninformative priors such as entropy, but they then face computational difficulties in actually determining the posterior variance.

Finally, MCMC can be used to study the prior itself. It is rarely the case that samples drawn from the prior used in image reconstruction bear any resemblance to real objects, but we might hope that they capture certain local features such as the joint density of neighboring pixels (Herman and Chan, 1995). MCMC applied to the prior offers a way of determining if this hope is justified.

For an excellent treatment of Bayesian applications of MCMC, see Besag *et al.* (1995)—and don't overlook the 25 pages of lively comment following the article.

Planar Imaging with X Rays and Gamma Rays

This chapter is the first of four that provide detailed case studies of selected imaging modalities. The goal of these applications chapters is to illustrate how the mathematical techniques developed in earlier chapters can be used in the analysis and optimization of real-world imaging systems. The applications have been chosen to illustrate specific mathematical methods, with the hope that these case studies will provide templates for the reader to use in extending the analysis to other imaging realms.

Specifically, this chapter covers two distinct modalities in medical radiological imaging. Both modalities are direct imaging, in the sense that the measured data are immediately the desired image without the need for image reconstruction or further processing. Both produce 2D projection images of 3D objects, and for this reason they are referred to as *planar imaging*. Tomographic methods, where 3D objects yield 3D images, are treated in the next chapter.

The first modality considered here, in Sec. 16.1, is digital radiography, where discrete arrays of detectors are used to sense the distribution of x rays transmitted through a patient's body. We chose to include this application because of high current interest in the medical community, but also because it is an excellent vehicle to elucidate many aspects of imaging introduced earlier. Digital radiography is fundamentally a continuous-to-discrete mapping, but only approximately a linear one; thus it provides an object lesson on how to apply the linear deterministic descriptions of Chap. 7 as well as an illustration of their limitations. Image formation in radiography is most rigorously described by the Boltzmann transport equation of Chap. 10, and the relation of that approach to linear methods is described in this chapter.

In stochastic terms as well, digital radiography provides concrete illustrations of many subtle points. X-ray images suffer from Poisson noise, so the whole theoretical structure developed in Chap. 11 comes into play, but the detectors themselves have excess, non-Poisson, noise as treated in Chap. 12.

Finally, digital radiography provides an excellent application of our general approach to objective assessment of image quality. Image quality in radiology is closely linked to the radiation dose given to the patient; Poisson noise can be reduced by using more intense x-ray beams, but the potential biological damage cannot be ignored. Therefore it is crucial to provide quantitative assessments of task performance and to identify the system components that limit that performance. The methodology of Chaps. 13 and 14 will stand us in good stead in this endeavor.

The second modality considered here, in Sec. 16.2, is planar nuclear medicine. In brief, nuclear medicine is the use of radioactive tracers to follow some physiological pathway or to identify tumors or other pathologies. The tracers can have exquisite biological specificity, targeting specific cell-surface receptors or disease-specific antigens. Indeed, a whole new approach to biology and medicine, referred to as molecular imaging, is now emerging, and nuclear imaging is one of the key technologies making it possible.

In physical terms, a key distinction between radiography and nuclear medicine is that the radiation source is outside the body in the former, inside the body in the latter. In radiography the object is the distribution of x-ray attenuation coefficient, while in nuclear medicine the object is the radiation source itself. Thus radiography is *transmission imaging* while nuclear medicine is *emission imaging*. Both, however, use high-energy photons; there is no essential distinction between the x rays used in radiography and the gamma rays used in nuclear medicine except that x rays result from electronic transitions and gamma rays come from nuclear transitions during radioactive decay.

Another difference between the two modalities is the method of image formation. In transmission radiography the image is produced by simple shadow casting, but in nuclear medicine some image-forming element is required. Since gamma rays are not appreciably refracted or reflected by matter, image formation must rely on absorption. Options include pinholes, multibore collimators and coded apertures, but we concentrate here on collimators.

Many of the same mathematical themes adduced in Sec. 16.1 will recur in Sec. 16.2 in the context of gamma-ray emission imaging, but some differences are worth noting. The Boltzmann transport equation is again the rigorous means of describing deterministic image formation in nuclear medicine, but the scattering term is more important than in transmission radiography. CD imaging models are again required, but linearity is much more justifiable in nuclear medicine than in radiography. Both x-ray and gamma-ray detectors respond approximately linearly to the flux incident on them, and that flux is linearly related to the object in the case of emission imaging. In transmission radiography, on the other hand, the flux is nonlinearly related to the object, which is the distribution of x-ray attenuation coefficient.

Stochastically, Poisson noise is paramount in nuclear medicine, and it is still closely linked to the radiation dose given to the patient. In nuclear medicine, however, there is an important trade-off between noise and spatial resolution; coarser collimators collect more photons but produce blurrier images. Moreover, the detectors used in nuclear medicine, unlike those used in digital radiography, are essentially ideal photon counters, so non-Poisson noise seldom arises in gamma-ray images. Instead, photon-counting gamma cameras require an estimation step to relate the observable output signals to position and energy of the individual gamma-ray photon. These differences will lead to rather different assessment methodologies and

design considerations when we discuss image quality in nuclear medicine at the end of Sec. 16.2.

16.1 DIGITAL RADIOGRAPHY

From Roentgen's discovery of x rays at the end of the 19th century through the end of the 20th century, x-ray imaging was predominantly based on fluorescent screens and photographic film. At the beginning of the 21st century, however, film-based radiography is giving way to fully electronic systems. Farsighted prognosticators (*e.g.*, Capp, 1981) who have been heralding the all-digital radiology department for decades may soon be proven correct.

Many technological advances have contributed to this change, including computers to process the images, large disks to store them, and high-resolution image displays to reproduce fine details. The enabling technology, however, has been large-area digital x-ray detectors with spatial resolution comparable to that of film-screen systems.

Before launching into the mathematical analysis of digital radiography systems, we present a qualitative discussion of the underlying physical principles that impact the imaging performance. In Sec. 16.1.1 we give a brief account of x-ray sources and some considerations on the object being imaged. In Sec. 16.1.2 we describe the main detectors used for digital radiography, and in Sec. 16.1.3, we discuss an important practical issue, scattered radiation.

In Sec. 16.1.4, we begin the mathematical analysis, starting with deterministic properties. One goal here is to see what approximations are needed if we wish to use linear systems theory. In Sec. 16.1.5, we treat the stochastic properties of digital radiographs in detail. Sections 16.1.6 and 16.1.7 bring together the deterministic and stochastic properties and show how they influence image quality for detection and estimation tasks, respectively.

Essential background material for this discussion is found in Chaps. 10 and 12, especially Secs. 10.3, 10.4 and 12.3. An excellent general reference is the three-volume SPIE Handbook of Medical Imaging.

16.1.1 The source and the object

X-ray sources Though radioisotope sources and synchrotrons have been used for x-ray imaging, by far the most common source today is the one used by Roentgen himself, a vacuum tube in which high-energy electrons bombard a metal anode and create x rays. Two kinds of x rays are produced, Bremsstrahlung (German for *braking radiation*) and characteristic x rays. Bremsstrahlung arises from the deceleration of the electrons in the anode material and has a continuous energy spectrum extending up to the electron energy. The characteristic radiation is produced when the electron collides with an atom in the anode and creates a vacancy in an inner electron shell; this vacancy is then filled by an electron dropping into it from a higher energy level, liberating energy in the form of an x ray. X rays produced in this way by transitions between discrete energy levels have a discrete spectrum characteristic of the anode material. As discussed in Sec. 12.3.1, characteristic x rays are also produced in x-ray detectors, though there the initial inner-shell vacancy is produced by photoelectric absorption rather than electron impact.

As a numerical example, suppose the anode is tungsten (W), for which the K-shell binding energy is about 70 keV, and that the applied potential across the x-ray tube is 100 kV. Since the electrons are produced thermally, they have very low energy when they exit the cathode, but they are accelerated toward the anode and have an energy of 100 keV when they arrive there. This energy is sufficient to create a vacancy in the K shell, and a transition from the L shell to the K shell will then produce an x ray of about 59 keV. Vacancies in the L shell itself result in x rays around 8–9 keV. The 100 keV electrons also produce Bremsstrahlung photons with energies ranging up to 100 keV. Thus the overall energy spectrum, shown in Fig. 16.1, consists of discrete lines characteristic of W plus a continuous Bremsstrahlung spectrum depending mainly on the electron energy (or accelerating voltage).

Fig. 16.1 Energy spectrum for a tungsten-target x-ray tube operated at 100 kV.

To get sharp images, it is necessary to focus the electrons tightly so that the x-ray source approximates a point source, but it is also desirable to use a large current in order to get a large x-ray flux. These two conditions are contradictory since forcing a large amount of current into a small area can result in strong local heating of the anode, possibly even to the melting point. One way to minimize this problem is to use a tilted anode as shown in Fig. 16.2 and to focus the electrons into something approximating a line rather than a point; viewed end-on, the line looks like a small point, but from other directions it has a greater extent. Another

Fig. 16.2 Illustration of an x-ray imaging system using an x-ray tube with a tilted anode. The anode may rotate to spread the heat load over a larger area.

common measure to allow greater current and hence greater x-ray flux is to rotate the anode, spreading the heat over a much larger area. As we shall see in Sec. 16.1.4, tilting the anode leads to a strongly shift-variant blur, but the rotation has no effect on the blur because the electron focal spot does not move.

Objects At the energies used in radiography, x-ray wavelengths are very small compared to resolvable image details; for example, 60 keV x rays have a wavelength of about 0.2 Angstrom or 0.02 nm, and digital radiography systems have spatial resolutions around 50–100 μm , so diffraction in the object is negligible on this scale. Moreover, the refractive index of all materials for x rays is very close to unity, so refractive effects are negligible as well. The physical effects that we do have to consider are photoelectric absorption and Compton scattering. (See Sec. 12.3.1 for a brief review of the x-ray physics.) The object is thus described by the distribution of x-ray absorption and scattering coefficients, and the propagation of x rays through the object is well described by the Boltzmann transport equation (Chap. 10).

A transmission image of a scattering and absorbing object, obtained with a point-like x-ray source, consists of two components. First, an x-ray photon may travel without scattering along a straight line from the source point to the detector, but the probability of this happening depends on the total x-ray attenuation (absorption plus scattering) along the line. The unscattered photons thus produce a 2D shadow image of the 3D object on the detector. The shadow is sharp if the x-ray source is small.

The second component of the image consists of photons that have undergone one or more Compton-scattering events in the object. These photons form a diffuse background that reduces the contrast of the shadow image and increases the noise level.

Motion of the object is also an issue in medical imaging. Beating of the heart, respiration in the lung or peristalsis in the esophagus during an exposure time can blur the images of these organs, and patient fidgeting can also be problematic. Breath-holding and various Torquemadian restraint devices will reduce motion blur, but the best solution is to shorten the exposure time; unfortunately this requires an increased current through the x-ray tube if the same total number of photons are to be detected.

Radiation dose In any imaging application, we need to know how the object affects the image, but in medical radiography we also need to know how the imaging system affects the object. X-ray photons that are absorbed or scattered in a patient's body deliver energy to it and can cause biological damage. A full analysis of the system should therefore include computation of the *radiation dose* (absorbed energy per unit mass) along with some assessment of the biological hazards from the dose. Part of the problem of system design is to choose the total x-ray flux and the energy spectrum in such a way as to minimize patient dose while maximizing the image information (as measured by task performance).

16.1.2 X-ray detection

X rays are detected either by converting them to light and detecting the light or by converting them to electrical charge and detecting the charge. Detectors

operating on the first principle include film-screen systems, x-ray image intensifiers, scintillator-photodiode arrays, systems in which a lens or mirror couples light from a scintillator to an optical detector, and photostimulable phosphors. Systems that avoid the conversion to light include semiconductor detector arrays and x-ray-sensitive television cameras such as vidicons.

All of these detectors involve an amplification process: one x-ray photon produces a large number of secondary particles, either optical photons or electrons and holes. The randomness in this amplification process, discussed in general terms in Sec. 11.4 and specifically for x-ray detectors in Sec. 12.3, contributes to the image statistics and the resulting image quality. Whatever detector is used, it is always the goal to have the final image quality limited only by the inevitable Poisson statistics of the x-ray beam. If this happy condition is achieved, we say that the detector is *quantum limited*.

In the remainder of this section, we shall sketch the operation of each of these detectors and comment on the major contributions to blur and image statistics.

Film-screen detectors In a film-screen detector, shown in Fig. 16.3, the fluorescent screen absorbs an x-ray photon and produces hundreds of optical photons, which then diffuse out of the screen and expose the film placed in contact with the screen. It is also possible for x rays to be photoelectrically absorbed in the film itself, in which case the exposure is produced by the high-energy photoelectron, but this process is much less probable than absorption in the screen since the screen is usually much thicker than the photographic emulsion and has a higher atomic number.

Fig. 16.3 Film-screen detector.

Since thin photographic emulsions have very high spatial resolution, blur in a film-screen detector is dominated by the diffusion of the light from the interaction point to the emulsion. The screen usually consists of relatively small ($1\text{--}10\ \mu\text{m}$) fluorescent crystallites or grains in a transparent or translucent binder, so the diffusion of light can be controlled to a degree by varying the grain size and the optical properties of the binder. When these properties are optimized, the only way to get better resolution is to use a thinner screen, but this increases image noise by reducing the number of x-ray photons absorbed. For this reason practical x-ray detectors often use two screens and films with emulsions on both sides, thereby doubling the total screen thickness for a given spatial resolution.

Major statistical limitations in a film-screen detector arise from the random x-ray absorption process, random conversion of the x-ray energy to light, and ran-

dom conversion of light to latent (developable) photographic grains. We refer to these noise sources, respectively, as quantum noise, amplification noise and film-grain noise. For an excellent treatise on these topics, see Dainty and Shaw (1974).

The developed x-ray film can, of course, be digitized with a scanning microdensitometer, in which case the overall system — film-screen, development process and microdensitometer — could be considered as a digital radiography system, but we shall understand that term in a narrower sense and not consider film-based systems any further in this chapter.

X-ray image intensifiers In an x-ray image intensifier, illustrated in Fig. 16.4, the initial x-ray absorption again takes place in a fluorescent screen, but now the light from the screen impinges on a photocathode rather than a photographic emulsion. Electrons emerging from the photocathode are accelerated and focused by an electrode structure serving as an electron lens, and they then impinge on a second fluorescent screen known as the output phosphor. The physical processes in the output phosphor are essentially the same as in the first fluorescent screen except that there the x-ray photon produces a high-energy photoelectron that excites the luminescence, while in the output phosphor the high-energy electron impinges from the outside.

Fig. 16.4 An x-ray image intensifier.

The x-ray image intensifier thus involves two separate amplification steps. Each x-ray photon produces many photoelectrons in the photocathode, and each photoelectron is accelerated to high energy and can produce many optical photons in the output phosphor. The overall gain — optical photons per x-ray photon — is quite high, so there are many options for reading out the final optical image. One important method, known as fluoroscopy or ciné-radiography, records the output with a movie camera so that dynamic images of moving objects can be captured.

There are several sources of blurring in an image intensifier. As with a film-screen system, the light diffuses in the input screen before reaching the photocathode. Then the photoelectrons are not focused perfectly by the electron lens, and the diffusion of light in the output phosphor increases the blur still further. Sometimes the input screen consists of columnar structures such as long, thin crystallites of CsI or hollow tubes loaded with a polycrystalline scintillator material. If these columns are oriented perpendicular to the photocathode, they restrict the lateral diffusion of the light and reduce the blur in the input screen. Also, the output phosphor can be made relatively thin since it must absorb only electrons, not x-ray photons. Under these conditions, the blur may be dominated by the electron optics.

An insidious source of blur in many image intensifiers is the thin glass window that separates the input screen from the photocathode. Light that strikes this window near normal incidence passes through with relatively little reflection loss, but at greater incidence angles the reflection coefficient increases and the light might be reflected several times before finally emerging from the glass. These multiple reflections produce long tails on the point spread function. Even though the tails have fairly low amplitude, they can greatly reduce the contrast of a small detail in a large background since the convolution of the tails with the background can be large. A common term for this phenomenon is *veiling glare*.

Factors influencing the image statistics in an image-intensifier system include the statistics of light production in both the input screen and the output phosphor, the quantum efficiency of the photocathode and, of course, the Poisson statistics of the x-ray flux. Further noise can, in principle, be contributed by the movie camera or other optical device used to record the output image, but noise from this source is usually negligible because of the high gain of the intensifier.

Fluorescent screens with optically coupled readouts Because of the cost and complexity of image intensifiers and the blur in the electron optics, there is an incentive to eliminate the optical intensification and couple the light from a fluorescent screen directly to a CCD camera or other optical readout with a lens, focusing mirror or fiber optics.

The basic problem with this approach is that optical readouts have a small area, while the fluorescent screen must have a large area to cover the desired field of view. If a lens or mirror is used to image the large screen onto the small readout, the optical magnification M must be small. For a simple lens, we know from Sec. 9.6.2 that $M = -q/p$, where p is the distance from the object to the lens and q is the distance from the lens to the image plane. To make M small and still satisfy the imaging equation (9.169), we must take $q \approx f$ and $p \approx -f/M$ (where f is the focal length of the lens). The lens-to-screen distance p must increase as M gets smaller (larger demagnification). As a result, the lens subtends a smaller solid angle at the screen and hence collects fewer of the optical photons emitted by it. A similar conclusion holds for more complicated lenses, mirror systems and even fiber optics; large demagnifications always mean inefficient photon collection.

In fact, the photon collection efficiency in these systems may be so poor that less than one optical photon is collected per absorbed x-ray photon. Since photon collection is a rare event, the statistics of the collected photons approaches Poisson (see Sec. 11.4.1) as M gets small, and in this limit the image noise is much larger, relative to the mean image, than when the Poisson statistics of the x-ray beam dominate. Moreover, even if we succeed in getting the collection efficiency up to the point where more than one optical photon is collected per absorbed x-ray photon, the optical image on the readout is still weak, and noise in the readout itself is more important than it would be with an image intensifier.

Scintillator-photodiode arrays One way to improve the optical collection efficiency is to make a large-area readout such as a photodiode array and place it in contact with the fluorescent screen, thereby producing the electronic counterpart of a film-screen detector. One of the more promising configurations at this writing is a CsI screen and an amorphous-Si photodiode array. These photodiodes are noisier than ones made of crystalline Si, but they are much easier to fabricate into large arrays.

The amplifiers for each photodiode can also be fabricated in the same amorphous-Si structure.

With any kind of integrated-circuit detector array, there is an inevitable problem with variations in gain of the amplifiers. In addition, there can be variations across the array in the mean dark signal because of variations in dark current through the photodiode and offset voltages in the amplifiers. If left uncorrected, these gain and offset variations would show up as an objectionable structure, called *fixed-pattern noise*, superimposed on the desired x-ray image. Fixed-pattern noise can be removed by measuring the gains and offsets of each element in the array and applying the appropriate correction during readout, but one must then be cognizant of the effect of the correction on the image statistics.

Semiconductor detector arrays In any x-ray detector with optical readout, the x-ray photon first produces a high-energy photoelectron (or Compton electron) which then generates a large number of electron-hole pairs. These electrons and holes recombine at a luminescent center and produce optical photons, which are collected with some efficiency in an optical detector where they again produce electron-hole pairs. In a semiconductor detector array, the initial electron-hole pairs produced by the photoelectron are sensed directly with an electrode array.

Detectors based on this principle were treated in detail in Sec. 12.3. As discussed there, trapping of the charge carriers before they reach the electrodes contributes in a complicated way to both the image statistics and the blur.

Other readout mechanisms have also been proposed for semiconductor detectors. One approach is to use a semiconductor with no electrode on one side and to charge this surface with an electron beam or corona discharge. The charge will leak off as a result of the finite conductivity of the material, but absorbed x rays will create free carriers and increase the conductivity, so the remaining charge after some exposure time will be related to the x-ray exposure. This charge can be sensed with a moving electrode scanned over the free surface or with a scanning electron beam as in a vidicon. It is also possible to read out the charge pattern by converting it into a pattern of toner particles as in the Xerox copying process.

Photostimulable phosphors Though trapping is generally deleterious in semiconductor detectors, it is essential in x-ray detectors based on *photostimulable phosphors*. In these materials an absorbed x ray produces many hole-electron pairs, just as in a semiconductor detector, but they are trapped in impurity levels deep within the bandgap. Because the binding energy of these traps is so large, thermal detrapping essentially does not occur, and the spatial pattern of trapped charge is a latent image of the pattern of absorbed x rays. To read out this pattern, the phosphor is scanned with a focused laser beam, usually red light. The energy of a red photon is sufficient to excite a trapped carrier to the conduction band, from which there is some probability that it will recombine and produce an optical photon with approximately the bandgap energy, which makes it blue or ultraviolet. A simple optical detector such as a photomultiplier can then be used to detect this shorter-wavelength light, with a spectral filter to reject the red excitation light. No imaging optics are needed on the collection channel since the emitted light must have come from the point illuminated by the scanning red beam.

Digital imaging systems based on photostimulable phosphors are known commercially as *computed radiography* or CR systems. This is an unfortunate mis-

nomer since the computer plays very little role in this kind of imaging. Of course, the image is stored digitally, possibly manipulated in the computer and then displayed on a CRT screen, but the image-formation process is purely analog. Unlike computed tomography, where no image at all could be formed without computation, computed radiography could have been invented before the computer.

The main sources of blur in CR systems are the finite focal spot of the scanning beam and diffusion of the red light into the photostimulable phosphor. Image statistics are again determined by amplification processes; we must consider the random number of trapped carriers per x-ray photon, the probability of detrapping under red excitation and the probability that a short-wavelength optical photon will be registered in the collection detector. These processes are complicated but understandable within the framework presented in Sec. 11.4.

16.1.3 Scattered radiation

So far we have considered only unscattered radiation, but in many practical situations the majority of x-ray photons arriving at the detector plane have been scattered at least once in the object. These scattered photons reduce the image contrast and increase the noise level. Methods for computing the scatter distribution function were discussed in detail in Chap. 10, so here we confine the discussion to methods for minimization of the scatter component of radiographic images. The photon flux at the detector plane is characterized by the distribution function $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$, and we shall discuss in turn how each of the variables in this function can potentially be used to distinguish scattered from unscattered photons.

Temporal gating The time variable is of interest only if the source is pulsed rapidly compared to the transit time of photons across the object and if the detector has similar time resolution; neither of these conditions is satisfied in systems designed for medical radiography. Since the speed of light in American units is one foot per nanosecond, and typical clinical objects are a foot or so across, we would need a subnanosecond source and detector. Such rapid pulses of x rays can be created with pulsed beams of electrons or pulsed lasers, but the technology required is too expensive for the medical market, and it would be of no use without a detector with nanosecond resolution.

An individual x-ray detector can indeed have the requisite response time, but it requires a fast amplifier and electronic gate or sample-and-hold circuit, which would then have to be duplicated for each element in a detector array. There is no reason in principle why this could not be done with an array of gated integrators as discussed in Sec. 12.2.4, but the detector arrays being developed at this writing have much slower response.

The other option to consider is a rapid shutter that admits photons to the detector surface for only a brief time. Optical detectors can be gated in this way by use of electro-optic shutters, but no comparable shutter exists for x rays. An x-ray image intensifier could, in principle, be gated either by putting an optical shutter between the output phosphor and the final optical readout or by gating the electron-amplification stage, but the response time would always be limited by the input fluorescent screen. Current scintillators have an optical rise time of at least a few nanoseconds and decay times up to a microsecond or more, so it is unlikely that subnanosecond response could be obtained by gating an image intensifier.

Energy discrimination The energy variable is potentially useful for discriminating against scattered radiation since photons lose energy upon Compton scattering (see Sec. 10.3.7). As with the time variable, however, energy is useful only if the source has a narrow spread in energies and the detector has good energy resolution. As seen in Fig. 16.1, commonly used x-ray sources have both a discrete line component and a continuous spectrum. With judicious choice of operating voltage and filtration in the x-ray beam, the relative strength of the discrete component can be enhanced, but some continuum background will always remain with electron-beam tubes. Heavier charged particles such as protons or heavy ions can also be used to excite x rays, and they produce a higher ratio of characteristic radiation to Bremsstrahlung, but the expense is prohibitive for clinical use. Finally, synchrotrons can produce quite monoenergetic x-ray beams, but again the issue is expense.

The energy resolution of semiconductor and scintillation detectors was discussed in Sec. 12.3. Since energy discrimination depends on the ability to analyze an individual photon absorption event, energy information is useless if more than one event occurs in a detector element during one readout period. Moreover, as discussed in Sec. 12.3, an event can produce signals in neighboring readout channels as a result of light spread in scintillators or charge trapping in semiconductors, so the requirement is really that there be no more than one event per readout period in some cluster of detector elements. Furenlid *et al.* (2000) have analyzed the probability of this happening as a function of input flux rate, detector element size and readout time. As a rule of thumb, the flux should be kept to less than 0.1 x-ray photons per cluster per readout period.

Even if a monoenergetic source could be used and the input flux could be kept low enough to resolve individual photons, it is still not evident that energy discrimination would be useful in digital radiography. The problem is that the fractional energy loss upon Compton scattering, $\Delta\mathcal{E}/\mathcal{E}_0$, is small at energies much less than mc^2 , where m is the mass of the electron [see (10.226)]. Since $mc^2 = 511$ keV and diagnostic radiology mainly uses photons in the 10–100 keV range, the energy loss is small, and excellent energy resolution would be required to distinguish a scattered photon from an unscattered one.

While photon-by-photon energy discrimination is probably not useful for scatter rejection, it may still be advantageous to modify the energy-dependence of the source function $\Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$ and the detector response $d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$. For example, if the x rays are produced by bombarding a W target, we can place a tantalum (Ta) sheet in front of the x-ray tube. Since Ta has a K absorption edge of 67.4 keV, it has a relatively low absorption for W characteristic x rays of energy around 58 keV, and the relative strength of the line spectrum will be increased. Then, if we use Gd₂O₂S (gadolinium oxysulfide) as the detector material, the detector will be very efficient for the unscattered W characteristic photons, but relatively inefficient for scattered radiation that falls below the Gd K edge at 50 keV. The thicknesses of the Ta sheet and the Gd₂O₂S then become parameters to be optimized in terms of task performance.

Angular discrimination The angular distributions of scattered and unscattered radiation are quite different. All of the unscattered photons travel along straight lines from the focal spot to the detector, so the radiance at any point on the detector is nearly an angular delta function. The scattered photons, on the other hand, have

a very broad angular distribution, and they can be rejected by making $d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ a sharp function of $\hat{\mathbf{s}}$.

One way to do this is to use an anti-scatter collimator as shown in Fig. 16.5. The bores in the collimator point to the focal spot, so they do not impede any unscattered photons that hit the open areas, but they have a narrow acceptance angle and reject most of the scattered photons. Sometimes the collimator is moved during the exposure to wash out moiré effects between the collimator and the detector array.

Fig. 16.5 Illustration of the use of an anti-scatter grid in a film-screen x-ray imaging system.

A related approach is to confine the x-ray beam to a thin slab with a slot collimator placed between the x-ray source and the object as shown in Fig. 16.6. With a similar slot collimator in front of the detector, unscattered photons pass unimpeded from source to detector, but scattered photons are likely to scatter out of the slab and miss the detector. Even if they scatter back into the slab, they are likely to be out of the angular acceptance of the detector collimator. The desired field of view is then covered by scanning the entire structure — source, detector and two collimators — in the direction perpendicular to the slab. A side benefit of this geometry is that the required detector area is much less than the area of the field of view; even 1D detector arrays can be used.

Fig. 16.6 Slot-scanning system.

Spatial filtering The final variable we can use for discriminating against scattered radiation is spatial position. There is nothing useful we can do to modify the dependence of $d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ on \mathbf{r} since scattered and unscattered photons occupy the same area on the detector face, but we can operate on the recorded data as a function of the spatial index m . That is, we can spatially filter the digital image.

One approach to spatial filtering is to recognize that scattered radiation contains no fine details, hence consists mainly of low spatial frequencies, so a high-pass filter implemented in the discrete Fourier domain should preferentially exclude scattered radiation and preserve the interesting image details. On average, this statement is true, but scattered radiation also has spatially uncorrelated fluctuations or noise associated with it, and this noise will pass through the filter. Moreover, the relative contribution of primary and scattered radiation will vary over the image, so shift-invariant filtering may not be optimal.

Another approach, which sounds different but turns out to be equivalent to Fourier-domain filtering, is unsharp masking. In this approach, a local estimate of the low-frequency background is made by averaging the image over a region and then subtracting the average from the original image. The result is equivalent to convolving the image with a digital filter having a central positive core one pixel wide and a small negative value over the averaging region.

A more sophisticated approach is to estimate the amount of scatter locally and subtract off just that component of the background rather than all low-frequency components. This estimate could be obtained from an approximate solution of the Boltzmann equation or through a Monte Carlo simulation. In both cases a greatly simplified model of the object, such as a uniform cylinder, might give an adequate estimate of the scatter image. If there are unknown parameters such as the diameter of the cylinder, they could be estimated from the measured image data.

16.1.4 Deterministic properties of shadow images

As noted above, propagation of x-ray photons through an object can be described by the Boltzmann transport equation (10.132), with terms accounting for the x-ray source, photon propagation, Compton scattering and photoelectric absorption. In this section we shall ignore the scattering term and compute the mean image produced by unscattered photons.

Since the x-ray source is pulsed in digital radiography, it is necessary in general to use the full time-dependent Boltzmann equation, but we can usually assume that the pulse width is long compared to the propagation time of the x rays across the object. For simplicity, we shall also assume that the object is independent of time over the pulse duration. With these assumptions, we can use the steady-state equation even with a time-dependent source, and (10.132) takes the form

$$-c\mu_{tot}(\mathbf{r}, \mathcal{E})w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) + \Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) + [\mathcal{K}w](\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) - c\hat{\mathbf{s}} \cdot \nabla w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = 0, \quad (16.1)$$

where c is the speed of light (recall that the refractive index is near one for x rays, so $c_m \approx c$), and the other quantities are defined in Chap. 10.

If a solution to (16.1) has been found for a given object and source-detector configuration, the next step is compute the mean output of each detector. It will be convenient to designate the detector elements by the 2D multi-index $\mathbf{m} = (m_x, m_y)$, where the components take on integer values. If the detector is linear, then the mean

output of the \mathbf{m}^{th} detector is given by (10.239) as

$$\bar{g}_{\mathbf{m}} = \int_P d^2r \int_0^\infty d\mathcal{E} \int_{2\pi} d\Omega \int_0^\tau dt d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t), \quad (16.2)$$

where τ is the exposure time, $d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ is the detector response function (assumed independent of time), and the spatial integral is over a plane immediately adjacent to the detector. Recall from Chap. 10 that we use the 2D vector \mathbf{r} and the 3D vector \mathbf{r} to refer to the same spatial point. Thus, if we take the plane P to be $z = 0$, then $\mathbf{r} = (x, y, 0)$, $\mathbf{r} = (x, y)$ and $d^2r = dx dy$. Note also that we have added an overbar to $g_{\mathbf{m}}$ to emphasize that the Boltzmann equation gives the mean photon distribution and hence the mean detector output.

The unscattered image If we consider only the unscattered photons, the Boltzmann equation takes the form of (10.147):

$$\hat{\mathbf{s}} \cdot \nabla w = \frac{1}{c} \Xi_{p,\mathcal{E}} - \mu_{tot} w. \quad (16.3)$$

We know from Sec. 10.3.3 that the general solution to this equation is the attenuated x-ray transform of the source distribution. An explicit solution was given in that section for an ideal point source, and an ideal detector model was discussed in Sec. 10.4.2; in this section we extend the discussion to more realistic source and detector models.

To describe the source, we assume that the anode of the x-ray tube lies in the plane defined by $\mathbf{r} \cdot \hat{\mathbf{n}}_a = p_a$ (where subscript a indicates *anode*), $\hat{\mathbf{n}}_a$ is a unit vector normal to the anode and p_a specifies the location of the anode along the line defined by this unit vector. We assume also that the temporal and spectral dependences of the source function are independent of the spatial and angular dependences, so we can write

$$\Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = A(t) N(\mathcal{E}) (\hat{\mathbf{n}}_a \cdot \hat{\mathbf{s}}) L_p(\mathbf{r}, \hat{\mathbf{s}}) \delta(p_a - \mathbf{r} \cdot \hat{\mathbf{n}}_a), \quad (16.4)$$

where $N(\mathcal{E})$ is a normalized spectral function satisfying $\int_0^\infty N(\mathcal{E}) d\mathcal{E} = 1$, and $A(t) L_p(\mathbf{r}, \hat{\mathbf{s}})$ is the photon radiance of the source. The factor $(\hat{\mathbf{n}}_a \cdot \hat{\mathbf{s}})$ is discussed in Sec. 10.4.3 [see (10.269)].

With this source model and (10.151), the distribution function is given by

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = \frac{1}{c} A(t) N(\mathcal{E}) \times \int_0^\infty d\ell (\hat{\mathbf{n}}_a \cdot \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell, \hat{\mathbf{s}}) \delta[p_a - (\mathbf{r} - \hat{\mathbf{s}}\ell) \cdot \hat{\mathbf{n}}_a] \exp \left[- \int_0^\ell d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell', \mathcal{E}) \right]. \quad (16.5)$$

The argument of the delta function vanishes when

$$\ell = \frac{\hat{\mathbf{n}}_a \cdot \mathbf{r} - p_a}{\hat{\mathbf{n}}_a \cdot \hat{\mathbf{s}}} \equiv \ell_0, \quad (16.6)$$

which occurs when a ray extended along $-\hat{\mathbf{s}}$ from point \mathbf{r} intersects the anode plane. The delta function transforms via (2.28) to $(\hat{\mathbf{n}}_a \cdot \hat{\mathbf{s}}) \delta[p_a - (\mathbf{r} - \hat{\mathbf{s}}\ell) \cdot \hat{\mathbf{n}}_a] = \delta(\ell - \ell_0)$, so (16.5) integrates to

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = \frac{1}{c} A(t) N(\mathcal{E}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) \exp \left[- \int_0^{\ell_0} d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell', \mathcal{E}) \right]. \quad (16.7)$$

The interpretation of this equation is straightforward when one recalls from Sec. 10.2 that c times the distribution function is the spectral photon radiance, and that radiance is conserved along rays in free space; thus (16.7) says that the radiance at point \mathbf{r} and direction $\hat{\mathbf{s}}$ is the source radiance along the same ray but attenuated by passage through the object. Note that the factor $(\hat{\mathbf{n}}_a \cdot \hat{\mathbf{s}})$ has cancelled out; we do not need to know the tilt angle of the anode explicitly if we know the source radiance.

With this distribution function and (16.2), the mean output of the \mathbf{m}^{th} detector is

$$\bar{g}_{\mathbf{m}} = \frac{1}{c} \int_{-\infty}^{\infty} dt A(t) \int_0^{\infty} d\mathcal{E} N(\mathcal{E}) \times \int_P d^2r \int_{2\pi} d\Omega d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) \exp \left[- \int_0^{\ell_0} d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell', \mathcal{E}) \right]. \quad (16.8)$$

This is the general nonlinear mapping from the object, described by the function $\mu_{tot}(\mathbf{r}, \mathcal{E})$, to the digital data.

To simplify this equation a bit, we can assume that the spectral response of the detector is the same for all \mathbf{m} and is independent of direction and position of the radiation, so we can write

$$d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) S_d(\mathcal{E}), \quad (16.9)$$

where $S_d(\mathcal{E})$ is the spectral response function. If we also assume that the x-ray attenuation coefficient is approximately independent of energy, we have

$$\bar{g}_{\mathbf{m}} = C \int_P d^2r \int_{2\pi} d\Omega d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) \exp \left[- \int_0^{\ell_0} d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell') \right], \quad (16.10)$$

where

$$C \equiv \frac{1}{c} \int_{-\infty}^{\infty} dt A(t) \int_0^{\infty} d\mathcal{E} N(\mathcal{E}) S_d(\mathcal{E}). \quad (16.11)$$

The object is now described by the purely spatial function $\mu_{tot}(\mathbf{r})$, and (16.10) is the mapping of this object to the mean data.

Linearization In spite of the simplifications, (16.10) is still highly nonlinear. To secure the blessings of linear systems theory, we might consider expanding the exponential in (16.10) and retaining only linear terms in $\mu_{tot}(\mathbf{r})$, but this approximation is rarely valid; the x-ray attenuation coefficient in soft tissue is about 0.2 cm^{-1} for energies used in diagnostic radiology, so 10 cm of tissue corresponds to an attenuation of e^{-2} .

A better way to linearize is to consider a thick object to be made up of thin slabs parallel to the detector and to look at the image of one slab at a time. To do this, we adopt a coordinate system in which the detector lies in the plane $z = 0$ and the x rays propagate generally in the $+z$ direction. In this plane, then, $\mathbf{r} = (x, y, 0) \equiv (\mathbf{r}, 0)$, and $d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}})$ becomes $d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}})$. Also, if $\hat{\mathbf{s}} = (s_x, s_y, s_z)$, we define the 2D vector $\mathbf{s}_{\perp} = (s_x, s_y)$. Note that \mathbf{s}_{\perp} is not a unit vector and that $s_z = \cos \theta$, where θ is the angle between $\hat{\mathbf{s}}$ and the z axis. With these definitions, the argument of μ_{tot} in (16.10) is $\mathbf{r} - \hat{\mathbf{s}}\ell' = (\mathbf{r} - \mathbf{s}_{\perp}\ell', -s_z\ell')$.

We can now divide the object into slabs of thickness Δz and approximate the integral in the exponential factor of (16.10) with a Riemann sum:

$$\begin{aligned} \exp \left[- \int_0^{\ell_0} d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell') \right] &\approx \exp \left[- \Delta\ell \sum_{j=1}^J \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}j\Delta\ell) \right] \\ &= \prod_{j=1}^J \exp \left[- \frac{\Delta z}{s_z} \mu_{tot} \left(\mathbf{r} + \mathbf{s}_\perp \frac{z_j}{s_z}, -z_j \right) \right], \end{aligned} \quad (16.12)$$

where $J = \ell_0/\Delta\ell$, $z_j = -js_z\Delta\ell$ and $\Delta z/s_z = \Delta\ell$. Each factor in this product can be expressed in terms of the transmission of the slab for x rays travelling in the $\hat{\mathbf{s}}$ direction. Since this transmission depends on the angle θ between the slab normal and $\hat{\mathbf{s}}$, we write it as

$$t_j^{(\theta)}(\mathbf{r}) \equiv \exp \left[- \frac{\Delta z}{\cos \theta} \mu_{tot}(\mathbf{r}, -z_j) \right], \quad (16.13)$$

and (16.10) becomes

$$\bar{g}_m = C \int_P d^2r \int_{2\pi} d\Omega d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) \left[\prod_{j=1}^J t_j^{(\theta)} \left(\mathbf{r} + \mathbf{s}_\perp \frac{z_j}{s_z} \right) \right]. \quad (16.14)$$

If we are interested in one particular slab, say $j = k$, we can factor out the transmittance of that slab and write

$$\bar{g}_m = C \int_P d^2r \int_{2\pi} d\Omega d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) \left[\prod_{j \neq k}^J t_j^{(\theta)} \left(\mathbf{r} + \mathbf{s}_\perp \frac{z_j}{s_z} \right) \right] t_k^{(\theta)} \left(\mathbf{r} + \mathbf{s}_\perp \frac{z_k}{s_z} \right). \quad (16.15)$$

This equation is now a linear mapping from $t_k^{(\theta)}(\mathbf{r})$ to \bar{g}_m , but it is highly shift-variant since the effective source distribution depends on all of the other $t_j^{(\theta)}(\mathbf{r})$. In fact, (16.15) is a good example of an object-dependent system function as introduced in Sec. 7.5.3.

Note that the linearization has been obtained without expanding the exponential; \bar{g}_m is a linear functional of the transmittance of the slab of interest, though it is still a nonlinear functional of the attenuation coefficient in the slab. If we choose Δz small enough, of course, we can expand the exponential and retain only the constant and linear terms. Then we find that \bar{g}_m is an affine functional of μ_{tot} in the slab.

Another way to attempt to linearize the imaging equation is to take its logarithm. It is not obvious that this will work since we cannot take the logarithm under the integral sign in (16.10), but it often leads to a good linear approximation. We shall discuss this option in more detail in Sec. 16.1.7 in the context of estimation tasks.

Spatial resolution in a single slab To better understand (16.15) and the spatial-resolution limitations in digital radiography, let us consider an object consisting of just one slab. In fact, radiographic systems are often evaluated with test patterns consisting of fine openings in a thin slab of lead, tungsten or other highly absorbing

material. This test pattern then mimics the transmittance of a single slab out of a thick object, but at much higher contrast and without the confusion caused by overlying layers.

With an object consisting of a single slab in the plane $z = -z_0$ and specified by the transmittance $t_{obj}^{(\theta)}(\mathbf{r})$, (16.15) becomes

$$\bar{g}_{\mathbf{m}} = C \int_P d^2r \int_{2\pi} d\Omega d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) t_{obj}^{(\theta)}\left(\mathbf{r} + \mathbf{s}_{\perp} \frac{z_0}{s_z}\right). \quad (16.16)$$

This expression is now strictly linear in the object transmittance $t^{(\theta)}(\mathbf{r})$; the system function no longer depends on the object in any way, though the measured object property depends on the system since the transmittance depends on ray angle θ in general. (The transmittance is approximately independent of θ for a test pattern consisting of openings in a thin plate if the size of the openings is large compared to the thickness, but continuous slabs of attenuating material such as tissue will always exhibit some angular dependence.)

To simplify the integrals in (16.16), we can take advantage of the small size of the detector elements in practical digital radiography systems and the small solid angle subtended by practical focal spots. Even though the integral over solid angle allows a range of 2π ster in general, the spatial dependences (the first arguments) of the functions $d_{\mathbf{m}}$ and L_p restrict the range to rays close to $\hat{\mathbf{s}}_{\mathbf{m}}$, the unit vector directed from the center of the focal spot to the center of the \mathbf{m}^{th} detector element. If the angular dependences (the second arguments) of $d_{\mathbf{m}}$ and L_p are weak over this range, then $d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) \approx d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}_{\mathbf{m}})$ and $L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) \approx L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}_{\mathbf{m}})$ in (16.16).

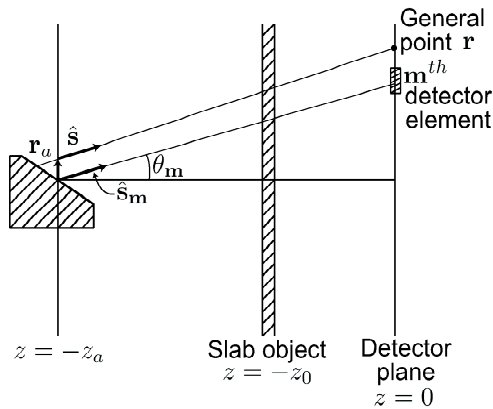

Fig. 16.7 Geometry for imaging a thin slab object with a tilted-anode x-ray source.

We can now erect a plane normal to the z axis and passing through the focal spot. We denote this plane by $z = -z_a$ and let transverse position in the plane be specified by the 2D vector \mathbf{r}_a (see Fig. 16.7). We know that ℓ_0 is the distance along direction $-\hat{\mathbf{s}}_{\mathbf{m}}$ from a general point \mathbf{r} in the detector plane ($z = 0$) to a point on the anode plane, and we can approximate it with ℓ_{0m} , the distance from the center of the \mathbf{m}^{th} detector element to the center of the focal spot. Noting also that $z_a \approx -\ell_{0m} \cos \theta_m$, where θ_m is the angle between the z axis and the line from the

focal spot to the \mathbf{m}^{th} detector, we can write the element of solid angle as

$$d\Omega = \frac{\cos \theta_{\mathbf{m}}}{\ell_{0m}^2} d^2 r_a = \frac{\cos^3 \theta_{\mathbf{m}}}{z_a^2} d^2 r_a. \quad (16.17)$$

Moreover, $\mathbf{r}_a = \ell_0 \mathbf{s}_{\perp} \approx \ell_{0m} \mathbf{s}_{\perp}$. Thus, since $\mathbf{r} = (\mathbf{r}, 0)$ in plane P , we can rewrite the 3D spatial argument of L_p as

$$\mathbf{r} - \hat{\mathbf{s}}\ell_0 = (\mathbf{r} - \mathbf{r}_a, -z_a). \quad (16.18)$$

With these approximations and substitutions, (16.16) becomes

$$\bar{g}_{\mathbf{m}} = \frac{C \cos^3 \theta_{\mathbf{m}}}{z_a^2} \int_{\infty} d^2 r \int_{\infty} d^2 r_a d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}_{\mathbf{m}}) L_p(\mathbf{r} - \mathbf{r}_a, -z_a, \hat{\mathbf{s}}_{\mathbf{m}}) t_{obj}^{(\theta_{\mathbf{m}})} \left(\mathbf{r} - \mathbf{r}_a \frac{z_0}{z_a} \right). \quad (16.19)$$

Note that we have extended the ranges of integration to the infinite planes, assured that the functions $d_{\mathbf{m}}$ and L_p will limit the integrands to small portions of the planes.

Magnification To help interpret (16.19), consider a point source of x rays and a small point-like detector element. Without loss of generality, we can put the point source at the 2D origin of coordinates in the plane $z = -z_a$, so $L_p(\mathbf{r}', -z_a, \hat{\mathbf{s}}_{\mathbf{m}}) \propto \delta(\mathbf{r}')$ and $d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}_{\mathbf{m}}) \propto \delta(\mathbf{r} - \mathbf{r}_{\mathbf{m}})$, where $\mathbf{r}_{\mathbf{m}}$ is the 2D location of the \mathbf{m}^{th} detector in the plane $z = 0$. Then (16.19) becomes

$$\bar{g}_{\mathbf{m}} \propto \int_{\infty} d^2 r \int_{\infty} d^2 r_a \delta(\mathbf{r} - \mathbf{r}_{\mathbf{m}}) \delta(\mathbf{r} - \mathbf{r}_a) t_{obj}^{(\theta_{\mathbf{m}})} \left(\mathbf{r} - \mathbf{r}_a \frac{z_0}{z_a} \right) = t_{obj}^{(\theta_{\mathbf{m}})} \left[\mathbf{r}_{\mathbf{m}} \left(1 - \frac{z_0}{z_a} \right) \right]. \quad (16.20)$$

Thus the image, as a function of the detector coordinate $\mathbf{r}_{\mathbf{m}}$, is a magnified version of the object transmittance. The magnification M is

$$M = \left(1 - \frac{z_0}{z_a} \right)^{-1} = \frac{z_a}{z_a - z_0}, \quad (16.21)$$

which is the source-to-detector distance divided by the source-to-object distance. If the object is in contact with the detector ($z_0 = 0$), then $M = 1$, but if the object is close to the source there is a large geometric magnification. Since z_a and z_0 are both negative numbers with our conventions, M is always positive (there is no inversion), and in fact $M \geq 1$.

Point response function If we allow a finite extent for the source and detector element, then the image of a slab object is not just a magnified version of the object, but it can always be cast into our usual form of a linear CD mapping. If we define the object as $f(\mathbf{r}) \equiv t_{obj}^{(\theta)}(\mathbf{r})$, then by a change of variables we can write

$$\bar{g}_{\mathbf{m}} = \int_{\infty} d^2 r' h_{\mathbf{m}}(\mathbf{r}') f(\mathbf{r}'), \quad (16.22)$$

where

$$h_{\mathbf{m}}(\mathbf{r}') = \frac{C \cos^3 \theta_{\mathbf{m}}}{z_a^2} \int_{\infty} d^2 r_a d_{\mathbf{m}} \left(\mathbf{r}' + \mathbf{r}_a \frac{M-1}{M}, \hat{\mathbf{s}}_{\mathbf{m}} \right) L_p \left(\mathbf{r}' - \mathbf{r}_a \frac{1}{M}, -z_a, \hat{\mathbf{s}}_{\mathbf{m}} \right). \quad (16.23)$$

In essence, this kernel is the cross-correlation of the detector response function and the spatial part of the source function, though these two functions appear with different magnifications in the integrand.

Two limits of (16.23) are of interest. First, if the object is in contact with the detector so that $z_0 = 0$ and $M = 1$, then $d_{\mathbf{m}}$ is independent of \mathbf{r}_a and can be removed from the integral, and the integral of L_p becomes independent of \mathbf{r}' by a change of variables. In that limit, therefore $h_{\mathbf{m}}(\mathbf{r}') \propto d_{\mathbf{m}}(\mathbf{r}', \hat{\mathbf{s}}_{\mathbf{m}})$. In other words, the size of the source is of no importance for contact printing, and the PRF is simply the detector function.

The opposite limit is when the object is placed close to the source and a long distance from the detector. The magnification is large in this case, so L_p is a broad function of \mathbf{r}_a , and the width of the detector response contributes little to the width of $h_{\mathbf{m}}$.

16.1.5 Stochastic properties

Many different random phenomena can affect the statistical properties of digital radiographic images. A convenient organization is to consider separately noise mechanisms that produce no correlations among the elements of \mathbf{g} , ones that produce short-range correlations and ones that produce long-range correlations.

As we know from Chap. 11, the x-ray photons produce uncorrelated noise if we can argue that they are described by Poisson statistics; we make that argument below in the context of x-ray production by electron bombardment. Other sources of uncorrelated noise include various kinds of electronic noise such as amplifier noise, shot noise due to dark current and kTC noise (see Sec. 12.2.4).

The gain processes in scintillation and semiconductor x-ray detectors produce both uncorrelated and correlated noise components. There is an uncorrelated component since the secondary particles (optical photons or charge carriers) form a point process, but there is a correlation since the secondaries produced by a single primary x ray are not independent. In the limit of a very large number of secondaries per primary, the gain mechanism is just a deterministic blur, so it produces a correlation over a scale approximately equal to the blur width as determined by the spread of the secondaries before detection. In practical detectors, this blur is only a few pixels, so the correlations associated with the gain process are short range.

Not all blur mechanisms produce correlation, however. If we consider an optically coupled scintillation detector with poor collection efficiency, for example, so that less than one optical photon is collected per x-ray photon, the rarity of secondary collection converts the statistics to Poisson and destroys the correlation in spite of the blur. As another example, blurring before detection by the finite size of the focal spot leaves the x-ray photons independent and does not introduce any correlation.

Another important source of short-range correlations is production of secondary x-ray photons in the detector by Compton scattering or K x-ray emission. These secondaries produce a correlation over a scale related to the mean distance they travel before reabsorption in the detector (see Sec. 12.3.9).

Long-range correlations can arise from blur mechanisms with long tails on their point response functions, such as veiling glare in image intensifiers. They can also arise, however, when the object being imaged is considered to be random, so that the image is doubly stochastic (see Sec. 11.3.6). Almost by definition, interesting

objects have long-range correlations, so this component of the image covariance is usually long-range.

All of these random phenomena have been discussed in previous chapters; in this section we shall try to bring the pieces together and present a comprehensive statistical model for digital radiographic images.

Poisson statistics The starting point for discussion of the statistical properties of digital radiographs is the statistics of the incident x-ray beam. We would like to assume that the number of photons detected during the exposure time is a Poisson random variable and that the pattern of photoelectric interactions in the detector is a Poisson random process, but we should look critically at the conditions that must be satisfied for the Poisson models to hold.

As we saw in Chap. 11, Poisson statistics can arise from two different principles: independence and rarity. X rays are produced by electron bombardment of an anode, and the number of emitted x-ray photons will obey Poisson statistics if the electrons act independently, but that requires that the mean current be constant; as illustrated qualitatively in Fig. 11.2, a random current makes the overall strength of the x-ray source random and the photon statistics non-Poisson.

The effect of a random source strength on image statistics for an array of ideal photon-counting detectors was discussed in Sec. 11.2.2. In particular, (11.56) shows that the covariance matrix of the data consists of two terms, a diagonal matrix accounting for the Poisson statistics and a nondiagonal one arising from the source fluctuations:

$$[\mathbf{K}_{\mathbf{g}}]_{ik} = P_k \overline{\overline{M}} \delta_{ik} + P_i P_k \left[\text{Var}(M) - \overline{\overline{M}} \right], \quad (16.24)$$

where, in digital radiography, $\overline{\overline{M}}$ is the mean number of x-ray photons emitted by the tube, and the average is over both the random photon-generation process and fluctuations in the tube current; P_k is the probability that an emitted photon is detected in the k^{th} detector. Physically, if the current in the x-ray tube is high on a particular exposure, all signals in a detector array tend to fluctuate high together, and conversely if the current fluctuates low.

We argued in Sec. 11.2.2 that the nondiagonal term was likely to be small if the probability of an x-ray photon being detected in a given detector element was small, but this argument is hard to sustain in digital radiography, as a numerical example will show.

Typical x-ray images are taken with integrated currents of $\sim 10\text{--}100$ mA-s, or $10^{17}\text{--}10^{18}$ electrons incident on the anode of the x-ray tube during the exposure time. Only about 1% of the electrons produce x rays, and only a small fraction of the emitted x rays reach an individual detector element. If we consider a $100\mu\text{m} \times 100\mu\text{m}$ detector element 1 m from a source, it collects $\sim 10^{-9}$ of the emitted photons if there is no intervening object; attenuation in the object reduces the number detected even further, say by a factor of 100–1000. With all of these factors, we might get $\sim 10^4$ detected photons in each detector element. even though $\overline{\overline{M}} \sim 10^{15}\text{--}10^{16}$. Thus photon detection in this element certainly sounds like a rare event, but a flux of 10^4 photons has an associated standard deviation that is 1% of the mean; the nondiagonal term in the covariance is negligible only if the current is stable to much better than 1%, which is very difficult to accomplish in practice.

One might question whether this effect is of any practical concern. Since only a single image is collected for a given patient, a small change in the current for that

image is equivalent to a small change in exposure time, the effect of which would be hard to discern. The only way to observe the nondiagonal term in the covariance matrix (11.56) would be to do repeated measurements on the same patient and compare the results.

In the spirit of this book, however, we pose the question differently: Does the departure from Poisson statistics and the resulting nondiagonal term in the covariance have any effect on task performance? We shall return to this point in the context of specific tasks in Secs. 16.2.5 and 16.2.6, but for now we make two remarks. First, an overall fluctuation in the strength of the x-ray beam arriving at the detector could have arisen from a spatially uniform change in transmittance through the object, so the second term in (16.24) can be lumped into object variability. Second, the nondiagonal term in the covariance is a rank-one matrix, and we will see that it has little effect on the performance of detection or estimation tasks. In terms of task performance, we shall show that we can treat the x-ray tube as a Poisson source, and we make that assumption for the remainder of this section.

Poisson random processes If we neglect the current variations, the total number of x-ray photons incident on the detector plane is well approximated by a Poisson random variable, and if we assume that the spatial position, angle of arrival and energy of one photon are independent of the properties of all other photons, then the pattern of photoelectric interactions in the detector is a Poisson random process. The particular Poisson process we should consider depends on what detector model we want to use, but in all cases the statistics of a Poisson random process are fully determined by its mean.

The simplest model of the detector is that the \mathbf{m}^{th} element responds with some quantum efficiency η to each x-ray photon that hits it, so the mean output $\bar{g}_{\mathbf{m}}$ is just η times the integral of the x-ray fluence $b(\mathbf{r})$ across the area of that element. There are no correlations from element to element with this model, so the image statistics are fully determined by the incident fluence, a 2D function.

In more realistic x-ray detectors, as discussed in Sec. 12.3.8, the important Poisson process is the spatio-spectral random process $g_{ss}(\mathbf{R})$, defined in (12.295), which specifies the spatial distribution of photoelectric interactions in the volume of the detector and the energy deposited in each interaction. In the argument of this process, \mathbf{R} is a 4D vector consisting of the 3D interaction position \mathbf{r} and energy \mathcal{E} .

All statistical properties of $g_{ss}(\mathbf{R})$ are determined by its mean, the spatio-spectral fluence $b_{ss}(\mathbf{R})$. To calculate this mean, we can first solve the Boltzmann equation for the distribution function $w_{det}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$ inside the detector, subject to a boundary condition obtained by solving the Boltzmann equation outside the detector. For example, if the detector is adequately modeled as a homogeneous slab and the only interaction process considered is photoelectric absorption, then the Boltzmann equation consists of just the propagation and absorption terms. The distribution function inside the detector is then given by [cf. (10.148)]

$$w_{det}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = w(\mathbf{r}_P - \hat{\mathbf{s}}|\mathbf{r} - \mathbf{r}_P|, \hat{\mathbf{s}}, \mathcal{E}, t) \exp(-\alpha_{pe}|\mathbf{r} - \mathbf{r}_P|), \quad (16.25)$$

where $w(\mathbf{r}_P, \hat{\mathbf{s}}, \mathcal{E}, t)$ is the distribution function on plane P (the entrance face of the detector) and α_{pe} is the photoelectric attenuation coefficient¹ in the detector.)

¹We use α for attenuation coefficients in the detector material for consistency with Chap. 12 and to distinguish them from attenuation coefficients in the object, which we are denoting as μ .

It then follows from the definitions of w_{det} and b_{ss} that

$$b_{ss}(\mathbf{R}) = b_{ss}(\mathbf{r}, \mathcal{E}) = c \int_0^\tau dt \int_{4\pi} d\Omega \alpha_{pe} w_{det}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t). \quad (16.26)$$

Statistics of the detector output For a given object, the spatio-spectral fluence can be determined (albeit by a complicated nonlinear equation), and the mean vector and covariance matrix for the digital images can be found if we specify the detector readout mechanism. For example, for a scintillation detector read out by an array of photodiodes and gated integrators, the conditional covariance matrix for a specified object is given by (12.302), which we repeat here for convenience with a slight change in notation:

$$\begin{aligned} & [\mathbf{K}_g(\mathbf{b}_{ss})]_{\mathbf{m}\mathbf{m}'} \\ &= \left\{ \Gamma_{\mathbf{m}}^2 \int_{\mathbf{m}} d^2r [\mathcal{H}_1 \mathbf{b}_{ss}](\mathbf{r}) + \sigma_{\mathbf{m}}^2 \right\} \delta_{\mathbf{m}\mathbf{m}'} + \Gamma_{\mathbf{m}} \Gamma_{\mathbf{m}'} \int_{\mathbf{m}} d^2r \int_{\mathbf{m}'} d^2r' [\mathcal{H}_2 \mathbf{b}_{ss}](\mathbf{r}, \mathbf{r}'), \end{aligned} \quad (16.27)$$

where $\Gamma_{\mathbf{m}}$ is the gain of the \mathbf{m}^{th} photodiode as defined in (12.301), and $\sigma_{\mathbf{m}}^2$ is the variance of its excess noise (electronic, dark current and kTC). The operators \mathcal{H}_1 and \mathcal{H}_2 , originally introduced in Sec. 11.4.3, are given explicitly in (12.297) and (12.298), respectively, which we repeat here as

$$[\mathcal{H}_1 \mathbf{b}_{ss}](\mathbf{r}) = \int_D d^4R_n p_d(\mathbf{r}, \mathbf{R}_n) b_{ss}(\mathbf{R}_n); \quad (16.28)$$

$$[\mathcal{H}_2 \mathbf{b}_{ss}](\mathbf{r}, \mathbf{r}') = \int_D d^4R_n \text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{r}_n | \mathbf{R}_n) \text{pr}_{\Delta\mathbf{r}'}(\mathbf{r}' - \mathbf{r}_n | \mathbf{R}_n) b_{ss}(\mathbf{R}_n) s(\mathbf{R}_n), \quad (16.29)$$

where $p_d(\mathbf{r}, \mathbf{R}_n)$ is the mean number of secondaries per unit area on the output plane if the n^{th} x-ray interaction is at the 4D point $\mathbf{R}_n = (\mathbf{r}_n, z_n, \mathcal{E}_n)$; $\text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{r}_n | \mathbf{R}_n)$ is the probability density function for the lateral displacement of the secondaries about the interaction position as they propagate to the output plane, and $s(\mathbf{R}_n)$ is defined in (11.219) as

$$s(\mathbf{R}_n) = \text{E}\{k_n^2 - k_n | \mathbf{R}_n\} = \text{Var}\{k_n | \mathbf{R}_n\} + [\text{E}\{k_n | \mathbf{R}_n\}]^2 - \text{E}\{k_n | \mathbf{R}_n\}, \quad (16.30)$$

where k_n is the number of secondaries produced by the n^{th} primary. The 4D integrals in (16.28) and (16.29) run over the volume of the detector and all energies from 0 to ∞ . Since the x rays are presumed to be indistinguishable, the integrals are independent of the index n .

The operator \mathcal{H}_1 serves also to express the mean output. From (11.214) as generalized to the spatio-spectral case, we have that

$$\bar{g}_{\mathbf{m}} = \Gamma_{\mathbf{m}} \int_{\mathbf{m}} d^2r [\mathcal{H}_1 \mathbf{b}_{ss}](\mathbf{r}). \quad (16.31)$$

Expressions very similar to (16.27) and (16.31) apply to semiconductor detectors with an array of pixel electrodes.

To make contact with Sec. 16.1.4, note that \mathbf{b}_{ss} is a linear functional of its boundary condition, specified by the distribution function w on the entrance face, and (16.31) shows that $\bar{g}_{\mathbf{m}}$ is a linear functional of \mathbf{b}_{ss} , so $\bar{g}_{\mathbf{m}}$ is linear in w . From

these nested functionals we can derive the measurement function $d_{\mathbf{m}}(\mathbf{t}, \hat{\mathbf{s}}, \mathcal{E})$; the reader is invited to do so for the detector model of (16.25).

If we consider only unscattered photons, then (16.31) is equivalent to (16.8) or (16.10), depending on what we want to assume about the detector response, but the spatio-spectral fluence must, in general, include contributions from both scattered and unscattered photons. Actually computing the input quantity \mathbf{b}_{ss} in (16.27) and (16.31) is thus a daunting task, requiring solution of the Boltzmann equation with a scatter term in the region between the source and the detector and then solving the Boltzmann equation again in the detector material.

One might worry that scatter in the object would introduce correlation in the data since scattered photons could enter the detector far from normal incidence, even if the unscattered ones are nearly normal. Fortunately, this complication does not occur since \mathbf{b}_{ss} is the mean of a Poisson random process if the x rays obey Poisson statistics. Each impulse in the spatio-spectral random process produces an independent response, and the only correlation is the result of the correlated secondary particles (*e.g.*, optical photons) reaching different detectors.

On the other hand, the spatio-spectral distribution can influence the form of the correlation function. For example, if the incident photons are mainly of low energy and therefore absorbed near the entrance face of the detector, then secondary optical photons in a scintillation detector can spread out as they propagate through the full thickness of the detector and therefore contribute to several adjacent photodiodes. X-ray photons of higher energy, however, may be absorbed much closer to the photodiode plane and therefore spread less.

Random objects If we consider random objects, then the spatio-spectral fluence becomes a doubly stochastic random process and \mathbf{g} becomes a doubly stochastic random vector. By generalizing (11.233) and integrating over detector areas, we find

$$[\mathbf{K}_{\mathbf{g}}]_{\mathbf{m}\mathbf{m}'} = \left[\Gamma_{\mathbf{m}}^2 \int_{\mathbf{m}} d^2r [\mathcal{H}_1 \bar{\mathbf{b}}_{ss}](\mathbf{r}) + \sigma_{\mathbf{m}}^2 \right] \delta_{\mathbf{m}\mathbf{m}'} \\ + \Gamma_{\mathbf{m}} \Gamma_{\mathbf{m}'} \int_{\mathbf{m}} d^2r \int_{\mathbf{m}'} d^2r' \left\{ [\mathcal{H}_2 \bar{\mathbf{b}}_{ss}](\mathbf{r}, \mathbf{r}') + [\mathcal{H}_1 \mathbf{K}_{\mathbf{b}_{ss}} \mathcal{H}_1^\dagger](\mathbf{r}, \mathbf{r}') \right\}, \quad (16.32)$$

where $\mathbf{K}_{\mathbf{b}_{ss}}$ is the covariance for the random spatio-spectral fluence, which must in general be calculated from the properties of the random object by use of the nonlinear equation (16.7). Note that the object randomness has the same qualitative effect as blur in the detector, introducing off-diagonal terms in the data covariance matrix.

Nonlocal charge deposition The effect of reabsorption of Compton-scattered or K x-ray photons on the image statistics was discussed in Sec. 12.3.9. The key result there was the autocovariance function (12.321) for the spatio-spectral random process $g_{ss}(\mathbf{R})$. That formula states that

$$K_{g_{ss}}(\mathbf{R}, \mathbf{R}' | \mathbf{b}_{ss}) = [b_{ss}^{pri}(\mathbf{R}) + b_{ss}^{sec}(\mathbf{R})] \delta(\mathbf{R} - \mathbf{R}') \\ + p_{p \rightarrow s} [pr_{p \rightarrow s}(\mathbf{R}' | \mathbf{R}) b_{ss}^{pri}(\mathbf{R}) + pr_{p \rightarrow s}(\mathbf{R} | \mathbf{R}') b_{ss}^{pri}(\mathbf{R}')], \quad (16.33)$$

where $p_{p \rightarrow s}$ is the probability that a primary x-ray photon will produce a secondary event somewhere in the detector, and $pr_{p \rightarrow s}(\mathbf{R} | \mathbf{R}')$ is the probability density function for a secondary x ray to be absorbed at the 4D point \mathbf{R} given a primary x-ray

interaction at \mathbf{R}' , or vice versa. The delta-correlated terms represent the independent Poisson-noise contributions of the primary and secondary x rays, and the next two terms represent their correlation.

Overall covariance To summarize this section, the physical effects that contribute to the noise in digital radiography are not all statistically independent, but it is nevertheless possible to write the overall covariance matrix in the form:

$$\mathbf{K}_{\mathbf{g}} = \mathbf{K}_{\mathbf{g}}^{(elec)} + \mathbf{K}_{\mathbf{g}}^{(x)} + \mathbf{K}_{\mathbf{g}}^{(gain)} + \mathbf{K}_{\mathbf{g}}^{(Kx)} + \mathbf{K}_{\mathbf{g}}^{(obj)}, \quad (16.34)$$

where the terms represent, respectively, the electronic noise; the Poisson statistics of the x rays as reflected through the gain mechanism; the excess noise of the gain mechanism; the effect of reabsorbed Compton-scattered and K x rays, and the effect of object randomness

The first two terms in (16.34) are diagonal matrices, even in the presence of noisy gain, object randomness or secondary x-ray events. As we have noted, the electronic noise has a covariance of the form

$$\left[\mathbf{K}_{\mathbf{g}}^{(elec)} \right]_{\mathbf{m}\mathbf{m}'} = \sigma_{\mathbf{m}}^2 \delta_{\mathbf{m}\mathbf{m}'}, \quad (16.35)$$

which is independent of the x-ray exposure, the object and the gain mechanism in the detector.

On the other hand, the second term, $\mathbf{K}_{\mathbf{g}}^{(x)}$, does depend on the x-ray exposure, the object and the gains. It can be read off explicitly as the term involving \mathcal{H}_1 in (16.27) or (16.32), but with (16.31) it can also be summarized as

$$\left[\mathbf{K}_{\mathbf{g}}^{(x)} \right]_{\mathbf{m}\mathbf{m}'} = \Gamma_{\mathbf{m}} \bar{g}_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'}. \quad (16.36)$$

The covariance $\mathbf{K}_{\mathbf{g}}^{(gain)}$ refers specifically to the term involving \mathcal{H}_2 in (16.27) or (16.32). It can be thought of as the correlated part of the gain process, but in fact it may also be a diagonal matrix, or nearly so. In a scintillator-photodiode detector, for example, the random process $y(\mathbf{r})$ describing optical photons on the photodiode plane has a correlated term involving \mathcal{H}_2 [see (12.299)], but the range of this correlation is approximately the range over which the optical photons spread in propagating to the output plane, which in turn is approximately the detector thickness. This range might be small compared to the size ϵ of a photodiode, and if so, then $\mathbf{K}_{\mathbf{g}}^{(gain)}$ will be diagonal even though $y(\mathbf{r})$ is not delta-correlated. If the spread of the optical photons is comparable to ϵ , then a correlation will be induced in \mathbf{g} between adjacent photodiodes but not between more distant ones.

The situation is only slightly more complicated in semiconductor detectors. As discussed in Sec. 12.3, the charge carriers not only spread out as they propagate to the electrode plane, but they can also be trapped *en route*. Trapped carriers can induce correlated charges on neighboring electrodes, but there is no significant correlation from this effect on two electrodes that are separated by several times the detector thickness.

Our use of the multi-index \mathbf{m} to denote the detector elements makes it very simple to characterize the short-range correlations associated with $\mathbf{K}_{\mathbf{g}}^{(gain)}$. We can say that

$$\left[\mathbf{K}_{\mathbf{g}}^{(gain)} \right]_{\mathbf{m}\mathbf{m}'} \approx 0 \quad \text{if} \quad \epsilon |\mathbf{m} - \mathbf{m}'| > \delta_{gain}, \quad (16.37)$$

where δ_{gain} is the correlation length of the secondary process $y(\mathbf{r})$. If we had not used multi-indices, it would have been more complicated to state which elements of $\mathbf{K}_g^{(gain)}$ were zero; with multi-indices, we can think of this covariance matrix as confined to a narrow band around the diagonal, and we shall refer to it as a *banded matrix*.

The covariance $\mathbf{K}_g^{(Kx)}$ is the covariance associated with reabsorption of K x rays or Compton-scattered photons. If they don't escape from the detector material, the secondary x rays have a pathlength of order $1/\alpha_{tot}$, where α_{tot} is the total attenuation coefficient for the secondary photons in the detector material, and twice this pathlength is a reasonable estimate for the correlation range for this term. We can thus say, roughly, that

$$\left[\mathbf{K}_g^{(Kx)} \right]_{\mathbf{m}\mathbf{m}'} \approx 0 \quad \text{if} \quad \epsilon \alpha_{tot} |\mathbf{m} - \mathbf{m}'| > 2. \quad (16.38)$$

Often this condition will lead to the conclusion that $\mathbf{K}_g^{(Kx)}$ is confined to a band one or two elements wide around the diagonal (in the multi-index notation).

Finally, $\mathbf{K}_g^{(obj)}$ in (16.34) refers to the term involving $\mathbf{K}_{b_{s,s}}$ in (16.32). A random object creates a random spatio-spectral fluence, which is then transformed through the amplification process to the output data. A key point about this term is that it varies quadratically with the x-ray exposure (since \mathcal{H}_1 varies linearly with exposure), so at large exposures it will be the dominant noise contribution. The range of the correlations associated with this term might be quite large since object structures can have large scales.

Estimating the covariance In order to make use of the covariance in image-quality assessment, we must be able to evaluate or estimate each of the five terms. Possible methods include model-based theoretical calculation, theory augmented by measurement, Monte Carlo simulation, and collection of sample images.

To evaluate the expressions for $\mathbf{K}^{(x)}$ and $\mathbf{K}^{(gain)}$, we need to know the first two moments of the random number of secondaries as well as how the secondaries are distributed on the readout plane of the detector. These unknowns can be determined from theoretical models or Monte Carlo simulation, but simple measurements with tightly collimated x-ray beams can be used also.

Similarly, $\mathbf{K}^{(elec)}$ can be computed theoretically from knowledge of the circuit design and standard electronic simulation software. If we know that this component matrix is diagonal as in (16.35), then the only unknowns are the variances, and we can also get those by direct measurement with no x-ray beam.

The contribution $\mathbf{K}^{(Kx)}$ is probably best determined by Monte Carlo simulation. Alternatively, the combination $\mathbf{K}^{(elec)} + \mathbf{K}^{(x)} + \mathbf{K}^{(gain)} + \mathbf{K}^{(Kx)}$ can be measured directly by using a uniform x-ray fluence and acquiring a large number of image frames. All of these terms are diagonal or banded around the diagonal, so only a very small subset of all possible elements in the covariance matrix needs to be computed; elements far from the diagonal are zero *a priori* by (16.37) and (16.38) and do not need to be computed or measured. Once the diagonal and near-diagonal terms are established, we have a full-rank estimate of the sum of the first four terms in (16.34). We denote that estimate as $\hat{\mathbf{K}}_g^{(noise)}$.

The most difficult term is $\mathbf{K}_g^{(obj)}$, which is simply neglected in many detectability studies. Any covariance matrix can be estimated from samples, but if we want the resulting sample covariance matrix to represent $\mathbf{K}_g^{(obj)}$, the other noise sources

must be negligible. To achieve this goal, we can take advantage of the fact that $\mathbf{K}_g^{(obj)}$ is the only term that varies quadratically with the x-ray exposure. If clinical (or animal or cadaver) images can be taken at high enough exposure, the resulting sample covariance matrix on the images is directly an estimate of $\mathbf{K}_g^{(obj)}$, denoted $\hat{\mathbf{K}}_g^{(obj)}$. Alternatively, several images of each object can be taken at lower exposures, and the sample covariance matrix can be analyzed element by element to tease out $\hat{\mathbf{K}}_g^{(obj)}$ separately.

Another useful approach is to simulate realistic objects and then simulate their images without the other noise sources being present. Methods of simulation were discussed in Sec. 8.4. In the context of digital mammography we mention particularly the clustered lumpy background of Bochud *et al.* (1999a), which gives quite realistic simulated mammograms.

Whether actual images or simulated ones are used to estimate $\mathbf{K}_g^{(obj)}$, it is important to note that the overall covariance estimate $\hat{\mathbf{K}}_g^{(noise)} + \hat{\mathbf{K}}_g^{(obj)}$ will have full rank even if the number of sample images is small. The great advantage we have in this application is that $\mathbf{K}_g^{(elec)}$ and $\mathbf{K}_g^{(x)}$ are diagonal (hence full rank) and do not have to be estimated from samples.

16.1.6 Image quality: Detection tasks

We shall begin the discussion of image quality in digital radiography with the simplest of detection tasks, SKE/BKE (signal known exactly, background known exactly). As we saw in Sec. 13.2.12, the Hotelling observer is ideal if the noise is Gaussian and independent of the signal. We shall argue below that these conditions prevail, to a good approximation, and the Hotelling SNR is the relevant figure of merit for this task in digital radiography.

Computation of this SNR requires knowledge of the mean signal in the data and the covariance matrix, along with some method for performing the inversion of the covariance. We shall show how to carry out this computation first for an x-ray detector that has no element-to-element noise correlation and then with short-range correlations of the sort that can arise from reabsorption of secondary x-ray photons or spread of optical photons. Then we shall allow random backgrounds and signals, and in Sec. 16.1.7 we shall discuss estimation tasks.

The signal To derive an SNR for an SKE/BKE task, we must first define precisely what we mean by the signal. In medical radiography, the signal is the result of a local change in the x-ray attenuation coefficient in the patient's body. Such local changes, known generically as *lesions*, may result from tumors, cysts, blockages in blood-vessels, etc., and it is of great clinical importance to be able to detect them.

A change in x-ray attenuation in the object will, in general, cause rather complicated changes in the detector output. First, it will change the mean signal from the unscattered radiation since it changes the mean number of unscattered x-ray photons reaching the detector as well as their spatial distribution. Second, it will also change the mean distribution of scattered radiation. And finally, since the noise properties of the image all depend on the x-ray distribution function on the detector face, any change in x-ray attenuation coefficient will change the noise covariance.

To make the problem of computing the SNR tractable, we assume that the lesion makes only a small change in the unscattered x-ray distribution function on

the detector face and therefore only a small change in the mean detector outputs. Moreover, we shall neglect any changes in the scattered distribution on the basis that small changes in scatter properties of the object result in changes in the distribution function spread out over the entire detector surface and hence of very low contrast.

If we specify the lesion by a change in attenuation coefficient $\Delta\mu(\mathbf{r}, \mathcal{E})$, and if we ignore any changes in the scattered radiation, then the change in $\bar{g}_{\mathbf{m}}$ can be computed from (16.8). If we make a few simplifying assumptions about the detector, as indicated in (16.9), and if we also assume that the attenuation coefficients of the lesion and the background object are independent of \mathcal{E} , we can use the simpler form (16.10). We can then define the mean signal as

$$s_{\mathbf{m}} \equiv \Delta\bar{g}_{\mathbf{m}} = C \int_P d^2r \int_{2\pi} d\Omega d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) \times \left\{ \exp \left[- \int_0^{\ell_0} d\ell' [\mu_0(\mathbf{r} - \hat{\mathbf{s}}\ell') + \Delta\mu(\mathbf{r} - \hat{\mathbf{s}}\ell')] \right] - \exp \left[- \int_0^{\ell_0} d\ell' \mu_0(\mathbf{r} - \hat{\mathbf{s}}\ell') \right] \right\}, \quad (16.39)$$

where $\mu_0(\mathbf{r})$ is the total attenuation coefficient of the object in the absence of the lesion.

A useful alternative way to write (16.39) is

$$s_{\mathbf{m}} = C \int_P d^2r \int_{2\pi} d\Omega d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) \times \left\{ \exp \left[- \int_0^{\ell_0} d\ell'' \Delta\mu(\mathbf{r} - \hat{\mathbf{s}}\ell'') \right] - 1 \right\} \exp \left[- \int_0^{\ell_0} d\ell' \mu_0(\mathbf{r} - \hat{\mathbf{s}}\ell') \right]. \quad (16.40)$$

The factor in large curly brackets can be interpreted as $t_{les} - 1$, where t_{les} is the relative transmission of the lesion (possibly greater than one if the lesion exhibits reduced attenuation compared to the background object). The signal is thus a line-integral projection image of $t_{les} - 1$ modulated by the projection of the background object and blurred by the finite focal spot and detector response function. The modulation is similar to what we saw in (16.15) when we divided the object into slabs and considered the effect of all other slabs on the slab of interest. Here the slab of interest is defined by the lesion, and there is no requirement that the slab be physically thin.

If the lesion has sufficiently low contrast that $\int_0^{\ell_0} d\ell'' \mu_0(\mathbf{r} - \hat{\mathbf{s}}\ell'') \ll 1$ for all \mathbf{r} and $\hat{\mathbf{s}}$, then we can expand the first exponential in (16.40) and write

$$s_{\mathbf{m}} \approx -C \int_P d^2r \int_{2\pi} d\Omega d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) \left[\int_0^{\ell_0} d\ell'' \Delta\mu(\mathbf{r} - \hat{\mathbf{s}}\ell'') \right] \times \exp \left[- \int_0^{\ell_0} d\ell' \mu_0(\mathbf{r} - \hat{\mathbf{s}}\ell') \right]. \quad (16.41)$$

With this approximation, the signal is linear in the attenuation coefficient of the lesion rather than its transmission minus one.

SKE/BKE detectability for detectors with uncorrelated noise Consider a detector in which the gain process entails a negligible blur and in which reabsorption of Compton and K x rays can be neglected. Then the first three covariance terms in (16.34) are diagonal matrices, the fourth is neglected and the fifth is absent for a BKE task. The noise sources we retain in this model are all well described as Gaussian. Electronic noise is certainly Gaussian, as discussed in Chap. 12, and the terms associated with the x-ray flux are Gaussian if the number of absorbed x-ray photons per detector element is larger than 10 or so. The term associated with object variability can be decidedly non-Gaussian (see Sec. 8.4), but we are not considering that term here, and we are also neglecting signal variability. Thus an overall Gaussian noise model is accurate, and the Hotelling SNR is the relevant figure of merit.

We know from Sec. 13.2.12 how to compute the Hotelling SNR for an SKE/BKE task with signal-independent noise, and we have argued above that the noise is independent of the signal if the latter results from a small change in the x-ray attenuation coefficient of the object. We know also from (13.123) that the Hotelling SNR is particularly simple if we can choose a data representation, called the Karhunen-Loève or KL domain, where the data covariance matrix is diagonal. The KL domain is the original data domain (the detector pixel domain) under the present assumptions, and we have at once from (13.134) that²

$$\text{SNR}^2 = \sum_{\mathbf{m}=1}^M \frac{s_{\mathbf{m}}^2}{\text{Var}(g_{\mathbf{m}})}. \quad (16.42)$$

The only remaining problem is to compute $\text{Var}(g_{\mathbf{m}})$. We know from (16.27) that, for the present noise model,

$$\text{Var}(g_{\mathbf{m}}) = \sigma_{\mathbf{m}}^2 + \Gamma_{\mathbf{m}}^2 \int_{\mathbf{m}} d^2r [\mathcal{H}_1 \mathbf{b}_{ss}](\mathbf{r}) + \Gamma_{\mathbf{m}}^2 \int_{\mathbf{m}} d^2r \int_{\mathbf{m}} d^2r' [\mathcal{H}_2 \mathbf{b}_{ss}](\mathbf{r}, \mathbf{r}'). \quad (16.43)$$

To evaluate this expression, we need to know the quantities $p_d(\mathbf{r}, \mathbf{R}_n)$ and $\text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{r}_n | \mathbf{R}_n)$ that appear in the definitions of \mathcal{H}_1 and \mathcal{H}_2 . If there is no blur in the gain process, then $\text{pr}_{\Delta\mathbf{r}}(\mathbf{r} - \mathbf{r}_n | \mathbf{R}_n)$ is the 2D delta function $\delta(\mathbf{r} - \mathbf{r}_n)$, and

$$p_d(\mathbf{r}, \mathbf{R}_n) = E\{k_n | \mathbf{R}_n\} \delta(\mathbf{r} - \mathbf{r}_n), \quad (16.44)$$

where k_n is the number of secondaries produced in the n^{th} x-ray interaction. With a little algebra, we then find

$$\text{Var}(g_{\mathbf{m}}) = \sigma_{\mathbf{m}}^2 + \Gamma_{\mathbf{m}}^2 \int_{\mathbf{m}} d^2r_n \int_0^{L_z} dz_n \int_0^{\infty} d\mathcal{E} b_{ss}(\mathbf{r}_n, z_n, \mathcal{E}_n) E\{k_n^2 | \mathbf{R}_n\}, \quad (16.45)$$

where L_z is the thickness of the detector.

If the gain process were noise-free, then $E\{k_n^2\}$ would be the constant \bar{k}_n^2 , independent of \mathbf{R}_n , and we could remove it from the integral. The product $\Gamma_{\mathbf{m}}^2 \bar{k}_n^2$ is then the square of the overall gain, including (for scintillation detectors) the production of optical photons, the photodiode and any electronic gain. Therefore, in

²The summation convention used here is the one introduced in Sec. 7.1.2: letting \mathbf{m} go from 1 to M means letting each component of the vector run over this range, so (16.42) applies to an $M \times M$ detector array, with M^2 total elements.

this unrealistic case, (16.45) just says that the variance of g_m is the mean number of absorbed x-ray photons times the gain squared, plus the variance of the electronic noise.

With realistic models for the amplification noise, even without blur, the variance of g_m is increased by the random variation of the number of secondaries with depth of interaction and deposited energy. We encountered this situation in Sec. 11.4.1 where we initially discussed random amplification in single-element detectors, and it should be no surprise that the same mathematics recurs here since an array without blur or correlation is just a collection of independent single-element detectors. From (11.183) we know that the variance of the number of secondaries is the mean number of primary x-ray absorptions times the second moment of the gain distribution, and (16.45) generalizes that statement to include random depth of interaction and energy per event. Moreover, if we factor out \bar{k}_n^2 , we can rewrite (16.45) as

$$\text{Var}(g_{\mathbf{m}}) = \sigma_{\mathbf{m}}^2 + \Gamma_{\mathbf{m}}^2 \bar{k}_n^2 \int_{\mathbf{m}} d^2 r_n \int_0^{L_z} dz_n \int_0^{\infty} d\mathcal{E} b_{ss}(\mathbf{r}_n, z_n, \mathcal{E}_n) \left[\frac{\text{E}\{k_n^2 | \mathbf{R}_n\}}{\bar{k}_n^2} \right], \quad (16.46)$$

and the factor in square brackets can be interpreted as the reciprocal of a Swank factor, as introduced in Sec. 11.4.1.

To summarize, the Hotelling SNR for this case is

$$\text{SNR}^2 = \sum_{\mathbf{m}=1}^M \frac{s_{\mathbf{m}}^2}{\sigma_{\mathbf{m}}^2 + \Gamma_{\mathbf{m}}^2 \int_{\mathbf{m}} d^2 r_n \int_0^{L_z} dz_n \int_0^{\infty} d\mathcal{E} b_{ss}(\mathbf{r}_n, z_n, \mathcal{E}_n) \text{E}\{k_n^2 | \mathbf{R}_n\}}. \quad (16.47)$$

For sufficiently small x-ray fluences, $\sigma_{\mathbf{m}}^2$ will be larger than the second term in the denominator, and the detectability will be determined solely by the signal strength and the electronic noise. A similar limit can occur if the gain factor $\Gamma_{\mathbf{m}} \bar{k}_n$ gets small, as it might, for example, in an optically coupled detector with large demagnification. For sufficiently large fluences, on the other hand, the SNR becomes independent of the gain factor $\Gamma_{\mathbf{m}} \bar{k}_n$ since $s_{\mathbf{m}}$ is also linear in this factor.

The dependence of the SNR on the background object is contained in the spatio-spectral fluence $b_{ss}(\mathbf{r}_n, z_n, \mathcal{E}_n)$. The gross effect is that thicker objects absorb more x rays and reduce the value of both $s_{\mathbf{m}}^2$ and the second term in the variance. Since $s_{\mathbf{m}}^2$ is quadratic in b_{ss} , the net effect is the expected one: thicker objects lead to fewer detected x rays and a smaller SNR for the same signal. In addition, thicker objects usually produce more scatter, increasing that component of $b_{ss}(\mathbf{r}_n, z_n, \mathcal{E}_n)$ and reducing the SNR further.

Effect of correlations on SKE/BKE tasks When we consider nondiagonal covariance matrices, we can no longer simply write down the Hotelling SNR. Instead we must somehow compute or estimate $\mathbf{s}^t \mathbf{K}^{-1} \mathbf{s}$. Direct inversion loses its appeal when one contemplates the size of \mathbf{K} in digital radiography; for a $1,000 \times 1,000$ detector, \mathbf{K} is $1,000,000 \times 1,000,000$! Therefore we must look for methods that bring in prior information and thereby reduce the computational burden; several ways of doing so were developed in Sec. 14.3.2. As we saw there, useful prior information can include signal location (in an SKE problem), smoothness and symmetry of the Hotelling template, and knowledge of the structure of the covariance matrix.

For SKE/BKE problems in digital radiology, one key piece of prior information is that the noise correlations have short range. Since the background is being treated as nonrandom for now, we are considering the first four terms in the overall covariance (16.34). We argued in Sec. 16.1.5 that these covariance components are likely to be nearly diagonal (at least with the multi-index convention), and we should take advantage of that fact.

Two methods from Sec. 14.3.2 that are particularly useful for a nearly diagonal covariance matrix are iterative estimation of the Hotelling template and Neumann-series expansion for the SNR. Estimation of the template by, say, the Landweber algorithm works for any covariance matrix, but it is much more efficient for nearly diagonal ones since a large fraction of the elements are zero.

The Neumann series makes use of the decomposition of the covariance \mathbf{K} into a diagonal part \mathbf{D} plus a matrix \mathbf{A} with only off-diagonal terms. Conditions for convergence of the series are discussed in Sec. 14.3.2. If the series converges, we know from (14.43) that

$$\text{SNR}^2 = \mathbf{s}^t \mathbf{K}^{-1} \mathbf{s} = \mathbf{s}^t \mathbf{D}^{-1} \mathbf{s} - \mathbf{s}^t \mathbf{D}^{-1} \mathbf{A} \mathbf{D}^{-1} \mathbf{s} + \mathbf{s}^t \mathbf{D}^{-1} \mathbf{A} \mathbf{D}^{-1} \mathbf{A} \mathbf{D}^{-1} \mathbf{s} + \dots \quad (16.48)$$

The first term in this expansion, $\mathbf{s}^t \mathbf{D}^{-1} \mathbf{s}$, is what we would get if there were no off-diagonal terms, and the remaining terms are the corrections arising from correlations induced by the detector. If these correlations are sufficiently weak, we may be able to truncate the series after a few terms.

If we keep only the first two terms in this expansion, we can see that the effect of the off-diagonal terms is to reduce the SNR; the expression $\mathbf{s}^t \mathbf{D}^{-1} \mathbf{A} \mathbf{D}^{-1} \mathbf{s}$ is nonnegative and it appears with a negative sign in (16.48). In fact, this is a general result: for fixed signal \mathbf{s} and fixed diagonal part \mathbf{A} , addition of off-diagonal terms can only reduce the SNR. One should not conclude, however, that radiographic detectors should never have correlations. Using a thicker detector, for example, increases the correlations associated with $\mathbf{K}_g^{(gain)}$ and $\mathbf{K}_g^{(Kx)}$, but it also increases the mean number of detected photons; detecting more photons increases SNR, but increasing blur could reduce SNR. In short, changing detector characteristics can have complicated effects on the SNR, perhaps increasing it overall for some tasks and decreasing it for others (Pineda *et al.*, 2003).

Random signals and backgrounds To be more realistic, we need to move away from SKE/BKE tasks and consider random signals and backgrounds.

Random signals do not pose any special difficulties with the Hotelling observer. We know from Sec. 13.2.12 that we merely have to replace the known signal in an SKE task with the average signal. As we discussed in that section, this approach is likely to work well for variations in signal size or shape, but randomness in signal location can greatly degrade the performance of any linear discriminant.

Random backgrounds arising from spatial inhomogeneity in the object can be treated by methods developed in Sec. 14.3.2. When we add in the object-variability part of the covariance, we inevitably introduce longer-range correlations; meaningful radiographic objects are almost always correlated over distances of many detector pixels. Therefore we cannot assume that the overall covariance (or an estimate of it) is nearly diagonal. Of the methods developed in Sec. 14.3.2, the one that is most appealing in this case is iterative estimation of the Hotelling template. Use of the Woodbury matrix-inversion lemma as in (14.47) greatly reduces the size of

the matrices involved. Another viable option is to use Laguerre-Gauss or wavelet filters to reduce the dimensionality.

Source fluctuations One extreme case of random backgrounds with long-range correlations is when there are fluctuations in the strength of the x-ray source. In this case, the number of x-ray photons impinging on the detector is not Poisson, even for a nonrandom object, but the signals from all detector elements fluctuate together, and the range of the correlations is the whole width of the detector array. Mathematically, as we saw in Sec. 16.1.5 [*cf.* (16.24)], the effect of source fluctuations is to add a rank-one matrix to the covariance matrix associated with Poisson statistics.

We analyzed a similar problem in Sec. 13.2.12. For a spatially uniform background fluence of mean \bar{b} and variance σ_b^2 and an array of ideal photon counters, we found that the SKE discriminability for a difference signal $\Delta \mathbf{s}$ was given in (13.216) by

$$\text{SNR}^2 = \frac{\|\Delta \mathbf{s}\|^2}{\bar{b}} - \frac{[\Delta \mathbf{s}^t \mathbf{u}]^2}{\bar{b}^2 + M\bar{b}\sigma_b^2}, \quad (16.49)$$

where M is the total number of detector elements and \mathbf{u} is an $M \times 1$ vector with all elements equal to σ_b . Note that both $\Delta \mathbf{s}$ and \bar{b} are dimensionless numbers, representing detected photons per pixel; for this discussion we are neglecting the subtleties of real x-ray detectors and just considering the SNR as limited by Poisson noise and current fluctuations in the x-ray tube.

As a numerical example, suppose we have $\bar{b} \sim 10^4$ photons per pixel and $M \sim 10^6$ pixels in the array, and that the tube current fluctuates by 1% so that $\sigma_b \sim 100$. Then $M\bar{b}\sigma_b^2$ is 10^6 times larger than \bar{b}^2 . With any similar assumptions about the number of pixels and number of photons per pixel, we will always have $M\bar{b}\sigma_b^2 \gg \bar{b}^2$, and we can write

$$\text{SNR}^2 = \frac{\sum_{m=1}^M \Delta s_m^2}{\bar{b}} - \frac{1}{M\bar{b}} \left[\sum_{m=1}^M \Delta s_m \right]^2, \quad (16.50)$$

The first term in this expression is the detectability as limited only by photon-counting statistics, and the second term represents the reduction in detectability arising from source fluctuations. The key point is the factor of $1/M$; the ideal observer can look over the whole array and estimate the background on a particular x-ray exposure with high precision. For any practical number of elements in the array, the effect of source fluctuations is completely negligible for this task and observer.

Human observers, too, are quite insensitive to fluctuations in the source strength. We know from Sec. 14.2 that human observers are very insensitive to low spatial frequencies, and that is what we have in this problem since all elements in the array fluctuate together as the source strength varies. By contrast, the Poisson term corresponds to completely uncorrelated fluctuations in different detector elements, hence high spatial frequencies that do go through the human visual system.

Finally, we note that the second term in (16.50) is absent if $\sum \Delta s_m \equiv 0$. This condition holds for the Rayleigh discrimination task, to be discussed in Sec. 16.2.5 and illustrated in Fig. 16.15. In general, the Rayleigh task (or any task where the difference signal sums to zero) is a good way of assessing SKE detectability without having to worry about source fluctuations.

Why not Fourier? By far the most common way of attempting to estimate an SNR in digital radiography is to assume stationarity and then assume implicitly that the covariance matrix is diagonalized by a discrete Fourier transform. Both parts of this assumption are usually wrong: digital radiographs are not really stationary in any sense, and even if some degree of stationarity can be justified, the covariance may not be diagonalized by a DFT.

The first problem is that the Poisson noise is never stationary for interesting radiographic images. An interesting image, virtually by definition, is one where the x-ray fluence conveys interesting information and hence varies spatially. The x rays constitute a random point process, and the mean and autocovariance function of this process are functions of position on the detector. For a stationary random process, by contrast, the mean would have to be constant, and the autocovariance function could depend only on the relative location of the two points to which it refers, not the absolute position. Thus the very fact that we are imaging an actual object, as opposed to just a uniform x-ray beam, immediately invalidates stationarity, even if we regard that object as nonrandom. Moreover, the simple fact that radiographs have finite size also spoils strict stationarity; the autocovariance between two image points cannot be invariant when one or both of the points falls off the detector.

The stationarity assumption runs into several additional difficulties for digital radiography. The sampling of the x-ray beam by an array of detector elements converts the autocovariance function to a covariance matrix, and we need to assume that this matrix is stationary in some sense. One sense of stationarity in a discrete image is that the covariance matrix is *Toeplitz*, so that the covariance between the signals from two detector elements depends on their relative position in the array, not on absolute location. For an ideal detector that simply samples a continuous random process, the covariance matrix is Toeplitz if the random process is stationary, in the sense that the autocovariance function depends only on relative position. If we ignore the anatomical noise and consider only the Poisson noise of the x rays, then the covariance matrix is diagonal, and if we further assume that the x-ray fluence does not depend on position across the array, then the covariance matrix is a multiple of the unit matrix, hence Toeplitz.

As we know from the discussion above, digital x-ray detectors involve a gain mechanism where each x-ray photon is converted to many secondary optical photons or charge carriers, which are then detected. This gain process is random and hence a source of noise. Moreover, there is electronic noise in the amplifiers associated with each detector element, and additional noise arises from production and possible escape of Compton-scattered or K x rays. All of these effects must be stationary for the overall system to be stationary.

The Poisson and electronic contributions to the covariance are diagonal, so they are Toeplitz only if they are multiples of the unit matrix. That means that not only must the x-ray fluence be constant, but also the electronic noise variance must be the same in every element. The random gain mechanism and Compton and K x rays introduce short-range correlations between neighboring detector elements, and these effects must also be invariant to absolute location for stationarity to hold. Again, this can happen only if the x-ray fluence is spatially uniform, but it also requires that the detector itself be uniform from element to element, which real detectors never are.

Finally, the inevitable departures from stationarity in the anatomy induce a departure from Toeplitz character in the covariance term $\mathbf{K}_g^{(obj)}$. There is no reason

at all to regard anatomy as stationary in any global sense, though local stationarity may sometimes describe the local texture (see Sec. 8.4).

The Toeplitz assumption, questionable though it may be, is still not strong enough for Fourier methods to be useful. To diagonalize a matrix by a discrete Fourier transform (DFT), we must assume that it is *circulant*, not Toeplitz. For a circulant covariance matrix, two elements at opposite sides of the array have the same covariance as two adjacent elements in the center. This “digital wrap-around” has no physical basis, but it is what we must assume if we want to diagonalize the matrix with DFTs. Fourier aficionados skirt the Toeplitz-vs.-circulant issue by arguing that the correlations are short range, but this statement is not true for anatomical noise. Moreover, even if one considers only BKE problems without anatomical noise and does a simulation in which all of the other requisite assumptions are valid, substantial errors can still be made in the computation of SNR by approximating a Toeplitz matrix by a circulant one (Pineda *et al.*, 2003).

NEQ and DQE In spite of these difficulties, Fourier methods are firmly entrenched in the digital radiography community, and it is common, even mandatory in some circles, to express the performance of digital x-ray detectors in terms of a frequency-dependent NEQ (noise-equivalent quanta) or DQE (detective quantum efficiency). We defined DQE as a ratio of squared SNRs for single-element detectors in Sec. 12.1.1, and the concept was extended to continuous shift-invariant systems with stationary noise in Sec. 13.2.13. For such systems and SKE/BKE tasks, we found that the ideal-observer SNR is given approximately³ by [*cf.* (13.242)]

$$\text{SNR}_\lambda^2 = |H(0)|^2 \int_{-\infty}^{\infty} d^2\rho |\Delta F_{rel}(\boldsymbol{\rho})|^2 \text{NEQ}(\boldsymbol{\rho}), \quad (16.51)$$

where $H(0)$ is the system transfer function at zero spatial frequency, $\Delta F_{rel}(\boldsymbol{\rho})$ is the difference signal expressed as a fractional or relative change in the Fourier transform of the nonrandom object, and $\text{NEQ}(\boldsymbol{\rho})$ is defined in (13.243) as

$$\text{NEQ}(\boldsymbol{\rho}) = \frac{b_0^2 \text{MTF}^2(\boldsymbol{\rho})}{W_{\mathbf{g}}(\boldsymbol{\rho})} = \frac{b_0^2 \text{MTF}^2(\boldsymbol{\rho})}{b_0 + W_{exc}(\boldsymbol{\rho})}. \quad (16.52)$$

Here, $W_{\mathbf{g}}(\boldsymbol{\rho})$ is the noise power spectrum (NPS) of the data (treated as a stationary random process), b_0 is the Poisson contribution to this power spectrum from a nonrandom photon stream, and $W_{exc}(\boldsymbol{\rho})$ is the excess noise arising from amplification processes or electronics, but again treated as stationary random processes. The frequency-dependent DQE is just $\text{NEQ}(\boldsymbol{\rho})$ normalized by the photon fluence [*cf.* (13.244)]:

$$\text{DQE}(\boldsymbol{\rho}) = \frac{\text{NEQ}(\boldsymbol{\rho})}{b_0} = \left[\frac{b_0}{b_0 + W_{exc}(\boldsymbol{\rho})} \right] \text{MTF}^2(\boldsymbol{\rho}). \quad (16.53)$$

One challenge in applying the NEQ and DQE concepts to digital radiography—or any other digital imaging system—is knowing how to interpret the NPS

³As discussed in Sec. 13.2.12, the expression in (16.49) is the correct SNR for the log-likelihood ratio if the noise is Gaussian, but it is approximately correct if the noise is Poisson and the fluence is large and/or the signal is weak. It is the correct expression for the Hotelling observer whenever the task is SKE/BKE, the system is CC and shift-invariant, and the noise is stationary, without regard to whether the noise is exactly or approximately Gaussian.

when the data are discrete. It is always tacitly assumed that Fourier transforms are to be replaced with discrete Fourier transforms and hence the integral in (16.51) is replaced by a sum. Most methods then simulate or measure x-ray images of a uniform object, perform the DFT and interpret the variance of the DFT values as an NPS.

This interpretation is analogous to the situation with Fourier *transforms* (not DFTs) of continuous random processes; we know from Sec. 8.2.7 that Fourier transformation is also Karhunen-Loève transformation for stationary random processes, and we saw in (8.181) that

$$\langle F(\boldsymbol{\rho}) F^*(\boldsymbol{\rho}') \rangle = S(\boldsymbol{\rho}) \delta(\boldsymbol{\rho} - \boldsymbol{\rho}'), \quad (16.54)$$

where $S(\boldsymbol{\rho})$ is the NPS of a random process $f(\mathbf{r})$, whose Fourier transform is $F(\boldsymbol{\rho})$. Practitioners of digital DQE analysis implicitly *assume* that DFTs are Karhunen-Loève transformations for discrete images, and they *define* a discrete NPS as

$$\langle F_{\mathbf{n}} F_{\mathbf{n}}^* \rangle \equiv S_{\mathbf{n}}, \quad (16.55)$$

where $F_{\mathbf{n}}$ is the DFT value associated with the discrete spatial frequency $\boldsymbol{\rho}_{\mathbf{n}}$.

A complete analogy with the continuous result in (16.54) would require, in addition to (16.55), that

$$\langle F_{\mathbf{n}} F_{\mathbf{n}'}^* \rangle \equiv S_{\mathbf{n}} \delta_{\mathbf{nn}'}, \quad (16.56)$$

but this additional requirement is seldom checked. A simple example will reveal why. Suppose that we have an x-ray detector array with electronic and Poisson noise but no other noise sources. We know from (16.35) and (16.36) that the covariance matrix in this case is

$$[\mathbf{K}_{\mathbf{g}}]_{\mathbf{mm}'} = \sigma_{\mathbf{m}}^2 \delta_{\mathbf{mm}'} + \Gamma_{\mathbf{m}} \bar{g}_{\mathbf{m}} \delta_{\mathbf{mm}'}. \quad (16.57)$$

Thus the covariance matrix is diagonal without any need for Fourier or any other transformation, and the ideal-observer SNR for a SKE/BKE task can be written down immediately from (16.42). In fact, performing a DFT will serve only to *undiagonalize* the covariance unless $\sigma_{\mathbf{m}}^2$, $\Gamma_{\mathbf{m}}$ and $\bar{g}_{\mathbf{m}}$ are all independent of the pixel index \mathbf{m} , in which case the covariance matrix is a multiple of the unit matrix, so the DFT and all other unitary transforms are simply irrelevant. It is a useful exercise to compute the exact Hotelling SNR for this problem and to compare it to some version of SNR based on (16.56). As a side benefit, this computation will demonstrate why it is *not* useful to normalize the gain variations.

Other difficulties with the Fourier methods have already been mentioned and need not be reiterated, but we can take a broader look. The basic assumption underlying *all* uses of Fourier transformations for computing detection-based SNRs is that the same transform diagonalizes both the deterministic imaging operator and the noise covariance matrix. Since the imaging operator is fundamentally a CD mapping and the image is fundamentally a discrete array of finite extent, no single transform can perform both functions.

Some recommendations regarding Fourier analysis One can, of course, regard digital NPS, NEQ or DQE as empirical characterizations of digital x-ray detectors, much the same as quantum efficiency, uniformity, pixel size or even cost. These are things we want to know before buying a detector, and they should be reported

in a standardized way for ease of comparison. To the extent that detective quantum efficiency is to be associated with detection tasks, however, some additional considerations arise. We offer the following recommendations:

- Check the off-diagonal elements. If measured or simulated images are available, one can estimate the covariances of the DFT components as well as the variances. A full row of the DFT covariance matrix can be computed for no more effort than computing the diagonal elements, the so-called digital NPS.
- Determine whether the off-diagonal elements are significant for detection tasks. For some methods of doing this, see Pineda *et al.* (2003) and Gallas *et al.* 2003.
- Check other measures of stationarity. Stationarity requires that the mean image, the noise variance and the pixel-to-pixel covariances should all be independent of the absolute position in the array. These items can be studied empirically.
- Check boundary effects. Since the distinction between Toeplitz and circulant matrices disappears as the array size goes to infinity, it is advisable to treat array size as an experimental variable. It is difficult to make the array larger, but straightforward to mask the array and use fewer pixels.
- If only local stationarity applies, use local Fourier methods. As we have noted in Chaps. 13 and 14, the stochastic Wigner distribution describes the frequency content of the noise as a function of location and can be related to variations of SKE-detection SNRs with position.
- Check the result against other methods for computing SNR. In Chap. 14 we surveyed methods for computing SNRs for ideal, Hotelling and channelized Hotelling observers. The researcher who doubts the validity of Fourier-based methods can check it against one of these methods.
- Consider the use of more realistic tasks. At best, Fourier methods apply only to SKE/BKE tasks in noise that is stationary in some sense. There are numerous examples in the literature where such idealized tasks can give misleading conclusions, even when the figure of merit is computed correctly. As facility is gained with other methods, the researcher will be able to explore the limits of this task choice.

Detectability by a human observer Methods for measuring and predicting lesion detectability by a human observer were discussed extensively in Chap. 14, and there is relatively little to add that is specific to digital radiography. Human detection performance can be assessed by psychophysical methods and analyzed in terms of ROC curves, even for complex random signals and background, so long as the task is posed as a binary decision. For simple signals and backgrounds, at least,

the outcome of these psychophysical experiments can be predicted with observer models such as the channelized Hotelling observer.

One factor that is prevalent in radiographic images, and that can degrade the performance of a human observer, is the low contrast of the lesion images. The Hotelling and channelized Hotelling observers are sensitive to this contrast since low contrast means low SNR, but it would make no difference to them if the signal and noise were both reduced by the same factor. For the human, on the other hand, there is an additional randomness, which we described in Sec. 14.2.1 as internal noise. If the signal and the noise in the image are reduced in the same proportion, the internal noise becomes more significant and human performance degrades relative to that of models without internal noise. To make the models predict this behavior, we must include internal noise in them as discussed in Sec. 14.2.2.

To minimize the degradation of human performance, we must take care to display the images at adequate contrast. Interactive contrast manipulations and automatic ones such as histogram equalization can be very useful in this regard. The qualitative guidelines given in Sec. 14.2.3 for the conduct of psychophysical studies are equally applicable to the display of real images in real clinical settings: the dominant image noise, whether it be the anatomical background or the measurement noise, should be readily apparent to the observer, and the lesion should be readily detectable if it were displayed without image noise.

Another aspect of the human observer that is not accounted for in our models, yet which is important in making real radiological diagnoses, is the human search strategy. If the lesion is randomly located within the image field, a physician will have some prior knowledge on anatomical and physiological grounds of where to look for it and will search this field in a way that attempts to optimize detection performance for a limited total viewing time. Radiologists differ greatly in their ability to carry out this optimization, and the relation of their performance to our objective measures of image quality has not been elucidated at this writing.

16.1.7 Image quality: Estimation tasks

Though the task in radiology is usually detection or classification, there are some circumstances where the task is estimation. For example, a radiographic contrast agent might be injected into the left ventricle of the heart with the goal of estimating the volume of the chamber or the volume of blood expelled on each beat. The interest might also be in whether the diameter of a tumor is decreasing in response to therapy, or in the degree of stenosis (narrowing) of a blood vessel.

Performance on an estimation task is specified in terms of the bias and variance of the estimator, but we have stressed in Chaps. 13 and 15 that bias is not well defined if the parameter is not estimable (see Secs. 13.3.1 and 15.1.3). The linear tests of estimability stated in Sec. 15.1.3 are not applicable here since the data are not linearly related to the object distribution, and in many cases the parameter of interest is not linearly related to the object either. We shall therefore consider various situations where estimability holds, at least approximately, in spite of the nonlinearity.

Estimability in the absence of blur If there were no blur from the detector or the focal spot, then certain line integrals of the object attenuation coefficient would be

estimable. Suppose

$$d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0) \propto \delta(\mathbf{r} - \mathbf{r}_{\mathbf{m}}) \delta(\hat{\mathbf{s}} - \hat{\mathbf{s}}_{\mathbf{m}}). \quad (16.58)$$

Then (16.10) would become

$$\bar{g}_{\mathbf{m}} \propto \exp \left[- \int_0^{\ell_0} d\ell' \mu_{tot}(\mathbf{r}_{\mathbf{m}} - \hat{\mathbf{s}}_{\mathbf{m}}\ell') \right], \quad (16.59)$$

and the simple operation of taking a logarithm would recover the line integral of μ_{tot} along a line determined by the positions of the detector and focal spot.

Thus, in the absence of blur, a parameter of the form

$$\Theta = \int_{\infty} d^3\mathbf{r} \mu_{tot}(\mathbf{r}) \chi(\mathbf{r}) \quad (16.60)$$

is estimable⁴ if $\chi(\mathbf{r})$ can be written as a linear superposition of line delta functions corresponding to the measured projections. If only a single image is taken from a single focal-spot location, then these line deltas form a cone, and $\chi(\mathbf{r})$ must be a weighted sum of the rays in this cone. In computed tomography, however, many different source locations are used, and a much wider variety of parameters is at least approximately estimable.

Subtraction imaging A common technique in digital radiography is *subtraction imaging* in which two images are recorded, one before and one after administration of a contrast agent that locally increases the x-ray attenuation coefficient. The most important applications of this method are to visualize blood vessels or the cardiac chambers.

To isolate the structure of interest, the logarithm of each image is computed pixel-by-pixel, and the second logarithmic image is subtracted from the first. When there is no blur, the difference of the logarithmic images is directly related to the change in line integrals of the attenuation coefficient. Denoting the elements of the first image by $g_{\mathbf{m}}$ and those of the second by $g'_{\mathbf{m}}$ and ignoring noise, we see from (16.59) that

$$\ln g'_{\mathbf{m}} - \ln g_{\mathbf{m}} = \int_0^{\ell_0} d\ell' \Delta\mu_{tot}(\mathbf{r}_{\mathbf{m}} - \hat{\mathbf{s}}_{\mathbf{m}}\ell'), \quad (16.61)$$

where $\Delta\mu_{tot}(\mathbf{r})$ is the change in attenuation coefficient between the two images. This difference image is thus a projection of the change in μ from the point source to the detector plane.

Often the parameter of interest in subtraction imaging is the total amount of contrast agent in a volume of interest, such as the left ventricle. If one assumes that the agent is mixed thoroughly with the blood, then the total amount of the agent is proportional to the blood volume. One way to attempt to estimate this parameter

⁴Note that the estimate is a nonlinear function of the data because of the logarithm. The statistics literature usually says that a parameter is estimable (identifiable) if there exists a linear unbiased estimator for all values of the parameter, but here we must consider nonlinear estimators and a more general definition of estimability.

is to sum both sides of (16.61) over \mathbf{m} . If we assume that the detector spacing is sufficiently small that we can replace the sum by an integral, we have

$$\sum_{\mathbf{m}} [\ln g'_{\mathbf{m}} - \ln g_{\mathbf{m}}] \approx \frac{1}{\epsilon^2} \int_P d^2 r_{\mathbf{m}} \int_0^{\ell_0} d\ell' \Delta\mu_{tot}(\mathbf{r}_{\mathbf{m}} - \hat{\mathbf{s}}_{\mathbf{m}} \ell'), \quad (16.62)$$

where ϵ^2 is the area of a detector element. We next make the change of variables $\mathbf{r}' = (\mathbf{r}_{\mathbf{m}} - \hat{\mathbf{s}}_{\mathbf{m}} \ell')$. The volume element is

$$d^3 \mathbf{r}' = \frac{|\mathbf{r}' - \mathbf{r}_a|^2}{z_a^2} \cos^3 \theta_{\mathbf{m}} d^2 r_{\mathbf{m}} d\ell'. \quad (16.63)$$

If we incorporate the factor $\cos^3 \theta_{\mathbf{m}}$ into the sum, (16.62) becomes

$$\sum_{\mathbf{m}} \cos^3 \theta_{\mathbf{m}} [\ln g'_{\mathbf{m}} - \ln g_{\mathbf{m}}] \approx \frac{z_a^2}{\epsilon^2} \int_V d^3 \mathbf{r}' \frac{1}{|\mathbf{r}' - \mathbf{r}_a|^2} \Delta\mu_{tot}(\mathbf{r}'), \quad (16.64)$$

where V is a conical volume defined by the detector elements chosen and the source location. Thus, even without noise, blur or finite detector sampling, the integrated change in μ is still not determined. All we can get is the weighted integral indicated in (16.64); no choice of weighting factors in the sum will remove the weighting in the integral since we cannot synthesize a constant from rays emanating from a single point. Even if we assume that $\Delta\mu$ is spatially compact, so that $|\mathbf{r}' - \mathbf{r}_a|^2$ is nearly constant over the volume of interest, we seldom know accurately how far this volume is from the detector, so we do not know $|\mathbf{r}' - \mathbf{r}_a|^2$ and hence cannot estimate the integral of $\Delta\mu$. The only recourse is to place the source at a large distance from the object and detector so that $|\mathbf{r}' - \mathbf{r}_a|^2 \approx \mathbf{r}_a^2$. Absent this approximation, even the simplest of parameters, an integral over the object, turns out not to be estimable from a single radiograph.

Effects of blur We now return to the more realistic situation where the image is blurred by the detector response and the focal spot, but we shall continue to ignore noise for a while longer. If we take a logarithm of (16.10) in an attempt to linearize, we obtain

$$\ln g_{\mathbf{m}} = \ln C + \ln \int_P d^2 r \int_{2\pi} d\Omega d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) = L_p(\mathbf{r} - \hat{\mathbf{s}} \ell_0, \hat{\mathbf{s}}) \exp \left[- \int_0^{\ell_0} d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}} \ell') \right]. \quad (16.65)$$

Since we cannot take the logarithm inside the integral, the second term on the right is not a linear transformation of the line integral of μ_{tot} , but a linear approximation might be valid. Two such approximations will now be described.

The exponential is a function of \mathbf{r} and $\hat{\mathbf{s}}$, which can be written as $\exp[f(\mathbf{r}, \hat{\mathbf{s}})]$. If this function varies sufficiently slowly compared to $d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}} \ell_0, \hat{\mathbf{s}})$, it can be replaced by the constant $\exp[f(\mathbf{r}_{\mathbf{m}}, \hat{\mathbf{s}}_{\mathbf{m}})]$ and pulled out of the integral, and application of the logarithm then yields a linear functional of μ_{tot} .

Instead of just replacing the exponential by a constant, a better approximation can be obtained by expanding it in a Taylor series and retaining the constant and linear terms. To simplify the notation temporarily, consider the expression

$$\ln[g_m] = \ln \int_{\infty} dx p_m(x) \exp[f(x)], \quad (16.66)$$

where $p_m(x)$ is peaked around $x = x_m$ and normalized such that $\int_{-\infty}^{\infty} dx p(x) = 1$. We can write the exponential as

$$\begin{aligned} \exp[f(x)] &= \exp[f(x_m) + f(x) - f(x_m)] = \exp[f(x_m)] \exp[f(x) - f(x_m)] \\ &= \exp[f(x_m)] \{1 + f(x) - f(x_m) + \dots\}. \end{aligned} \quad (16.67)$$

If $\exp[f(x)]$ varies slowly in the vicinity of x_m , we can drop the unstated terms, all of which are nonlinear in $f(x)$. Inserting the truncated version of (16.67) into (16.66), we find

$$\begin{aligned} \ln[g_m] &\approx \ln \left\{ \exp[f(x_m)] \int_{-\infty}^{\infty} dx p_m(x) [1 + f(x) - f(x_m)] \right\} \\ &= f(x_m) + \ln \left\{ 1 - f(x_m) + \int_{-\infty}^{\infty} dx p_m(x) f(x) \right\}, \end{aligned} \quad (16.68)$$

where we have used the normalization of $p(x)$. If we now use $\ln(1 + \epsilon) \approx \epsilon$, we see that

$$\ln[g_m] \approx \int_{-\infty}^{\infty} dx p_m(x) f(x). \quad (16.69)$$

Up through terms linear in $f(x)$, therefore, the logarithm commutes with blurring, and a linear functional results. Note that this kind of linearization is rather different from the ones we discussed in Sec. 16.1.4. We do not require here that $\exp[f(x)]$ be near one or have small total variation; it suffices if it varies slowly over the range of x where $p(x)$ is nonzero.

Applying a similar argument to (16.65), we see that

$$\ln g_{\mathbf{m}} \approx A_{\mathbf{m}} - \int_P d^2r \int_{2\pi} d\Omega d_{\mathbf{m}}(\mathbf{r}, \hat{\mathbf{s}}) L_p(\mathbf{r} - \hat{\mathbf{s}}\ell_0, \hat{\mathbf{s}}) \left[\int_0^{\ell_0} d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell') \right], \quad (16.70)$$

where $A_{\mathbf{m}}$ is a constant. We can define $y_{\mathbf{m}} \equiv A_{\mathbf{m}} - \ln g_{\mathbf{m}}$, and within the stated approximations $y_{\mathbf{m}}$ is a blurred version of the line integral of μ_{tot} .

To see the implications of this result for estimability, we apply a change of variables similar to the one that led to (16.63) and obtain

$$y_{\mathbf{m}} \approx \int_{-\infty}^{\infty} d^3\mathbf{r}' \chi_{\mathbf{m}}(\mathbf{r}') \mu_{tot}(\mathbf{r}'). \quad (16.71)$$

It will be left as an exercise to determine the mathematical form of $\chi_{\mathbf{m}}(\mathbf{r})$, but physically it describes a blurred ray extending from the focal spot to the \mathbf{m}^{th} detector. The line integral of μ_{tot} is not itself an estimable parameter, but the integral of μ_{tot} over this blurred ray is approximately estimable, and so is any linear parameter formed from a linear combination of the functions $\{\chi_{\mathbf{m}}(\mathbf{r})\}$. This observation is critical to the success of computed tomography, but it is seldom stated explicitly.

Effects of noise So far we have neglected noise in the discussion of estimation tasks, but we shall now remedy this defect. The actual measured data from the \mathbf{m}^{th} detector can be written, as usual, as

$$g_{\mathbf{m}} = \bar{g}_{\mathbf{m}} + n_{\mathbf{m}}. \quad (16.72)$$

If the noise level is low enough, $y_{\mathbf{m}}$ can be approximated as

$$y_{\mathbf{m}} \approx \int_{\infty} d^3\mathbf{r} \chi_{\mathbf{m}}(\mathbf{r}') \mu_{tot}(\mathbf{r}') + \frac{n_{\mathbf{m}}}{\bar{g}_{\mathbf{m}}}. \quad (16.73)$$

To the extent that the modeling error attributable to neglecting terms nonlinear in μ_{tot} is negligible, the mean of $n_{\mathbf{m}}$ is zero and $y_{\mathbf{m}}$ is an unbiased estimator of the indicated integral. The variance of this estimate is given by

$$\text{Var}\{y_{\mathbf{m}}\} = \frac{\text{Var}\{n_{\mathbf{m}}\}}{\bar{g}_{\mathbf{m}}^2}. \quad (16.74)$$

If the only noise in the data were the Poisson noise of the x rays, then we would have $\text{Var}\{n_{\mathbf{m}}\} = \bar{g}_{\mathbf{m}}$ and $\text{Var}\{y_{\mathbf{m}}\} = 1/\bar{g}_{\mathbf{m}}$. If the dominant noise is independent of the x-ray flux, as it would be for dark current or electronic noise, then $\text{Var}\{y_{\mathbf{m}}\} \propto 1/\bar{g}_{\mathbf{m}}^2$. In both cases, increasing the mean number of detected photons decreases the variance in the estimate of the integral.

Effect of source fluctuations In Sec. 16.1.5 we pointed out that fluctuations in the current in an x-ray tube can lead to an additional term in the data covariance matrix [see (16.24)]. The elements in this extra part of the covariance might be comparable to or even larger than those that we have been discussing, but the matrix has rank one, and we showed in Sec. 16.1.6 that its contribution to SKE detectability was negligible [see (16.50)]. Now we need to see what effect it has on estimation tasks.

Suppose the goal is to estimate the average x-ray transmittance of an object over some large area, so that issues of estimability do not arise. If the area covers many pixels, a reasonable estimator is just the sum of the pixel values over the region of interest. Consider the limit of large x-ray flux so that the only limitation is variations in source strength. Since all pixels fluctuate together as the source strength varies, a change of $x\%$ in current through the x-ray tube leads to an $x\%$ change in the estimated transmittance.

If this number is too large, we need to take some auxiliary measurement in order to normalize for the source strength. A separate detector in the x-ray beam can be used, or the imaging detector can be used by looking at x rays that miss the object. Since the auxiliary detector can have large area, Poisson noise in the estimate of source strength should be small. The situation is analogous to the SKE detection problem discussed in 16.1.6 where the ideal observer could average over the entire array and estimate and correct for the source fluctuations.

Similar considerations will apply to other detection or estimation problems. In short, even though fluctuations in tube current lead to large variance and distinctly non-Poisson statistics, they can almost always be overcome by making good use of the measured data or by acquiring auxiliary data for normalization. In terms of task performance, we can almost always assume that the x-ray tube is a Poisson source.

16.2 PLANAR IMAGING IN NUCLEAR MEDICINE

The second direct-imaging method we discuss in this chapter is gamma-ray imaging of radioactive sources, especially for diagnosis in clinical nuclear medicine. We begin in Sec. 16.2.1 with a qualitative overview of the modality and the basic issues

affecting image quality. In Secs. 16.2.2 and 16.2.3 we analyze the image-formation and detection processes deterministically. Stochastic considerations are added in Sec. 16.2.4, and objective measures of image quality are developed in Secs. 16.2.5 and 16.2.6.

For an excellent, succinct introduction to clinical aspects of diagnostic nuclear medicine, see Alazraki (1988), and for a not-so-succinct survey of instrumentation issues, see Barrett and Swindell (1981, 1996).

16.2.1 Basic issues

The tracer principle In biology and medicine, a *tracer* is a fluorescent or radioactive marker that can be attached to a biologically important molecule without altering its biological properties. When the tracer is subsequently detected, its location and strength convey information about the function of the tagged molecule.

The advantage of radioactive tracers over fluorescent ones is that gamma rays are more penetrating than optical photons. Therefore gamma-ray imaging can be used to study physiological function deep within a patient's body. For this reason, nuclear medicine is often called *functional imaging*; it gives information about the function of the body as opposed to the anatomical or morphological information provided by transmission radiography or ultrasound. In addition, since the tracer acts at a molecular level, nuclear medicine is a form of *molecular medicine*.

The earliest use of radioactive tracers in biomedical research was by the Hungarian chemist George Charles de Hevesy. Working with Ernest Rutherford in 1911, de Hevesy was staying at a boarding house in Manchester. The guests strongly suspected that the landlady was serving them leftovers, but she insisted she was not. One night, de Hevesy surreptitiously sprinkled an "isotopic indicator," as he called it, into some leftover beef pie, and several days later he was able to detect the tracer in a soufflé (de Hevesy, 1962; Patton, 2000). In 1943, de Hevesy received the Nobel Prize in Chemistry, but this initial experiment was not cited.

Radioisotopes The radioisotopes used in nuclear medicine can emit gamma rays, beta particles (electrons) or positrons (anti-electrons). Beta particles have very short range in tissue, a few millimeters. They have found some use for imaging superficial structures or during surgery where a detector can be placed in the body, but they are not useful for imaging deeper structures with detectors outside the body. Positrons also have short range, but they can annihilate by interacting with electrons, producing high-energy gamma rays that can be detected outside the body in a technique called positron emission tomography or PET. In this chapter we consider only isotopes that emit low-energy gamma rays, typically in the range 100–400 keV.

Most tracers used in nuclear medicine are labelled with an isotope of technetium, ^{99m}Tc (where m stands for *metastable*). This isotope has a half-life of 6 hours and emits a single gamma ray of energy 140 keV. We shall use this energy when we give numerical examples in this section.

Technetium, especially in the form of the pertechnetate ion TcO_4^- , can be used to label a wide variety of pharmaceuticals, some with exquisite biological specificity. As an example, a tracer called sestamibi has an affinity to mitochondria in cells. Since the mitochondria are the cell's power plants, they are found in abundance in hard-working cells as in the heart muscle (myocardium) or in rapidly dividing cells

as in tumors. Thus sestamibi has found use in studying myocardial perfusion and in detecting breast cancer.

Attenuation and scatter Photons of energy 140 keV have an attenuation coefficient of about 0.14 cm^{-1} in soft tissue, so they travel about 7 cm on average before interacting with the tissue. The predominant interaction is Compton scattering, in which the photon changes its direction by scattering from a free electron, transferring some of its energy to the electron in the process. See Secs. 10.3.7 and 12.3.1 for more discussion of the physics of Compton scattering.

At 140 keV, about 1% of the interactions in soft tissue are photoelectric absorption rather than Compton scattering. In photoelectric absorption, as discussed in Sec. 12.3.1, the gamma-ray photon disappears, transferring all of its energy to a photoelectron.⁵ The relative probability of photoelectric absorption increases rapidly as the photon energy decreases, so after multiple Compton scatters, the photon is likely to be absorbed if it has not escaped the body. The primary mathematical tools for accounting for all of these possible events are Monte Carlo simulation and the Boltzmann transport equation (Sec. 10.3).

Radiation dose to the patient Both Compton scattering and photoelectric absorption result in a high-energy electron in the patient's body. This electron is absorbed in the body very near the interaction point, possibly causing local biological damage.

Though the basic interaction mechanisms are the same for x rays and gamma rays, there is an important difference between transmission radiography and emission imaging in terms of radiation dose. In transmission imaging, dose is delivered to the patient while the x-ray source is turned on, but dose delivery ceases instantaneously when the source is turned off. In emission imaging, the source cannot be turned off; it is injected into the body and delivers dose continuously until it decays or is biologically excreted. In transmission imaging, therefore, an increased exposure time or a stronger source will give more dose to the patient, but it will also result in more collected photons and hence better image quality. In emission imaging, on the other hand, the dose to the patient depends on the quantity of radiotracer used, but it has nothing to do with exposure time.

Usually the allowed exposure time in nuclear medicine is limited to a few minutes by patient motion or economic considerations, and relatively few gamma-ray photons can be collected in this time with allowable radiation dose. Typical planar nuclear medicine images consist of only 100,000 to 1,000,000 detected photons; the resulting Poisson noise is the main limitation to image quality, as we shall see in more detail in Secs. 16.2.5 and 16.2.6.

Collimators For all practical purposes, gamma rays are not reflected or refracted by matter, so all image-forming apertures in nuclear medicine must work by selective absorption of the photons. The two major alternatives are pinhole apertures and

⁵As discussed in Sec. 12.3.1, the energy imparted to the photoelectron is the gamma-ray energy minus the electron binding energy [see (12.160)], but in soft tissue this binding energy is less than 1 keV and can easily be neglected. For the same reason, we do not have to consider emission of K x rays in the body, though they are important in the detector material as we saw in Sec. 12.3.

multibore collimators. Pinholes were discussed in Sec. 10.4.2 as an illustration of the Boltzmann equation in imaging, and collimators will be analyzed below.

Collimators are basically just slabs of lead or other highly absorbing material with multiple bores through which gamma rays can pass. The bores may be parallel to one another, in which case we have a *parallel-hole collimator* (see Fig. 16.8), or they may be slanted in some manner.

Fig. 16.8 Illustration of a parallel-hole collimator.

For a parallel-hole collimator, key design parameters are the shape and size of each bore, the thickness of the septa between bores and the overall thickness or length of each bore. To a first approximation, only photons that pass down the bore without hitting any absorbing material can reach the detector. Making the bore size larger or the bore length smaller increases the number of photons that get through but reduces the spatial resolution, so these parameters provide a way of controlling the tradeoff between resolution and noise. The septal thickness and the collimator material are chosen to minimize penetration of gamma rays through nominally opaque portions of the collimator.

Typical bore diameters are 1–2 mm for 140 keV radiation, and typical bore lengths are 2–4 cm. With these numbers only about 10^{-4} of the emitted photons pass through the collimator.

Detectors Almost all commercial nuclear-medicine systems at this writing use an Anger scintillation camera as the detector. This detector is analyzed in Secs. 12.3.5 and 12.3.6, and the statistical properties of images obtained with it are discussed in Sec. 12.3.7.

There are several salient points to recall from Chap. 12 about the Anger camera. It counts individual gamma-ray photons and hence suffers from photon noise, but it has no other significant noise source. It provides continuous estimates of the 2D position and energy of each absorbed gamma-ray photon. Each photon is accepted into the final image based on its estimated energy, which is an indication of whether or not the photon has undergone a scattering event in the patient's body. This scatter-rejection technique is not perfect, however, and some scattered photons will contribute to the image.

Even with the position and energy estimation and rejection of some events, the continuous image can still be described as a sample function of a Poisson random process. If the continuous image is binned into a pixel array for storage, processing or display, the resulting discrete image is a Poisson random vector. It is only when the effects of object randomness are considered that the Poisson character is lost.

In spite of the widespread use of Anger cameras, there is considerable interest in discrete detector arrays such as semiconductor devices or scintillator-photodiode arrays, discussed in Secs. 12.3.3 and 12.3.4. Major advantages of discrete arrays are that the element size can be smaller than the spatial resolution of the Anger camera and (at least for the semiconductor devices) the energy resolution can be better, improving the ability to reject scattered radiation.

16.2.2 Image formation

The mathematical tools needed to analyze gamma-ray imaging systems were developed in Chap. 10. Since gamma rays have very short wavelength (less than 10^{-9} cm at 140 keV), they behave as particles, and their transport is well described by the Boltzmann equation as derived in Sec. 10.3.

Specifically, if we assume that scattered radiation is rejected by the detector and hence is effectively absorbed, the steady-state Boltzmann equation is given by (10.147) as

$$\hat{\mathbf{s}} \cdot \nabla w = \frac{1}{c} \Xi_{p,\mathcal{E}} - \mu_{tot} w, \quad (16.75)$$

where c is the speed of light, μ_{tot} is the total attenuation coefficient (arising mainly from Compton scattering), $w \equiv w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ is the distribution function and $\Xi_{p,\mathcal{E}} \equiv \Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ is the source distribution. For nuclear imaging with a monoenergetic radioisotope, the source has the form (10.253):

$$\Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = \frac{1}{4\pi} f(\mathbf{r}) \delta(\mathcal{E} - \mathcal{E}_0). \quad (16.76)$$

The function $f(\mathbf{r})$ describes the spatial distribution of the radiotracer and hence conveys the functional information that we want to extract. We can interpret $f(\mathbf{r})$ as the mean rate of photon emission per unit volume; *i.e.*, $f(\mathbf{r})d^3\mathbf{r}$ is the mean number of photons per second emitted in all directions from a volume element $d^3\mathbf{r}$ centered at point \mathbf{r} . This density is assumed to be independent of time over the exposure time for an image.

As in Sec. 10.4.2, we set up a reference plane P somewhere between the object and the detector. The photon distribution function on that plane is denoted $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$. Since we are assuming for now that scattered photons are rejected, all photons of interest have the original energy \mathcal{E}_0 , and we must have

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = w_0(\mathbf{r}, \hat{\mathbf{s}}) \delta(\mathcal{E} - \mathcal{E}_0). \quad (16.77)$$

The factor $w_0(\mathbf{r}, \hat{\mathbf{s}})$ is given from (16.76) and (10.151) as

$$w_0(\mathbf{r}, \hat{\mathbf{s}}) = \frac{1}{4\pi c} \int_0^\infty dl f(\mathbf{r} - \hat{\mathbf{s}}l) \exp \left[- \int_0^l dl' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}l', \mathcal{E}_0) \right], \quad (16.78)$$

where the 2D vector \mathbf{r} and the 3D vector \mathbf{r} denote the same point on plane P . The photon distribution at this point is thus given by a line integral of the source distribution weighted with an attenuation factor.

Mathematical description of the collimator Given an expression for the photon distribution on a plane P , the next step is to analyze the effect of the collimator. The first comprehensive analysis of properties of collimators was performed by Robert Beck (Beck, 1964a, 1964b, 1968a, 1968b). More recent treatments can be found in Barrett and Swindell (1981, 1996), Gunter (1996) and Tsui *et al.* (1996).

A convenient place to put plane P is *behind* the collimator, in which case $w_0(\mathbf{r}, \hat{\mathbf{s}})$ is the distribution in that plane when the collimator is not present. The actual distribution on P with the collimator in place has the form

$$w_c(\mathbf{r}, \hat{\mathbf{s}}) = w_0(\mathbf{r}, \hat{\mathbf{s}}) T(\mathbf{r}, \hat{\mathbf{s}}), \quad (16.79)$$

where $T(\mathbf{r}, \hat{\mathbf{s}})$ is the transmission of the collimator for photons travelling in direction $\hat{\mathbf{s}}$ and striking plane P at point \mathbf{r} .

To obtain an expression for $T(\mathbf{r}, \hat{\mathbf{s}})$, we need a geometrical model for the collimator. We consider a parallel-hole collimator with bores on a regular grid indexed by the 2D vector index \mathbf{n} , and we let $\mathbf{r}_\mathbf{n}$ denote the center of the \mathbf{n}^{th} bore. We define $\beta(\mathbf{r} - \mathbf{r}_\mathbf{n})$ as a function that is unity within the open area of that bore and zero otherwise.

If we neglect penetration through the septa, $T(\mathbf{r}, \hat{\mathbf{s}})$ is unity only if the point where the photon exits the collimator and the point where it enters both lie within the same bore. The exit point is just \mathbf{r} since the reference plane is the exit plane, but the entrance point is found by tracing backward from the exit point along direction $-\hat{\mathbf{s}}$. The 2D vector specifying this point is $\mathbf{r} - \mathbf{s}_\perp \frac{L_b}{s_z}$, where $\mathbf{s}_\perp = (s_x, s_y)$ if $\hat{\mathbf{s}} = (s_x, s_y, s_z)$ and plane P is $z = 0$. Thus we have

$$T(\mathbf{r}, \hat{\mathbf{s}}) = \sum_{\mathbf{n}} \beta(\mathbf{r} - \mathbf{r}_\mathbf{n}) \beta\left(\mathbf{r} - \mathbf{s}_\perp \frac{L_b}{s_z} - \mathbf{r}_\mathbf{n}\right), \quad (16.80)$$

where the sum is over all bores in the collimator.

Photon distribution on the collimator exit plane Combining (16.79) and (16.78), we arrive at the CC mapping from $f(\mathbf{r})$ to $w_c(\mathbf{r}, \hat{\mathbf{s}})$:

$$w_c(\mathbf{r}, \hat{\mathbf{s}}) = \frac{1}{4\pi c} T(\mathbf{r}, \hat{\mathbf{s}}) \int_0^\infty dl f(\mathbf{r} - \hat{\mathbf{s}}l) \exp\left[-\int_0^l dl' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}l', \mathcal{E}_0)\right]. \quad (16.81)$$

We can use this expression to compute the photon irradiance (mean number of photons per unit area) in plane P . In (10.140) we saw that the spectral photon irradiance $I_{p,\mathcal{E}}$ (photons per unit area per unit energy) is obtained from the spectral photon radiance $L_{p,\mathcal{E}}$ (photons per unit *projected* area per steradian per unit energy) by multiplying by a cosine factor (to convert projected area to true area) and then integrating over solid angle. We also know from (10.98) that $L_{p,\mathcal{E}}$ is c times the distribution function w_c . In the present problem the cosine factor is near unity, and the spectral dependence is simple because $L_{p,\mathcal{E}}(\mathbf{r}, \mathcal{E}) = L_p(\mathbf{r}) \delta(\mathcal{E} - \mathcal{E}_0)$, so we can also write $I_{p,\mathcal{E}}(\mathbf{r}, \mathcal{E}) = I_p(\mathbf{r}) \delta(\mathcal{E} - \mathcal{E}_0)$. Thus we have

$$\begin{aligned} & I_p(\mathbf{r}) \\ &= c \int_{2\pi} d\Omega w_c(\mathbf{r}, \hat{\mathbf{s}}) = \frac{1}{4\pi} \int_{2\pi} d\Omega T(\mathbf{r}, \hat{\mathbf{s}}) \int_0^\infty dl f(\mathbf{r} - \hat{\mathbf{s}}l) \exp\left[-\int_0^l dl' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}l', \mathcal{E}_0)\right]. \end{aligned} \quad (16.82)$$

To interpret this expression, we make a change of variables that proved useful several times in Chap. 10; we define $\mathbf{r}' = \mathbf{r} - \hat{\mathbf{s}}\ell$ and recognize that $\ell^2 d\ell d\Omega = d^3\mathbf{r}'$ and $\ell = |\mathbf{r} - \mathbf{r}'|$, yielding

$$I_p(\mathbf{r}) = \frac{1}{4\pi} \int_{\infty} \frac{d^3\mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^2} T\left(\mathbf{r}, \frac{\mathbf{r} - \mathbf{r}'}{z'}\right) f(\mathbf{r}') \exp\left[-\int_0^{|\mathbf{r}-\mathbf{r}'|} d\ell' \mu_{tot}\left(\mathbf{r} - \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \ell', \mathcal{E}_0\right)\right]. \quad (16.83)$$

Since we are concerned with the irradiance on the plane $z = 0$, the vectors $\mathbf{r} = (x, y, 0)$ and $\mathbf{r} = (x, y)$ specify the same point. The vector \mathbf{r}' is not confined to $z' = 0$, but we can write it as $\mathbf{r}' = (x', y', z') \equiv (\mathbf{r}', z')$; then, with (16.80) and a little algebra, we have

$$I_p(\mathbf{r}) = \frac{1}{4\pi} \sum_{\mathbf{n}} \beta(\mathbf{r} - \mathbf{r}_{\mathbf{n}}) \int_{L_b}^{\infty} \frac{dz'}{z'^2} \int_{\infty} d^2r' \beta\left[\left(1 - \frac{L_b}{z'}\right)\mathbf{r} + \frac{L_b}{z'}\mathbf{r}' - \mathbf{r}_{\mathbf{n}}\right] f(\mathbf{r}', z') \times \exp\left[-\int_0^{|\mathbf{r}-\mathbf{r}'|} d\ell' \mu_{tot}\left(\mathbf{r} - \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \ell', \mathcal{E}_0\right)\right], \quad (16.84)$$

where we have replaced $1/|\mathbf{r} - \mathbf{r}'|^2$ with $1/z'^2$ since the collimator accepts only photons that travel almost parallel to the z axis. In the z' integral, we have set the lower limit to L_b on the assumption that there is no radioactive material inside the collimator bores (though this condition presumes some minimal care in laboratory practice).

The transformation in (16.84) is a CC mapping from the 3D function $f(\mathbf{r}', z')$ to the 2D function $I_p(\mathbf{r})$; it has the general form

$$I_p(\mathbf{r}) = \int_{L_b}^{\infty} dz' \int_{\infty} d^2r' h(\mathbf{r}; \mathbf{r}', z') f(\mathbf{r}', z'), \quad (16.85)$$

where the kernel $h(\mathbf{r}; \mathbf{r}', z') f(\mathbf{r}', z')$ is the point response function (PRF) giving the response at point \mathbf{r} in the collimator exit plane to a point source at point (\mathbf{r}', z') in the 3D space. The remainder of this section is devoted to studying this PRF.

Point response function in air For a point source in air, where $\mu_{tot} \approx 0$, the PRF is given by

$$h(\mathbf{r}; \mathbf{r}', z') = \frac{1}{4\pi z'^2} \sum_{\mathbf{n}} \beta(\mathbf{r} - \mathbf{r}_{\mathbf{n}}) \beta\left[\left(1 - \frac{L_b}{z'}\right)\mathbf{r} + \frac{L_b}{z'}\mathbf{r}' - \mathbf{r}_{\mathbf{n}}\right]. \quad (16.86)$$

This PRF is highly shift-variant, depending in a complicated way on the lateral source coordinates \mathbf{r}' , the longitudinal position of the source z' , and the position on the collimator exit face \mathbf{r} . Some examples are shown in Fig. 16.9.

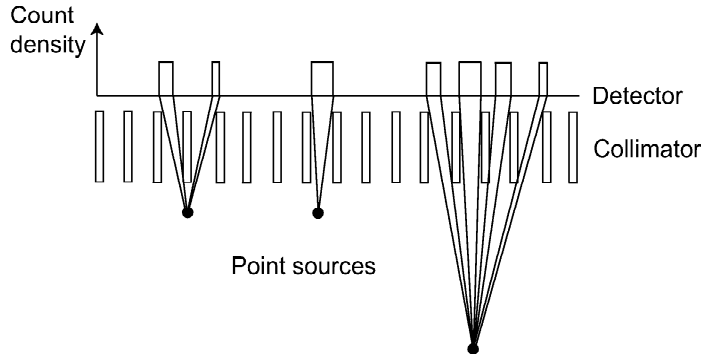

Fig. 16.9 Illustration of photon paths through the collimator for different source positions.

When the point source is on the collimator entrance face, we see graphically from Fig. 16.9 that the PRF as a function of \mathbf{r} is just the transmission function of a single bore, so long as the source point lies over a bore; the response is zero if the source is hidden behind a septum. We reach this same conclusion analytically by setting $z' = L_b$ in (16.86), so that the summand becomes $\beta(\mathbf{r} - \mathbf{r}_n)\beta(\mathbf{r}' - \mathbf{r}_n)$. The second factor is nonzero only when the source lies within bore \mathbf{n} , and the first factor requires that the output point \mathbf{r} lie within that same bore.

For z' substantially greater than L_b , however, photons can reach the exit plane through several different bores, as shown graphically in Fig. 16.9. To understand how this happens analytically, consider circular bores of diameter D_b , so that $\beta(\mathbf{r}) = \text{cyl}(\mathbf{r}/D_b)$. For simplicity, consider a point source centered laterally over the origin, so that $\mathbf{r}' = 0$ but $z' > L_b$. Then the summand of (16.86) can be rewritten as

$$\begin{aligned} & \beta(\mathbf{r} - \mathbf{r}_n) \beta \left[\left(1 - \frac{L_b}{z'}\right) \mathbf{r} + \frac{L_b}{z'} \mathbf{r}' - \mathbf{r}_n \right] \\ &= \text{cyl} \left[\frac{1}{D_b} (\mathbf{r} - \mathbf{r}_n) \right] \text{cyl} \left\{ \frac{1}{D_b} \left[\left(1 - \frac{L_b}{z'}\right) \mathbf{r} - \mathbf{r}_n \right] \right\}. \end{aligned} \quad (16.87)$$

The first factor is nonzero when \mathbf{r} lies within a circle of diameter D_b centered on \mathbf{r}_n . The second factor, however, is nonzero when \mathbf{r} lies in a circle of diameter $D_b z' / (z' - L_b)$ centered on $z' \mathbf{r}_n / (z' - L_b)$. The complicated PRF seen in Fig. 16.9 is the overlap of these two cylinder functions summed over bores.

Another way to think about $h(\mathbf{r}; \mathbf{r}', z')$ is that it is the kernel of the adjoint mapping (or backprojection) from the 2D collimator exit face to the 3D object volume. In that view, we pick an \mathbf{r} and study $h(\mathbf{r}; \mathbf{r}', z')$ as a function of \mathbf{r}' and z' . The first factor in (16.87) requires that only a single bore, or a single index \mathbf{n} , can contribute to $h(\mathbf{r}; \mathbf{r}', z')$. The second factor defines a cone in the 3D space centered on this bore, as shown in Fig. 16.10. On plane z' , this kernel is constant for points \mathbf{r}' within a circle of diameter $D_b z' / L_b$ centered on the origin.

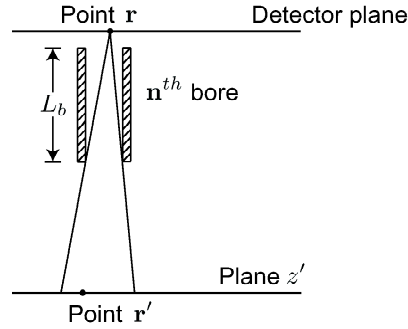

Fig. 16.10 Illustration of the kernel of the adjoint mapping from the collimator exit plane to the 3D object space.

Average over collimator shifts The lateral shift variance of the PRF comes about since it matters just where the point source is with respect to the center of a collimator bore. Anger (1964) suggested that a more meaningful PRF could be defined by averaging over all positions of the collimator. Since shifting the collimator laterally is equivalent to shifting the object and detector together, the averaging blurs out the fine structure of the collimator but does not blur the image.

Following Barrett and Swindell (1981, 1996), we compute the average PRF by adding a 2D vector \mathbf{R} to each bore position \mathbf{r}_n , integrating the PRF over all \mathbf{R} within a disc of radius R_{max} , and dividing by the area of that disc. With the form of PRF given in (16.86), the average PRF is given by

$$\begin{aligned} \bar{h}(\mathbf{r}; \mathbf{r}', z') &= \frac{1}{4\pi z'^2} \sum_{\mathbf{n}} \frac{1}{\pi R_{max}^2} \int_{disc} d^2 R \beta(\mathbf{r} - \mathbf{r}_n - \mathbf{R}) \beta \left[\left(1 - \frac{L_b}{z'}\right) \mathbf{r} + \frac{L_b}{z'} \mathbf{r}' - \mathbf{r}_n - \mathbf{R} \right]. \end{aligned} \quad (16.88)$$

Making the change of variables $\mathbf{R}' = \mathbf{r} - \mathbf{r}_n - \mathbf{R}$ and letting R_{max} get large so we don't have to worry about limits of integration, we find

$$\bar{h}(\mathbf{r}; \mathbf{r}', z') = \frac{1}{4\pi z'^2} \sum_{\mathbf{n}} \frac{1}{\pi R_{max}^2} \int_{\infty} d^2 R' \beta(\mathbf{R}') \beta \left[\frac{L_b}{z'} (\mathbf{r}' - \mathbf{r}) + \mathbf{R}' \right]. \quad (16.89)$$

The integral is recognized as the autocorrelation integral of the bore function (see Sec. 3.4.3); since this autocorrelation is independent of \mathbf{n} , it can be taken out of the sum, and we have

$$\bar{h}(\mathbf{r}; \mathbf{r}', z') = \frac{1}{4\pi z'^2} \frac{N(R_{max})}{\pi R_{max}^2} [\beta \star \beta] \left[\frac{L_b}{z'} (\mathbf{r} - \mathbf{r}') \right], \quad (16.90)$$

where \star denotes the autocorrelation integral as defined in (3.115), and $N(R_{max})$ is the number of bores within the disc. If the collimator bores are arranged on a regular lattice with each bore lying in a unit cell of area A_{cell} , then $N(R_{max}) = \pi R_{max}^2 / A_{cell}$. The bore itself has an area A_{bore} (equal to $\pi D_b^2 / 4$ for circular bores), and we can define the *packing fraction* $\alpha_{pf} \equiv A_{bore} / A_{cell}$, so that $N(R_{max}) = \pi R_{max}^2 \alpha_{pf} / A_{bore}$, and we obtain, finally,

$$\bar{h}(\mathbf{r} - \mathbf{r}', z') = \frac{1}{4\pi z'^2} \frac{\alpha_{pf}}{A_{bore}} [\beta \star \beta] \left[\frac{L_b}{z'} (\mathbf{r} - \mathbf{r}') \right]. \quad (16.91)$$

Note that we have rewritten the average PRF as $\bar{h}(\mathbf{r}-\mathbf{r}', z')$ since the averaging process has removed the shift-variance that came from the collimator structure. The system is now an axial shift-invariant system of the kind discussed in Sec. 7.2.10, where the mapping from 3D object to 2D image is a convolution in the lateral variables x' and y' and an integration over depth z' .

Flood image and point sensitivity We know from Sec. 7.2.1 that the uniformity of a CC imaging system can be specified by its flood image and point-source sensitivity. The flood uniformity can be measured in practice by placing a uniform planar source parallel to the collimator face and recording an image. In the present discussion, the image is specified by the photon irradiance in plane P , and we denote the flood image as $I_{fld}(\mathbf{r})$. Mathematically, if $f(\mathbf{r}', z') = \delta(z' - z_0)$, then [cf. (7.111)]

$$\begin{aligned} I_{fld}(\mathbf{r}) &= \int_{L_b}^{\infty} dz' \int_{\infty} d^2r' h(\mathbf{r}; \mathbf{r}', z') \\ &= \frac{1}{4\pi z_0^2} \sum_{\mathbf{n}} \beta(\mathbf{r} - \mathbf{r}_{\mathbf{n}}) \int_{\infty} d^2r' \beta \left[\left(1 - \frac{L_b}{z_0}\right) \mathbf{r} + \frac{L_b}{z_0} \mathbf{r}' - \mathbf{r}_{\mathbf{n}} \right]. \end{aligned} \quad (16.92)$$

The integral can be performed if we again assume circular bores of diameter D_b . Since we know from Fig. 16.10 that the integrand is unity within a circle of diameter $D_b z_0 / L_b$ and zero otherwise, we find that

$$I_{fld}(\mathbf{r}) = \frac{D_b^2}{16L_b^2} \sum_{\mathbf{n}} \beta(\mathbf{r} - \mathbf{r}_{\mathbf{n}}). \quad (16.93)$$

Note that this result is independent of z_0 ; you cannot tell how far you are from a perfectly uniform source. The dependence on \mathbf{r} is just the collimator bore pattern.

The point sensitivity is defined generally in (7.113), and in the present problem it is given by

$$\begin{aligned} s_{pt}(\mathbf{r}', z') &\equiv \int_{\infty} d^2r h(\mathbf{r}; \mathbf{r}', z') \\ &= \frac{1}{4\pi z'^2} \sum_{\mathbf{n}} \int_{\infty} d^2r \beta(\mathbf{r} - \mathbf{r}_{\mathbf{n}}) \beta \left[\left(1 - \frac{L_b}{z'}\right) \mathbf{r} + \frac{L_b}{z'} \mathbf{r}' - \mathbf{r}_{\mathbf{n}} \right]. \end{aligned} \quad (16.94)$$

The integral is straightforward for circular bores and a point source on the collimator entrance face ($z' = L_b$), in which case we find

$$s_{pt}(\mathbf{r}', L_b) = \frac{D_b^2}{16L_b^2} \sum_{\mathbf{n}} \beta(\mathbf{r}' - \mathbf{r}_{\mathbf{n}}). \quad (16.95)$$

Note that $D_b^2/(16L_b^2)$ can also be written as $\frac{1}{4\pi}(\pi D_b^2/4L_b^2)$; the factor in parentheses in this form is the solid angle subtended by a bore on the exit face of the collimator from a point within that bore on the entrance face, and 4π is the solid angle subtended by a sphere centered on this point. Thus $D_b^2/(16L_b^2)$ is the fraction of the photons emitted from the point that pass through the collimator on average. The sum is unity unless the point is behind an opaque septum, in which case the sum is zero.

Computation of the point sensitivity is more difficult for $z_0 \neq L_b$, but an interesting insight can be obtained by considering $z' \gg L_b$. In that case, photons

from a point at (\mathbf{r}', z') can pass through many different bores of the collimator (see Fig. 16.9), and it may be a good approximation to replace the sum over \mathbf{n} by an integral:

$$\sum_{\mathbf{n}} \rightarrow \frac{1}{A_{\text{cell}}} \int_{\infty} d^2 r_{\mathbf{n}} = \frac{\alpha_{pf}}{A_{\text{bore}}} \int_{\infty} d^2 r_{\mathbf{n}}. \quad (16.96)$$

With this approximation and a change of variables, we find

$$s_{pt}(\mathbf{r}', z') = \frac{1}{4\pi z'^2} \frac{\alpha_{pf}}{A_{\text{bore}}} \int_{\infty} d^2 r [\beta \star \beta] \left[\frac{L_b}{z'} (\mathbf{r} - \mathbf{r}') \right], \quad (16.97)$$

which we could also have obtained immediately from the average PSF of (16.91). The remaining integral can be performed with the help of (3.135) and the central-ordinate theorem, (3.229); the result is

$$s_{pt}(\mathbf{r}', z') = \frac{1}{4\pi L_b^2} \alpha_{pf} A_{\text{bore}} = \frac{\alpha_{pf} D_b^2}{16L_b^2}, \quad (16.98)$$

where the last form is specifically for circular bores. Thus, when $z' \gg L_b$ so that many bores can be seen from one source point, the point sensitivity is independent of source position in both \mathbf{r}' and z' . In addition, this sensitivity is essentially the same as that given in (16.91) even though that expression was for the opposite limit of $z' = L_b$; averaging (16.91) over \mathbf{r}' just introduces a factor of α_{pf} since that fraction of source positions fall in open collimator bores. In this average sense, therefore, the point sensitivity is approximately independent of z' for the full range of depths. As we shall see in Chap. 17, this observation is important in SPECT imaging.

Attenuation in the object The sensitivity is by no means independent of source depth when attenuation is considered, and the PRF becomes difficult to analyze in full generality in this case. Fortunately, it is often valid to assume that the attenuation coefficient is either constant within the object or at least a slowly varying function of position.

When $\mu_{\text{tot}}(\mathbf{r}', z', \mathcal{E}_0)$ varies slowly with \mathbf{r}' (perpendicular to the collimator bores), the exponential factor in (16.84) can be approximated as

$$\exp \left[- \int_0^{|\mathbf{r}-\mathbf{r}'|} d\ell' \mu_{\text{tot}} \left(\mathbf{r} - \frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|} \ell', \mathcal{E}_0 \right) \right] \approx \exp \left[- \int_0^{z'} d\ell' \mu_{\text{tot}}(\mathbf{r}, \ell', \mathcal{E}_0) \right]. \quad (16.99)$$

Moreover, if μ_{tot} is a constant, this factor becomes $\exp[-\mu_{\text{tot}}L(\mathbf{r}', z')]$, where $L(\mathbf{r}', z')$ is the total path length through the attenuating material from point (\mathbf{r}', z') to the collimator face.

It is straightforward to carry these attenuation factors along in an analysis of the forward problem in gamma-ray imaging, but, as we shall see in Sec. 17.2, it is very tricky to compensate for them in the inverse problem, SPECT.

Other effects The discussion to this point has left out several effects that can be important in practical nuclear medicine systems. We have not yet explicitly included Compton scatter in the formalism above; though its effects are implicitly contained in the total attenuation μ_{tot} , we have not considered what happens to

the scattered photons and how they might affect the image. In addition, we considered only an idealized collimator, neglecting septal penetration and scattering and x-ray generation within the bore. All of these effects can, in principle, be analyzed with the Boltzmann equation.

Scatter within the object can be analyzed as in Sec. 10.3.4, and the scattered radiation can be treated as an additional emissive source to be imaged by the collimator. Because of the energy loss on Compton scattering, this secondary source is no longer monoenergetic, so the attenuation factors may be different for scattered and unscattered photons, and the detector response will definitely be different.

To include septal penetration in the collimator description, we require a double sum over bore indices \mathbf{n} and \mathbf{n}' in the transmission expression (16.80), and we have to compute the amount of absorbing material interposed between the exit point and the entrance point. The formal expression is not difficult to obtain but it must usually be evaluated numerically.

To include scatter in the collimator, we can use the *bidirectional transmission distribution function* or BTDF, as defined in (10.86), in place of the transmission $T(\mathbf{r}, \hat{\mathbf{s}})$. In fact, we could adopt the BTDF as the general description of the collimator, and in the limit of no scatter or x-ray generation it would be given by $\text{BTDF}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') = T(\mathbf{r}, \hat{\mathbf{s}}) \delta(\hat{\mathbf{s}} - \hat{\mathbf{s}}')$, with $T(\mathbf{r}, \hat{\mathbf{s}})$ given by (16.80).

16.2.3 The detector

Next we consider how a detector responds to the photons emerging from the collimator. For simplicity we assume that the detector entrance face exactly coincides with the collimator exit face (plane P), though in practice there is always a small gap. We assume also that the photons are normally incident on the detector since they have passed down a bore of a parallel-hole collimator; thus we can adequately specify the photon distribution by the irradiance on P rather than the full distribution function. We consider separately the cases of discrete detector arrays and Anger scintillation cameras.

Discrete detector array Consider first discrete detector elements, such as the photon-counting semiconductor detectors analyzed in Sec. 12.3.2. Suppose each element absorbs a fraction $\eta(\mathcal{E})$ of the incident photons of energy \mathcal{E} and that an absorbed photon has a probability $P_{acc}(\mathcal{E})$ of being accepted by the energy window and hence contributing to the image; both $\eta(\mathcal{E})$ and $P_{acc}(\mathcal{E})$ are assumed for simplicity to be independent of where the photon strikes the detector face. Thus the mean number of photons accepted in the \mathbf{m}^{th} detector in some exposure time τ is

$$\bar{g}_{\mathbf{m}} = \tau \int_{\mathbf{m}} d^2r \int_0^\infty d\mathcal{E} P_{acc}(\mathcal{E}) \eta(\mathcal{E}) I_p(\mathbf{r}, \mathcal{E}), \quad (16.100)$$

where the spatial integral is over the face of the detector. Note that $\tau I_p(\mathbf{r}, \mathcal{E})$ is the spectral photon fluence on the detector face.

If we consider only the unscattered photons, $I_p(\mathbf{r}, \mathcal{E}) = I_p(\mathbf{r}) \delta(\mathcal{E} - \mathcal{E}_0)$, and

$$\bar{g}_{\mathbf{m}} = \tau \eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0) \int_{\mathbf{m}} d^2r I_p(\mathbf{r}). \quad (16.101)$$

Next we insert (16.85) into (16.101), yielding

$$\bar{g}_{\mathbf{m}} = \tau\eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0) \int_{\mathbf{m}} d^2r \int_{L_b}^{\infty} dz' \int_{\infty} d^2r' h(\mathbf{r}; \mathbf{r}', z') f(\mathbf{r}', z'). \quad (16.102)$$

We can put this result in our standard CD form,

$$\bar{g}_{\mathbf{m}} = \int_{\infty} d^3\mathbf{r}' h_{\mathbf{m}}(\mathbf{r}') f(\mathbf{r}'), \quad (16.103)$$

by noting that $\mathbf{r}' = (\mathbf{r}', z')$ and defining

$$h_{\mathbf{m}}(\mathbf{r}') = \tau\eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0) \int_{\mathbf{m}} d^2r h(\mathbf{r}; \mathbf{r}'). \quad (16.104)$$

With $h(\mathbf{r}; \mathbf{r}')$ given by (16.86), this equation describes the overall mapping from the emissive object to the detector output when attenuation and scatter can be neglected. We shall put these effects back into the formalism shortly, but for now we concentrate on the effects of the collimator and the detector.

Small detector elements To perform the integral in (16.104), we assume initially that one detector element covers exactly one collimator bore, so that we can renumber the collimator bores with the detector index \mathbf{m} and drop the sum over bores. Neglecting attenuation, we can use (16.86) and write

$$h_{\mathbf{m}}(\mathbf{r}') = \eta\tau P_{acc}(\mathcal{E}_0) \frac{1}{4\pi z'^2} \int_{\infty} d^2r \beta(\mathbf{r} - \mathbf{r}_{\mathbf{m}}) \beta\left[\left(1 - \frac{L_b}{z'}\right)\mathbf{r} + \frac{L_b}{z'}\mathbf{r}' - \mathbf{r}_{\mathbf{m}}\right], \quad (16.105)$$

where we have been able to extend the limits of integration to ∞ because of the first factor in the integrand.

To visualize this kernel, recall from Fig. 16.10 that the integrand for fixed \mathbf{r} defines a cone in the 3D \mathbf{r}' space; the integral in (16.105) merely adds a lot of slightly tilted cones, fuzzing the edges as shown in Fig. 16.11.

Fig. 16.11 Illustration of the kernel of the adjoint mapping from a discrete detector element to the 3D object space when the element covers exactly one bore

Larger detector elements Now suppose that each detector element covers many collimator bores. Let $S_{\mathbf{m}}$ denote the set of collimator indices \mathbf{n} such that the open

bore of collimator \mathbf{n} falls entirely within the area of detector \mathbf{m} ; assume that no bores fall partially on a detector element. Then (16.105) is modified to

$$h_{\mathbf{m}}(\mathbf{r}') = \tau\eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0) \frac{1}{4\pi z'^2} \sum_{\mathbf{n} \in S_{\mathbf{m}}} \int_{\infty} d^2 r \beta(\mathbf{r} - \mathbf{r}_{\mathbf{n}}) \beta \left[\left(1 - \frac{L_b}{z'} \right) \mathbf{r} + \frac{L_b}{z'} \mathbf{r}' - \mathbf{r}_{\mathbf{n}} \right]. \quad (16.106)$$

This kernel is again a superposition of cones, as shown in Fig. 16.12, but now cones associated with different bores are displaced laterally. Thus the resulting kernel after integrating over each bore and summing over bores is more nearly a cylinder with fuzzy edges. The spatial resolution, as measured by the width of the intersection of the kernel with a plane of constant z' , is larger because the detector element is larger, but it is less dependent on z' , which may be an advantage in some applications. At the least, it will simplify the mathematics in SPECT imaging (see Sec. 17.1).

Fig. 16.12 Illustration of the kernel for the adjoint mapping when one discrete detector element covers several collimator bores.

Anger camera An Anger camera does not merely integrate the spectral photon irradiance over a fixed area. Instead, as discussed in Sec. 12.3.6, it estimates the position of each photon, and (in modern cameras, at least) it assigns the photon to one bin in a digital matrix based on the estimated coordinates. We can now use the index \mathbf{m} to refer to a bin in the final digital image rather than a discrete detector element.

We can describe the position-estimation process with a conditional probability density function $\text{pr}(\hat{\mathbf{r}}|\mathbf{r})$, where \mathbf{r} is the actual position where the photon strikes the camera face and $\hat{\mathbf{r}}$ is the estimated position. With the position-estimation step included, $\bar{g}_{\mathbf{m}}$ is given by

$$\begin{aligned} \bar{g}_{\mathbf{m}} &= \tau\eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0) \int_{\mathbf{m}} d^2 \hat{r} \int_{\infty} d^2 r \text{pr}(\hat{\mathbf{r}}|\mathbf{r}) I_p(\mathbf{r}) \\ &= \tau\eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0) \int_{\mathbf{m}} d^2 \hat{r} \int_{\infty} d^2 r \text{pr}(\hat{\mathbf{r}}|\mathbf{r}) \int_{\infty} d^3 \mathbf{r}' h(\mathbf{r}; \mathbf{r}') f(\mathbf{r}'). \end{aligned} \quad (16.107)$$

The overall kernel for the CD mapping, in the absence of scatter and attenuation, is thus

$$h_{\mathbf{m}}(\mathbf{r}') = \tau\eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0) \int_{\mathbf{m}} d^2 \hat{r} \int_{\infty} d^2 r \text{pr}(\hat{\mathbf{r}}|\mathbf{r}) h(\mathbf{r}; \mathbf{r}'), \quad (16.108)$$

where $h(\mathbf{r}; \mathbf{r}')$ is given explicitly by (16.86). This kernel accounts for the projection of the 3D object onto a 2D plane, collimator blur, blur introduced by position estimation and integration over a bin. Of these effects, only the collimator blur depends on depth in the object, z' ; blurring by position estimation and discrete binning occur after the 3D-to-2D projection.

Scatter and attenuation To include scattered radiation in the formalism, we must consider the spectral photon irradiance $I_{p,\mathcal{E}}$ (or equivalently, the spatio-spectral fluence $b(\mathbf{r}, \mathcal{E}) \equiv \tau I_{p,\mathcal{E}}$) incident on the detector. The first form of (16.107) generalizes to [*cf.* (16.100)]

$$\bar{g}_{\mathbf{m}} = \tau \int_{\mathbf{m}} d^2 \hat{r} \int_0^\infty d\hat{\mathcal{E}} P_{acc}(\hat{\mathcal{E}}) \int_\infty d^2 r \int_0^\infty d\mathcal{E} \text{pr}(\hat{\mathbf{r}}, \hat{\mathcal{E}} | \mathbf{r}, \mathcal{E}) \eta(\mathcal{E}) I_{p,\mathcal{E}}(\mathbf{r}, \mathcal{E}), \quad (16.109)$$

where $P_{acc}(\hat{\mathcal{E}})$ is unity if $\hat{\mathcal{E}}$ lies in the energy window and zero otherwise. (By contrast, $P_{acc}(\mathcal{E})$ in (16.100) can take on a continuous range of values since it depends on the actual energy rather than the estimated one.)

The spectral photon irradiance $I_{p,\mathcal{E}}$ can be found from the spectral photon radiance by integrating $L_{p,\mathcal{E}} \cos \theta$ over solid angle, and $L_{p,\mathcal{E}}$ in turn can be found by solving the Boltzmann equation. In this calculation, it may be a useful approximation to neglect photons that have undergone more than one scatter event on the grounds that multiply scattered photons are likely to have lost enough energy that they are rejected by the energy window. This approximation will break down for large objects or cameras with poor energy resolution.

The Boltzmann equation is linear, so (16.109) is an overall linear mapping from the source $f(\mathbf{r})$ to the data value $\bar{g}_{\mathbf{m}}$. Computation of the kernel for this mapping without the position and energy estimation is treated in Sec. 10.4.1, and the integrals over $\hat{\mathcal{E}}$ and $\hat{\mathbf{r}}$ in (16.109) account for the estimation steps. It is a useful exercise to derive an explicit expression for the kernel in the single-scatter approximation with position and energy estimation.

16.2.4 Stochastic properties

We already have a comprehensive account of the stochastic properties of gamma-ray images from the discussions in Chaps. 11 and 12. From Chap. 11 we know that Poisson statistics arise whenever we are counting independent events. From a nonrandom source, gamma rays are emitted independently, in full accord with the postulates presented in Sec. 11.1.1. Position and energy estimation and energy windowing do not introduce any dependence, and the postulates still apply after these operations (see Secs. 12.3.6 and 12.3.7). It follows, then, that the number of gamma rays emitted in some time interval is a Poisson random variable, the pattern of photons incident on any plane is a Poisson random process, and a discrete detected image is a Poisson random vector.

In this section we shall apply these general principles specifically to the case of planar nuclear medicine, but we shall be looking ahead to Chap. 17, where we discuss tomographic gamma-ray imaging; the stochastic models developed here will find their full use in that reconstruction problem. Three distinct ways of representing the random data — list, random process and image histogram — will be discussed, and the statistical properties of each representation will be presented.

List mode The first data representation to discuss is just a list of the raw data values. In the nuclear-medicine literature, this form of data storage is known as *list mode*. There is considerable freedom in choosing what information to include in the list.

For a scintillation camera, the rawest data are the photomultiplier signals for each absorbed events. If we wanted to preserve this information in its entirety, we could just construct a list containing all of these values. Suppose that J photons are absorbed in the scintillation crystal of an Anger camera, and that the j^{th} photon produces a peak voltage on the k^{th} photomultiplier of V_k , ($k = 1, \dots, K$). We can store these values in a list J elements long, with each entry in the list consisting of K numbers. We might also add other information to each entry, such as the time of arrival of the photon or an identifier specifying which of several cameras the photon struck. With this form of storage, we have preserved all of the information in the raw PMT data, but we must do substantial further processing to convert the list into an image.

A less raw approach is to first estimate position and energy of each photon and then to store these estimated values in a list. If the j^{th} photon is estimated to have a 2D position $\hat{\mathbf{r}}_j$ and an energy $\hat{\mathcal{E}}_j$, then each entry in the list consists of three numbers, \hat{x}_j , \hat{y}_j and $\hat{\mathcal{E}}_j$, plus time and possibly other identifiers.

To be general about the statistics of list-mode data, we can define an *attribute vector* \mathbf{A}_j for the j^{th} photon. For example, if we store raw PMT signals, the attribute vector has K elements, and for position and energy estimates it has three elements. Nonrandom parameters such as time might be included in the list but are not considered to be part of the attribute vector; instead they can be lumped into a parameter vector $\boldsymbol{\alpha}_j$, and the full list is $\{\mathbf{A}_j, \boldsymbol{\alpha}_j, j = 1, \dots, J\}$.

Statistical independence Whenever the Poisson postulates of Sec. 11.1.1 are satisfied, the attribute vectors for different photons are statistically independent. This is not a universally valid assumption, however, since it ignores some effects that can occur in a detector at high count rates. As we noted in Sec. 11.1.1, if one photon temporarily paralyzes the detector and there is a significant probability of another photon arriving before it recovers, the probability of detection of the second photon is dependent on the presence of the first. By the same token, the measured attributes of the second photon can depend on those of the first. For example, PMT signals can have tails extending for a microsecond or so after the peak. If the second photon occurs within a microsecond of the first, the observed signal will be the second signal plus the tail of the first (see Fig. 16.13); the peak signal will be altered, as will any position or energy estimates derived from the peak signals, and the attributes will not be independent.

Fig. 16.13 Typical photomultiplier signals showing pulse pileup.

If we neglect these high-count-rate effects, then we can assume that attribute vectors for different photons are statistically independent, and we can write

$$\text{pr}(\{\mathbf{A}_j\}|\mathbf{f}) = \prod_{j=1}^J \text{pr}(\mathbf{A}_j|\mathbf{f}). \quad (16.110)$$

Preset time vs. preset count As we discussed in Sec. 11.2.1, there are two different ways of acquiring data in nuclear medicine; we can collect photons for a preset time or until a preset number of counts is accumulated. If we collect for a preset time τ , the number of items in the list is random, and J therefore becomes part of the data. The overall data distribution is then⁶

$$\text{pr}(\{\mathbf{A}_j\}, J|\mathbf{f}) = \text{pr}(\{\mathbf{A}_j\}|J, \mathbf{f}) \text{Pr}(J|\mathbf{f}) = \exp[-\bar{J}(\mathbf{f})] \frac{[\bar{J}(\mathbf{f})]^J}{J!} \prod_{j=1}^J \text{pr}(\mathbf{A}_j|\mathbf{f}), \quad (16.110)$$

where the last form recognizes that J is a Poisson random variable with mean dependent on the object (and, of course, on the exposure time).

If we collect exactly J counts, the image itself contains no information on the absolute strength of the source, but we might also record the time τ_J needed to collect the counts. In that case, the data set includes τ_J as well as the attribute list, and we can write the overall PDF as

$$\text{pr}(\{\mathbf{A}_j\}, \tau_J|\mathbf{f}) = \text{pr}(\{\mathbf{A}_j\}|\mathbf{f}) \text{pr}(\tau_J|\mathbf{f}) = \text{pr}(\tau_J|\mathbf{f}) \prod_{j=1}^J \text{pr}(\mathbf{A}_j|\mathbf{f}). \quad (16.111)$$

The time needed to collect J counts from a Poisson source is a random variable, but for large J its density can be approximated by a delta function $\delta[\tau_J - J/a(\mathbf{f})]$, where $a(\mathbf{f})$ is the overall object-dependent count rate.

To complete these statistical descriptions, we need a way of computing the attribute density $\text{pr}(\mathbf{A}_j|\mathbf{f})$; we shall return to this problem shortly.

Random process For theoretical analysis, it is convenient to represent the items in a list in terms of a random process. For example, if the attribute vectors consist of position and energy estimates, we can use them to construct a spatio-spectral random process as in (12.277):

$$g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) \equiv \sum_{j=1}^J \delta(\hat{\mathbf{r}} - \hat{\mathbf{r}}_j) \delta(\hat{\mathcal{E}} - \hat{\mathcal{E}}_j), \quad (16.112)$$

where $\hat{\mathbf{r}}$ is the estimated 2D position on the camera face and $\hat{\mathcal{E}}$ is the estimated energy.

All properties of a Poisson random process are fully determined by its fluence. For the spatio-spectral random process $g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$, the relevant fluence is given by (12.282) as [cf. (16.109)]:

$$b_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) = \tau \int_{\infty} d^2r \int_0^{\infty} d\mathcal{E} \text{pr}(\hat{\mathbf{r}}, \hat{\mathcal{E}}|\mathbf{r}, \mathcal{E}) \eta(\mathcal{E}) I_{p,\mathcal{E}}(\mathbf{r}, \mathcal{E}). \quad (16.113)$$

⁶Recall that we use the lower-case $\text{pr}(\cdot)$ when we want to specify jointly a probability for a discrete random variable and a PDF for a continuous one.

This fluence is directly the mean of the random process, and it also specifies the autocovariance function in position and energy by (12.285):

$$K_{g_{det}}(\hat{\mathbf{r}}, \hat{\mathbf{r}}', \hat{\mathcal{E}}, \hat{\mathcal{E}}') = b_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) \delta(\hat{\mathbf{r}} - \hat{\mathbf{r}}') \delta(\hat{\mathcal{E}} - \hat{\mathcal{E}}'). \quad (16.114)$$

PDF for the attribute vector We know from Secs. 11.3.2 and 12.3.7 that the spatio-spectral fluence can be interpreted, after proper normalization, as the probability density function on the estimated position and energy of any individual count. Thus, if the attributes for an item in the list are estimated position and energy, the PDF needed in (16.110) and (16.111) is [cf. (12.281)]

$$\text{pr}(\hat{\mathbf{r}}, \hat{\mathcal{E}} | \mathbf{f}) = \frac{1}{\mathcal{J}(\mathbf{f})} b_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}). \quad (16.115)$$

Image histograms In gamma-ray imaging with a scintillation camera, the final image is usually obtained from the position and energy estimates by accepting photons whose estimated energies lie in some energy window and binning or histogramming the spatial positions as in (12.286). The integral of a Poisson random process over any area is a Poisson random variable, so we know the statistics of the discrete data vector at once. In particular, the covariance matrix is given by (12.288) as

$$[\mathbf{K}_{\mathbf{g}}]_{\mathbf{m}\mathbf{m}'} = \bar{g}_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'}. \quad (16.116)$$

If each $\bar{g}_{\mathbf{m}}$ is large, say greater than about 10, it is a good approximation to consider the data to be normally distributed with this covariance.

Noise due to scatter Since it was couched entirely in terms of the spatio-spectral fluence, this discussion on stochastic properties of gamma-ray images has made no distinction between scattered and unscattered photons. The scattering does not introduce any dependence among different photons and does not affect the Poisson character of the spatio-spectral random process or the random vector that results after binning. Each accepted photon contributes one count to the digital image; the energy loss influences the probability of acceptance but not the contribution of the photon to the image if it is accepted.

Object randomness Object randomness does lead to non-Poisson statistics in nuclear medicine. When the object varies, the spatio-spectral fluence varies also, and $g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}})$ becomes a doubly stochastic Poisson random process as discussed in Sec. 11.3.6. Similarly, the discrete image after energy windowing and spatial binning becomes a doubly stochastic Poisson random vector (see Sec. 11.2.2).

16.2.5 Image quality: Classification tasks

Planar nuclear medicine affords a good opportunity to discuss basic issues in image quality with relatively simple noise and system models. Unlike the discussion of image quality in digital radiography in Sec. 16.1.6, we need not worry about non-Poisson noise (other than object variability), and the system is strictly linear so we do not need contorted discussions of linearization.

In this section we shall discuss image quality in planar nuclear medicine for detection and discrimination tasks. We shall begin with SKE/BKE tasks, using

them to discuss the importance of detector resolution. When we get to collimator resolution, however, we shall see that it is hazardous to rely too much on SKE/BKE tasks. At that point we shall turn to discrimination tasks and random backgrounds.

SKE/BKE tasks and the ideal observer SKE/BKE detection tasks in pure Poisson noise were analyzed in Sec. 13.2.9. We know from (13.131) that the log-likelihood ratio for this case is given by

$$\lambda = \sum_{\mathbf{m}=1}^M g_{\mathbf{m}} \ln \frac{\bar{g}_{2\mathbf{m}}}{\bar{g}_{1\mathbf{m}}}, \quad (16.117)$$

and the ideal-observer SNR is given by (13.132) as

$$\text{SNR}_{\lambda}^2 = \frac{\left[\sum_{\mathbf{m}=1}^M (\bar{g}_{2\mathbf{m}} - \bar{g}_{1\mathbf{m}}) \ln \left(\frac{\bar{g}_{2\mathbf{m}}}{\bar{g}_{1\mathbf{m}}} \right) \right]^2}{\frac{1}{2} \sum_{\mathbf{m}=1}^M (\bar{g}_{2\mathbf{m}} + \bar{g}_{1\mathbf{m}}) \ln^2 \left(\frac{\bar{g}_{2\mathbf{m}}}{\bar{g}_{1\mathbf{m}}} \right)}. \quad (16.118)$$

Now suppose that the signal to be detected makes a small contribution to the mean data, so that we can write $\bar{g}_{2\mathbf{m}} = \bar{g}_{1\mathbf{m}} + s_{\mathbf{m}}$, with $s_{\mathbf{m}} \ll \bar{g}_{j\mathbf{m}}$ for $j = 1, 2$ and all \mathbf{m} . As we saw in (13.135), a Taylor expansion of the logarithms through terms linear in the signal yields

$$\text{SNR}_{\lambda}^2 \approx \sum_{\mathbf{m}=1}^M \frac{s_{\mathbf{m}}^2}{\bar{g}_{\mathbf{m}}}, \quad (16.119)$$

where $\bar{g}_{\mathbf{m}}$ can be either $\bar{g}_{1\mathbf{m}}$ or $\bar{g}_{2\mathbf{m}}$ to this approximation.

An alternative way to arrive at this expression is to assume that the mean number of counts in each bin is large enough that we can approximate the Poisson law with a Gaussian ($\bar{g}_{\mathbf{m}} > 10$ will suffice). In that case the Hotelling observer is approximately ideal, and the Hotelling SNR for a weak signal is given by

$$\text{SNR}_{Hot}^2 = \mathbf{s}^t \mathbf{K}_{\mathbf{g}}^{-1} \mathbf{s}. \quad (16.120)$$

With the help of (16.116), this general expression again reduces to (16.119).

A useful approximation to (16.119) is obtained by considering a spatially compact signal and a slowly varying object, such that $\bar{g}_{\mathbf{m}}$ is approximately the same for all pixels where the signal $s_{\mathbf{m}}$ is nonzero. If the signal is centered on pixel \mathbf{m}_0 , we then have

$$\text{SNR}_{\lambda}^2 \approx \frac{1}{\bar{g}_{\mathbf{m}_0}} \sum_{\mathbf{m}=1}^M s_{\mathbf{m}}^2, \quad (16.121)$$

and the sum is recognized as the \mathbb{L}_2 norm of the detected signal. Anything that reduces this norm, reduces the detectability of the signal in this approximation. Moreover, anything that increases $\bar{g}_{\mathbf{m}_0}$ without also increasing the sum also decreases the detectability; an immediate implication is that background activity overlapping the signal in the 2D projection must be deleterious.

As written, (16.119) is simpler than the corresponding expression for digital radiography, (16.47), because the covariance matrix is simpler, but it hides some essential factors that contribute to detection performance. We cannot see immediately, for example, how the spatial and energy resolution of the detector or the design of the collimator affect SNR^2 . We shall now consider each of these effects in turn for the weak-signal SKE/BKE problem.

Effect of position estimation In an Anger camera, the bins in the digital matrix can be made arbitrarily small, but there is still a resolution limitation arising from the position-estimation step, and this limitation can affect the detectability.

To isolate this effect, suppose that the bins in the digital image are so small that a sum over bins can be approximated as an integral. Suppose also that the estimation blur is shift-invariant, so that $\text{pr}(\hat{\mathbf{r}}|\mathbf{r}) = p_{est}(\hat{\mathbf{r}} - \mathbf{r})$. Then we can write (16.121) as

$$\text{SNR}_\lambda^2 = \frac{1}{b_0} \int_\infty d^2 \hat{r} \left[\int_\infty d^2 r p_{est}(\hat{\mathbf{r}} - \mathbf{r}) \Delta b(\mathbf{r}) \right]^2. \quad (16.122)$$

The integral over \mathbf{r} is recognized as a convolution, so we can use the convolution theorem (3.243) and Parseval's theorem (3.226) to write

$$\text{SNR}_\lambda^2 = \frac{1}{b_0} \int_\infty d^2 \rho |P_{est}(\boldsymbol{\rho}) \Delta B(\boldsymbol{\rho})|^2. \quad (16.123)$$

Since $p_{est}(\hat{\mathbf{r}} - \mathbf{r})$ is a properly normalized probability density function, it follows from the central-ordinate theorem (3.229) that $P_{est}(0) = 1$. Moreover, since $p_{est}(\hat{\mathbf{r}} - \mathbf{r})$ is nonnegative, it follows from the first inequality in (3.65) that $|P_{est}(\boldsymbol{\rho})| \leq 1$ for all $\boldsymbol{\rho}$. Therefore,

$$\text{SNR}_\lambda^2 \leq \frac{1}{b_0} \int_\infty d^2 \rho |\Delta B(\boldsymbol{\rho})|^2. \quad (16.124)$$

The right-hand side is what one would get with no estimation error. Thus the finite intrinsic resolution of the Anger camera will reduce the ideal-observer detectability unless the blur is negligible compared to the width of the pre-detection difference signal.

Effect of the collimator Another source of blur is the collimator; if we increase the bore diameter or reduce the bore length, the mean image incident on the detector plane is a more blurred representation of the 2D projection of the 3D object. Unlike the blur due to detector resolution or post-detection processing, however, collimator blur has a countervailing advantage: collimators with larger bore diameter or smaller bore length collect more photons and hence reduce the Poisson noise relative to the mean. It is not obvious how the collimator parameters should be chosen, but in keeping with our general philosophy, the collimator should be designed to optimize task performance. As we shall now see, this requirement leads to a surprising result if the task is SKE/BKE detection.

Since the collimator blur depends on distance from the collimator, it is convenient for this discussion to consider a planar object parallel to the face of the collimator. Thus we take $f(\mathbf{r}, z) = f(\mathbf{r}) \delta(z - z_0)$ in the absence of a signal and $f(\mathbf{r}, z) = [f(\mathbf{r}) + \Delta f(\mathbf{r})] \delta(z - z_0)$ when a signal is present. We assume for simplicity that $z_0 \gg L_b$ so that radiation can reach the detector plane through many bores. In that case, we can approximate the sum over bores with an integral as in (16.96), and the point response function is well approximated by the autocorrelation of the bore function as in (16.91). Recall, however, that this PRF maps the object $f(\mathbf{r})$ to the photon irradiance $I_p(\mathbf{r})$ incident on the detector plane P ; the corresponding fluence for the *detected* photons requires some constants. Neglecting scatter and attenuation, we obtain

$$b(\mathbf{r}) = C \int_\infty d^2 r' [\beta \star \beta] \left[\frac{L_b}{z_0} (\mathbf{r} - \mathbf{r}') \right] f(\mathbf{r}', z_0), \quad (16.125)$$

where

$$C = \frac{1}{4\pi z_0^2} \frac{\alpha_{pf}}{A_{bore}} \tau \eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0). \quad (16.126)$$

Note that the system is now shift-invariant since we have considered a planar object sufficiently far away that the fine structure of the collimator bores is not important. The same conclusion would hold for any z_0 if we averaged the PSF over collimator shifts.

To focus on the effect of the collimator, we assume an ideal detector and compute the detectability associated with the continuous image on plane P . If we consider a weak, spatially compact signal centered at $\mathbf{r} = \mathbf{r}_0$ and assume that the background object is slowly varying over the support of the signal, the expression we must evaluate is [cf. (16.121)]

$$\text{SNR}_\lambda^2 = \frac{1}{b_0} \|\Delta \mathbf{b}\|^2. \quad (16.127)$$

The denominator in (16.127) is given by

$$b_0 = C f(\mathbf{r}_0) \int_\infty d^2 r' [\beta \star \beta] \left[\frac{L_b}{z_0} (\mathbf{r} - \mathbf{r}') \right], \quad (16.128)$$

and the numerator is given by

$$\|\Delta \mathbf{b}\|^2 = C^2 \int_\infty d^2 r \left\{ \int_\infty d^2 r' [\beta \star \beta] \left[\frac{L_b}{z_0} (\mathbf{r} - \mathbf{r}') \right] \Delta f(\mathbf{r}') \right\}^2. \quad (16.129)$$

Various Fourier theorems can be applied to simplify this expression; details are left as an exercise, but hints can be found in Barrett and Swindell (1981, 1996). The result is

$$\text{SNR}_\lambda^2 = \frac{\tau \eta_{tot}}{f(\mathbf{r}_0)} \int_\infty d^2 \rho \left| M_{coll} \left(\frac{z_0}{L_b} \boldsymbol{\rho} \right) \Delta F(\boldsymbol{\rho}) \right|^2, \quad (16.130)$$

where η_{tot} is the total efficiency of the collimator and detector, defined by

$$\eta_{tot} = \frac{\alpha_{pf} A_{bore}}{4\pi L_b^2} \eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0), \quad (16.131)$$

and $M_{coll}(\boldsymbol{\rho})$ is the collimator MTF, given by

$$M_{coll}(\boldsymbol{\rho}) = \left[\frac{2J_1(\pi D_b \rho)}{\pi D_b \rho} \right]^2. \quad (16.132)$$

Two limits It is instructive to look at the behavior of the SNR for this problem in the limits of large and small collimator bores. In the limit as $D_b \rightarrow 0$, we can evaluate (16.130) by noting that the collimator MTF is a broad function compared to the signal transform $\Delta F(\boldsymbol{\rho})$. Since $M_{coll}(0) = 1$, we can then write

$$\text{SNR}_\lambda^2 \rightarrow \frac{\tau \eta_{tot}}{f(\mathbf{r}_0)} \int_\infty d^2 \rho |\Delta F(\boldsymbol{\rho})|^2 = \frac{\tau \eta_{tot} \|\Delta \mathbf{f}\|^2}{f(\mathbf{r}_0)}, \quad (16.133)$$

where the last step follows from Parseval's theorem. In this limit, therefore, SNR_λ^2 grows linearly with the efficiency and the exposure time, and it is directly proportional to the squared \mathbb{L}_2 norm of the signal in the object domain.

In the opposite limit, the signal transform $\Delta F(\boldsymbol{\rho})$ is large compared to $M_{coll}(z_0\boldsymbol{\rho}/L_b)$, and we have

$$\begin{aligned} \text{SNR}_\lambda^2 &\rightarrow \frac{\tau\eta_{tot}}{f(\mathbf{r}_0)} |\Delta F(0)|^2 \int_\infty d^2\rho \left| M_{coll}\left(\frac{z_0}{L_b}\boldsymbol{\rho}\right) \right|^2 \\ &= \frac{\tau\eta_{tot}}{f(\mathbf{r}_0)} \left| \int_\infty d^2r \Delta f(\mathbf{r}) \right|^2 \int_\infty d^2\rho \left| M_{coll}\left(\frac{z_0}{L_b}\boldsymbol{\rho}\right) \right|^2, \end{aligned} \quad (16.134)$$

where now the last step has used the central-ordinate theorem. A change of variables shows that the integral over $\boldsymbol{\rho}$ varies as $1/D_b^2$, cancelling the factor of D_b^2 in η_{tot} and yielding an SNR that is independent of D_b .

The factor $|\int_\infty d^2r \Delta f(\mathbf{r})|^2$ is also of interest. No longer does the \mathbb{L}_2 norm of $\Delta f(\mathbf{r})$ appear in the SNR; instead we now have the integrated activity in the difference object. If the difference object is nonnegative, then this integral is the \mathbb{L}_1 norm, but there is no absolute value in the integral, and there is nothing that requires $\Delta f(\mathbf{r}) \geq 0$.

What collimator should be used? Knowing the limiting behavior of SNR_λ , we can now sketch its dependence on bore diameter as in Fig. 16.14. The main conclusion from this plot is that the optimum collimator is no collimator at all! The bore diameter should be as large as possible in order to collect as many photons as possible, and there is no advantage in this task to getting good spatial resolution. The explanation for this counterintuitive result is that the task is so tightly specified that it is not necessary to resolve fine details; every detail of the two possible objects is known in advance, and it is required only to decide which object (background or signal plus background) is present. When the two objects differ by a known amount in the total number of photons they emit, the best strategy for deciding between them is just to reduce as much as possible the uncertainty in estimating this number, which we can do by collecting as many photons as possible.

Fig. 16.14 Dependence of the ideal-observer SNR for detection of a disc signal on diameter of the collimator bore.

Zero-DC tasks Since $\int_\infty d^2r \Delta f(\mathbf{r})$ is the zero-frequency or DC Fourier component of the difference object, we can refer to tasks where this component vanishes as *zero-DC tasks*. We see from (16.134) that the detectability goes to zero in the limit of large collimator blur for a zero-DC task; task performance requires more than just estimating the total activity in this case.

The first use of a zero-DC task in image-quality assessment was by Harris (1964), who suggested the *Rayleigh task* illustrated in Fig. 16.15. The goal in this task is to discriminate between a single Gaussian blob and two separated blobs of half the amplitude, so that the two signals have the same $\int_{\infty} d^2r f(\mathbf{r})$, and hence $\int_{\infty} d^2r \Delta f(\mathbf{r}) = 0$. Harris suggested using the minimum value of the separation at some specified level of discrimination performance as a measure of spatial resolution.

Fig. 16.15 Illustration of the Rayleigh task, where the object is either two Gaussian blobs or one Gaussian with the same integrated activity.

Wagner *et al.* (1981) used the Rayleigh task to evaluate nuclear-medicine imaging systems, but they still found paradoxical results. In particular, they found that coded apertures had no resolution advantage, in the Harris sense, over very large pinholes that collected the same number of photons. Coded-aperture images can be decoded to give a spatial resolution, as defined by the width of the point response function, that is much better than that of a pinhole of equal collection efficiency. Therefore the conclusion of Wagner *et al.* is equivalent to saying that spatial resolution in this conventional sense is not important for the stylized SKE/BKE task they considered. To get a more realistic assessment of the system, we must consider more realistic tasks.

Random signals and backgrounds As discussed in Sec. 13.2.11, one way to make the task more realistic is to consider detection on a random background. The first step in this direction in emission imaging was taken by Tsui *et al.* (1978, 1983), who considered detection of a spherical tumor of known size and location in a spatially uniform background of unknown level. One observer model they considered closely approximated the ideal Bayesian strategy for this task [see (13.215)]. The observer estimated the random background level by integrating the counts over an annular region surrounding the tumor and compared that value with the integrated counts over the signal location. With this model, the optimum aperture size was approximately equal to the size of the lesion to be detected, and increasing the aperture size beyond this point resulted in reduced detectability in spite of increased counts. When the background was assumed to be known, however, the optimum aperture size increased to infinity, in accord with the ideal-observer analysis presented in Fig. 16.14.

A somewhat more realistic background, the lumpy background described in Secs. 8.4.4 and 13.2.12, was used by Myers *et al.* (1990) and Rolland and Barrett (1992) to discuss aperture optimization in emission imaging. It was found that spatial resolution in the conventional sense (width of the point response function) was required to distinguish the signal from the background inhomogeneities. As in

the Tsui work, the optimum aperture size was found to be approximately equal to the size of the signal.

Still more realistic random backgrounds, and random signals, were used by Fiete *et al.* (1987) and later by White (summarized in Barrett *et al.*, 1992). Using a 3D mathematical liver model developed by Cargill (1989), these authors studied both human and Hotelling detection performance as a function of collimator bore diameter and bore length. Two key findings were that a long bore and small bore diameter optimized Hotelling performance, in spite of the relatively low collection efficiency, and that Hotelling performance was an accurate predictor of human performance in this case.

Psychophysical studies Psychophysical studies can be used without correlation with model observers to evaluate components of nuclear medicine systems. One example is the work of Buvat *et al.* (2001), who used a physical breast phantom and human ROC studies to compare collimators in scintimammography. Breast tumors were represented by hot spheres. It was demonstrated that ultrahigh-resolution collimators were advantageous for this task in spite of reduced collection efficiency.

Detection tasks and list-mode data So far we have assumed that the detection or discrimination tasks were performed by an observer with access to image histograms, but there may be some loss of information in going from the raw list-mode data to the binned histograms. For SKE/BKE discrimination tasks, the SNR for an ideal observer operating on list-mode data was computed by Barrett *et al.* (1997b). For preset time, they showed that

$$\text{SNR}_\lambda^2 = \frac{\left[\int_\infty d^2\hat{r} \int_0^\infty d\hat{\mathcal{E}} (b_2 - b_1) \ln\left(\frac{b_2}{b_1}\right) \right]^2}{\frac{1}{2} \int_\infty d^2\hat{r} \int_0^\infty d\hat{\mathcal{E}} (b_2 + b_1) \ln^2\left(\frac{b_2}{b_1}\right)}, \quad (16.135)$$

where we have simplified the notation by writing b_j for $b_{det,j}(\hat{r}, \hat{\mathcal{E}})$; with the j subscript distinguishing hypothesis 1 from hypothesis 2.

If we consider weak signals, so that $b_2 = b_1 + \Delta b$, with $\Delta b \ll b_j$ for $j = 1, 2$, then we find

$$\text{SNR}_\lambda^2 \approx \int_\infty d^2\hat{r} \int_0^\infty d\hat{\mathcal{E}} \frac{(\Delta b)^2}{b_j}. \quad (16.136)$$

Comparing (16.135) and (16.136) with their binned counterparts, (16.118) and (16.119), respectively, we see that the main difference is that the sum over bins has been replaced by an integral over attribute space. Thus (16.135) and (16.136) are the limits of the binned expressions as the bin widths go to zero. Recall, however, that the binned expressions were derived on the assumption that there was only one energy bin; either $\hat{\mathcal{E}}$ fell in the energy window and the event was accepted, or it did not and the event was rejected. In the list-mode expressions, there is no windowing and every event contributes, in principle. Even scattered photons are useful to the extent that Δb is nonzero.

Linear discriminants and random processes If we wish to move away from SKE/BKE tasks and consider random signals or backgrounds with list-mode data, we run into difficulties computing the ideal-observer detectability. In that case, it is again useful to consider the ideal linear or Hotelling observer. This observer is not defined as

a linear functional of the attributes in the list, but rather as a linear discriminant acting on the corresponding random process. For the spatio-spectral process given in (16.112), the linear discriminant function has the form [cf. (13.9)]

$$T(\mathbf{g}_{det}) = \mathbf{w}^\dagger \mathbf{g}_{det} = \int_{-\infty}^{\infty} d^2 \hat{\mathbf{r}} \int_0^{\infty} d\hat{\mathcal{E}} w_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}) g_{det}(\hat{\mathbf{r}}, \hat{\mathcal{E}}). \quad (16.137)$$

To compute the SNR for this discriminant, we need to know the mean and autocorrelation function for the random process. For the important special case of a doubly stochastic spatial Poisson random process, these expressions are found in Sec. 11.3.6, and they extend readily to the spatio-spectral case.

16.2.6 Image quality: Estimation tasks

Planar nuclear medicine is poorly suited to estimation tasks because of the 3D-to-2D mapping. If, for example, we wanted to estimate the activity in the left ventricle of the heart, counts from the ventricle would be confused with counts from tissues that overlap the ventricle in a single 2D projection. We encountered a similar situation in the context of digital radiography in Sec. 16.1.7, but there we avoided the issue of overlapping tissues by considering only changes in x-ray attenuation coefficient following injection of a contrast agent. The main problems that arose in that case were the system nonlinearity and the variation of system sensitivity with depth. In planar nuclear medicine, these two system problems do not come up, but we do not usually have the possibility of doing subtraction imaging, and we must therefore deal with the overlapping activity.

This fundamental difficulty can be solved only by tomographic imaging, which is the subject of Chap. 17, but it is instructive to analyze the problem further in the context of planar imaging. This discussion will illustrate the concept of estimability, introduced in Secs. 13.3.1 and 15.1.3, and it will provide some insights into the role of prior information in estimation problems.

Bias and estimability Suppose the task is to estimate the activity in a spherical region of interest (ROI) of known location in the body. As usual, we would like to assess performance on this task by bias and variance of the estimate, but we have emphasized that bias is well defined only for estimable parameters. If the parameter in question is the activity in an ROI, then the estimability condition is that the template defining the ROI be a linear combination of system sensitivity functions [see (15.23)]. For a parallel-hole collimator, the sensitivity functions are long, thin cones parallel to the axis of the bores (the z axis). The spherical template cannot be synthesized as a linear combination of such functions, so any estimate derived from a single 2D projection will necessarily have a bias of unknown magnitude arising from the overlapping tissue.

To discuss this problem quantitatively, we need to decompose the template into null and measurement components. To see the essential features of the calculation, let us first ignore blur and attenuation. The kernel for the mapping from the 3D object to the continuous 2D projection is obtained from (16.91) by letting $D_b \rightarrow 0$; a factor of $(z'/L_b)^2$ arises because of the scale factor in the argument of the autocorrelation, and we see that

$$\bar{h}(\mathbf{r} - \mathbf{r}', z') \rightarrow \frac{\alpha_{pf}}{4\pi L_b^2} \delta(\mathbf{r} - \mathbf{r}'). \quad (16.138)$$

There is no longer any dependence on z' ; the system sensitivity is independent of depth, so the projection is a simple line integral in the z' direction.

We learned in Sec. 7.2.10 how to compute the SVD for axial systems, which blur laterally and integrate along the z axis. For shift-invariant blur, we saw in (7.223) that the object-space singular functions corresponding to nonzero singular values are 2D plane waves $\exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r})$ modulated by the depth-dependent transfer function $H(-\boldsymbol{\rho}, z)$. In the present problem, there is no lateral blur and no dependence on z , so $H(-\boldsymbol{\rho}, z)$ is independent of $\boldsymbol{\rho}$ and constant over the region of support in the z direction; if we take that support as $0 < z \leq L_z$, we get

$$u_{\boldsymbol{\rho},j}(\mathbf{r}, z) = \frac{1}{\sqrt{L_z}} \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) \operatorname{rect}\left(\frac{z - \frac{1}{2}L_z}{L_z}\right), \quad (j = 1). \quad (16.139)$$

There is also an infinite set of functions $\{u_{\boldsymbol{\rho},j}(\mathbf{r}, z)\}$ with $j > 1$, but they are in the null space; the measurement space is spanned by $\{u_{\boldsymbol{\rho},j}(\mathbf{r}, z)\}$ for all $\boldsymbol{\rho}$ and $j = 1$.

With these singular functions, the projection of the ROI template onto measurement space is [*cf.* (1.165)]

$$\begin{aligned} \chi_{meas}(\mathbf{r}, z) &= [\mathcal{P}_{meas}\boldsymbol{\chi}](\mathbf{r}, z) = \int_{\infty} d^2\rho \mathbf{u}_{\boldsymbol{\rho},1} \mathbf{u}_{\boldsymbol{\rho},1}^{\dagger} \boldsymbol{\chi} \\ &= \frac{1}{L_z} \int_{\infty} d^2\rho \int_{\infty} d^2r' \int_0^{L_z} dz' \exp[2\pi i \boldsymbol{\rho} \cdot (\mathbf{r} - \mathbf{r}')] \chi(\mathbf{r}', z') = \frac{1}{L_z} \int_0^{L_z} dz' \chi(\mathbf{r}, z'), \end{aligned} \quad (16.140)$$

where we have used the completeness relation (3.218) in the last step. Thus, not surprisingly, the measurement component of the template is just the template averaged over depth.

One way to restate this result is to use a Fourier series in z for $\chi(\mathbf{r}, z)$:

$$\chi(\mathbf{r}, z) = \sum_{n=-\infty}^{\infty} \chi_n(\mathbf{r}) \exp(2\pi i n z / L_z). \quad (16.141)$$

As one might expect from the central-slice theorem (4.150), the measurement component is just the zero-frequency term:

$$\chi_{meas}(\mathbf{r}, z) = \chi_0(\mathbf{r}). \quad (16.142)$$

The null component contains all other frequencies; it is given by

$$\chi_{null}(\mathbf{r}, z) = \chi(\mathbf{r}, z) - \frac{1}{L_z} \int_0^{L_z} dz' \chi(\mathbf{r}, z'). \quad (16.143)$$

Integrating this expression over $0 < z \leq L_z$ yields zero, so it is indeed a null function for the system model of (16.138).

With uniform attenuation but no blur, the measurement-space singular functions are given by (16.139) with an extra factor of $\exp(-\mu z)$ and a modified normalization. In that case,

$$\chi_{meas}(\mathbf{r}, z) = \frac{\mu \exp(-\mu z)}{1 - \exp(-\mu L_z)} \int_0^{L_z} dz' \chi(\mathbf{r}, z') \exp(-\mu z'). \quad (16.144)$$

The reader may fill in the missing steps.

Knowing the decomposition of the template into measurement and null components, we can now begin to make some statements about bias in an ROI estimate. There are several ways to proceed. We can compute the bias (or bounds on the bias) for particular objects as in Sec. 15.1.4, or we can assume some prior knowledge about the class of possible objects. Prior knowledge can be either a statistical model or a deterministic model with unknown parameters. We shall sketch each of these approaches and then discuss objective evaluation of biased estimates.

Pseudoinverse estimators We shall first consider pseudoinverse estimators as discussed in Sec. 15.2.1 and see what we can say about bias for particular objects. Since the parameters of interest and the estimators are linear, we do not have to know anything about the noise in the data to compute the bias, but we note that if the noise is i.i.d. normal, the pseudoinverse estimators are also maximum likelihood.

The general form of a pseudoinverse estimator is given in (15.47). For estimation of a scalar parameter $\Theta \equiv \chi^\dagger \mathbf{f}$, that equation reduces to

$$\hat{\Theta} = \chi^\dagger \mathcal{H}^+ \mathbf{g}. \quad (16.145)$$

This estimate is unbiased if and only if Θ is estimable, which it isn't in the present discussion.

We can construct \mathcal{H}^+ from what we know about the SVD of laterally shift-invariant axial systems (see Sec. 7.2.10). It follows from (7.223), (7.224), (1.116) and (1.121) that

$$[\mathcal{H}^+ \mathbf{g}](\mathbf{r}, z) = \text{rect} \left(\frac{z - \frac{1}{2}L_z}{L_z} \right) \int_{-\infty}^{\infty} d^2\rho \frac{H^*(\boldsymbol{\rho}, z)}{\int_0^{L_z} dz' |H(\boldsymbol{\rho}, z')|^2} G(\boldsymbol{\rho}) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \quad (16.146)$$

If the transfer function is independent of z (as it would be for the intrinsic resolution of an Anger camera), this equation expresses a lateral inverse filter⁷ followed by backprojection in z . For depth-dependent blur, for example due to the collimator, the pseudoinverse is *not* a separate inverse filter at each z .

To go from $\mathcal{H}^+ \mathbf{g}$ to the desired $\hat{\Theta}$, we must take the scalar product with $\chi(\mathbf{r}, z)$; by Parseval's theorem, the result is

$$\hat{\Theta} = \int_0^{L_z} dz \int_{-\infty}^{\infty} d^2\rho \frac{H^*(\boldsymbol{\rho}, z)}{\int_0^{L_z} dz' |H(\boldsymbol{\rho}, z')|^2} X^*(\boldsymbol{\rho}, z) G(\boldsymbol{\rho}), \quad (16.147)$$

where $X(\boldsymbol{\rho}, z)$ is the 2D Fourier transform of $\chi(\mathbf{r}, z)$. (Note that X is capital χ .)

In the absence of blur and attenuation, $H(\boldsymbol{\rho}, z) = \alpha_{pf}/(4\pi L_b^2)$, so (16.147) simplifies to

$$\begin{aligned} \hat{\Theta} &= \frac{4\pi L_b^2}{\alpha_{pf}} \int_{-\infty}^{\infty} d^2\rho \left[\frac{1}{L_z} \int_0^{L_z} dz X^*(\boldsymbol{\rho}, z) \right] G(\boldsymbol{\rho}) \\ &= \frac{4\pi L_b^2}{\alpha_{pf}} \int_{-\infty}^{\infty} d^2r_d \left[\frac{1}{L_z} \int_0^{L_z} dz \chi(r_d, z) \right] g(r_d), \end{aligned} \quad (16.148)$$

⁷Note that $H^*(\boldsymbol{\rho})/|H(\boldsymbol{\rho})|^2 = 1/H(\boldsymbol{\rho})$.

where the last step has again invoked Parseval. In this case, therefore, the pseudoinverse estimate is obtained essentially by taking the scalar product of the data with the projection of the ROI template.

To determine a bound on the bias in the pseudoinverse estimate for some particular object, we can use (15.52). We shall illustrate the procedure by again neglecting attenuation and lateral blur. In that case, it follows from (16.143) that $\max_{\mathbf{r}} |\chi_{null}(\mathbf{r}, z)| = 1$, so the difference between the true Θ and its pseudoinverse estimate is bounded by

$$|\Theta - \hat{\Theta}| \leq \int_{\mathbf{S}(\chi_{null})} d^3\mathbf{r} |f(\mathbf{r})|. \tag{16.149}$$

Since there is no lateral blur, the support of χ_{null} is a cylinder parallel to the z axis and encompassing the ROI; object activity outside this cylinder is irrelevant to estimation of the activity in the ROI. Even with this restriction, however, the bound in (16.149) is not very useful. It says merely that the bias in estimating an integral of the object over an ROI cannot exceed the integral of the object over a cylinder encompassing the ROI. The worst case is when all of the object activity is outside the ROI.

Model-based background subtraction To get a better estimate of Θ in this grossly underdetermined problem, we must have better prior knowledge of the object. One form of prior information is a model for the object with a small number of free parameters.

As an example, consider a spherical ROI immersed in a uniform slab of known thickness but unknown background activity, so there are just two parameters of interest: the integrated activity in the ROI and the activity per unit volume in the background. We assume also, for now, that there is no blur from the detector or collimator, no attenuation and no scattered radiation.

With this model, we can define an unbiased estimator of the ROI activity, in spite of the lack of estimability, since we are not allowing much freedom in the object being imaged. Though the object can have arbitrary structure over the ROI, its behavior outside the region is specified by one number, the activity per unit volume. Recall the basic argument for estimability from Sec. 15.1.3. If a parameter θ is defined by a template $\chi(\mathbf{r})$ as in (15.15), it can be written via (15.19) as $\theta = (\chi_{meas}, \mathbf{f}_{meas}) + (\chi_{null}, \mathbf{f}_{null})$. The first term represents what we can learn about θ from noise-free data, and the second term is zero if either $\mathbf{f}_{null} = 0$ or $\chi_{null} = 0$. We argued in Chap. 15 that we cannot be guaranteed that $\mathbf{f}_{null} = 0$, so therefore we must require $\chi_{null} = 0$; this requirement is unnecessary here since we are, in essence, assuming that the portion of the object outside the ROI contains no null components.

In the absence of blur and attenuation, unbiased estimators of the two unknown parameters can be obtained rather simply. Both parameters contribute to the counts in region A of the image (see Fig. 16.16), but only the background activity contributes to region B . Knowing the geometry, we can estimate the background level from the pixels in B , and we can then construct a new image with no background contribution; summing the pixels in region A for this corrected image then gives an estimate of the activity in the ROI. In terms of estimability, the ROI can be taken as a cylinder in the corrected image rather than a sphere, and the template

defining the cylinder is well approximated as a linear combination of the sensitivity functions, so ROI activity is estimable within this model.

Attenuation can spoil estimability, even in this greatly oversimplified model, since it causes the system sensitivity to vary with depth. In the digital radiography problem discussed in Sec. 16.1.7, the integrated change in x-ray attenuation coefficient over a region of interest was not estimable, even in the absence of blur, because the $1/R^2$ factor seen in (16.64) caused the system sensitivity to depend on depth. For emission-imaging with a parallel-hole collimator, we know from (16.95) that the system sensitivity in air is approximately independent of depth, but attenuation causes a depth dependence. The sensitivity functions all contain an exponential factor, and even a cylinder cannot be synthesized by superimposing them. In order to ignore this effect, we must add more assumptions to our already overburdened model. If we assume that the depth of the spherical ROI is known and the diameter of the sphere is small compared to the reciprocal of the attenuation coefficient, we can correct for attenuation.

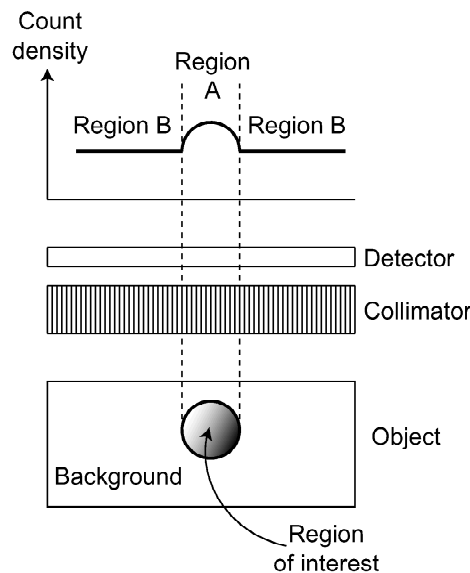

Fig. 16.16 Slab geometry for an idealized estimation problem.

An attempt at being Bayesian Another form of prior information is statistical. A Bayesian assumes that a prior PDF on the object is known and uses that information to minimize some risk function. We shall now pursue this approach in the context of ROI estimation with a quadratic risk.

As with most Bayesian analyses, we choose our prior knowledge not as something we really know but as something that will lead to a tractable solution. In statistics, *tractable* is almost synonymous with *Gaussian*, so we begin by assuming Gaussian statistics for the object and the measurement noise. Since we are regarding the data as continuous here, the noise $n(\mathbf{r}_d)$ is a 2D Gaussian random process and the object $f(\mathbf{r}, z)$ is a 3D one. The object random process is fully specified by the mean vector $\bar{f}(\mathbf{r}, z)$ and the autocovariance function $K_f(\mathbf{r}, \mathbf{r}'; z, z')$, corresponding to the autocovariance operator \mathcal{K}_f . The noise is, by definition, zero mean, and

its autocovariance function is denoted $K_{\mathbf{n}}(\mathbf{r}_d, \mathbf{r}'_d)$, with the corresponding operator being $\mathcal{K}_{\mathbf{n}}$.

We wish to use this prior model to minimize the mean-square error (MSE), averaged over both data realizations and the prior. The minimum-MSE estimate is given in terms of the generalized Wiener filter (see Sec. 13.3.7) as

$$\hat{\Theta}_{MMSE} = \chi^\dagger \hat{\mathbf{f}}_{MMSE} = \chi^\dagger \mathcal{K}_{\mathbf{f}} \mathcal{H}^\dagger \left[\mathcal{H} \mathcal{K}_{\mathbf{f}} \mathcal{H}^\dagger + \mathcal{K}_{\mathbf{n}} \right]^{-1} (\mathbf{g} - \bar{\mathbf{g}}) + \chi^\dagger \bar{\mathbf{f}}. \quad (16.150)$$

Since we have assumed that the imaging system is laterally shift-invariant, the only tractable way to proceed is to assume that the object and noise are laterally stationary. Thus we assume that

$$K_{\mathbf{f}}(\mathbf{r}, \mathbf{r}'; z, z') = K_{\mathbf{f}}(\mathbf{r} - \mathbf{r}'; z, z'), \quad K_{\mathbf{n}}(\mathbf{r}_d, \mathbf{r}'_d) = K_{\mathbf{n}}(\mathbf{r}_d - \mathbf{r}'_d). \quad (16.151)$$

These assumptions are plausible since the template confines our interest in (16.150) to a limited spatial region where the statistics might not vary too much.

Stationarity in z would be much more problematical. We are assuming a slab geometry where the object is contained in $0 < z \leq L_z$, so we definitely cannot assume strict stationarity. A common ruse in this situation is to assume cyclic stationarity, as discussed in Sec. 8.2.8, so that a DFT can be used, but there is no physical justification for this assumption either.

Fortunately, there is no need to assume anything about the z and z' dependence of $K_{\mathbf{f}}(\mathbf{r} - \mathbf{r}'; z, z')$ if we are considering only LSIV axial systems. If we represent this function by its 2D Fourier transform as

$$K_{\mathbf{f}}(\mathbf{r} - \mathbf{r}'; z, z') = \int_{\infty} d^2\rho S_{\mathbf{f}}(\boldsymbol{\rho}; z, z') \exp[2\pi i \boldsymbol{\rho} \cdot (\mathbf{r} - \mathbf{r}')], \quad (16.152)$$

similarly represent \mathcal{H} and $\mathcal{K}_{\mathbf{n}}$ as 2D inverse Fourier transforms, and do a considerable amount of algebra, we find [cf. (16.147)]

$$\hat{\Theta} = \bar{\bar{\Theta}} + \int_0^{L_z} dz \int_{\infty} d^2\rho X^*(\boldsymbol{\rho}, z) W(\boldsymbol{\rho}, z) [G(\boldsymbol{\rho}) - \bar{G}(\boldsymbol{\rho})], \quad (16.153)$$

where $\bar{\bar{\Theta}} = \chi^\dagger \bar{\mathbf{f}}$ is the prior mean of Θ , $\bar{G}(\boldsymbol{\rho})$ is the Fourier transform of $[\mathcal{H}\bar{\mathbf{f}}](\mathbf{r}_d)$ (*i.e.*, the prior mean of the data in the Fourier domain), and $W(\boldsymbol{\rho}, z)$ is a Wiener-like filter defined by

$$W(\boldsymbol{\rho}, z) = \frac{\int_0^{L_z} dz' S_{\mathbf{f}}(\boldsymbol{\rho}; z, z') H^*(\boldsymbol{\rho}, z')}{S_{\mathbf{n}}(\boldsymbol{\rho}) + \int_0^{L_z} dz' \int_0^{L_z} dz'' H(\boldsymbol{\rho}, z') S_{\mathbf{f}}(\boldsymbol{\rho}; z', z'') H^*(\boldsymbol{\rho}, z'')}. \quad (16.154)$$

To understand the behavior of this filter, consider again the case of no blur or attenuation, and suppose that the object has long-range lateral correlations so that $S_{\mathbf{f}}(\boldsymbol{\rho}; z, z')$ is a sharply peaked function of $\boldsymbol{\rho}$. By contrast, $S_{\mathbf{n}}(\boldsymbol{\rho})$ is a constant for uncorrelated noise, so the denominator has a large value near $\boldsymbol{\rho} = 0$, and it rapidly approaches a smaller constant value as ρ increases. We saw just this behavior in Sec. 13.2.12 when we discussed the form of the Hotelling observer for detection in a lumpy background. As shown in Fig. 13.11, the space-domain counterpart of this frequency-domain behavior is a positive peak at the origin and long negative tails. The function of the tails is to estimate and subtract off the background, just as with the Hotelling template. In other words, this Bayesian estimate is simply a more formal way of arriving at the same sort of background subtraction we discussed qualitatively above.

Performance evaluation In both the background-subtraction and Bayesian approaches, we had to make many simplifying assumptions in order to derive an estimate. If we really believed these assumptions, we could use them to compute figures of merit for image quality.

With the model used for background subtraction, the estimator is unbiased and the only randomness arises from the Poisson noise, so we can readily compute the variance in the estimate and use it as the figure of merit. Unfortunately this model is far from reality. We oversimplified the system (neglecting attenuation and blur) and we oversimplified the object description (assuming uniform activity outside the ROI).

With the Bayesian estimator, the objective was to minimize the posterior mean-square error, and a pure Bayesian would then use this MSE as the figure of merit. The difficulty in this approach is that we had to choose the prior for mathematical tractability, not because it accurately represented the randomness in real objects. Indeed, any object prior simple enough for incorporation in a Bayesian estimator is almost certainly unrealistic, and posterior MSE based on this prior is only a measure of self-consistency of our assumptions, not something indicative of performance in practice.

There is, however, nothing that says the estimate has to be evaluated on the basis of the same model under which it was derived. For any estimator, we can simulate a large number of realistic 3D models for the objects, compute the corresponding images, and apply the estimator to each. Since we know the true ROI activity for each simulated image, we can compute bias, variance and hence MSE in a frequentist sense. This MSE is then a joint figure of merit for the estimator and the imaging system.

Estimation of signal parameters So far we have been discussing estimation of parameters of the object, but we know from Sec. 8.4.5 that it is often useful to divide the object into signal and background components; loosely speaking, the signal is the component of the object in which we are most interested. Normally we talk about detection of signals, but there are many situations where we know the signal is there and just want to estimate parameters associated with it (see Sec. 14.3.4). For example, we may want to estimate the volume of a tumor to see if a patient is responding to therapy.

In a series of papers, Müller, Moore, Kijewski and co-workers have used such estimation tasks to evaluate and optimize collimators for planar nuclear medicine (Müller *et al.*, 1986; Müller *et al.*, 1990; Moore *et al.*, 1995). They use relatively simple models for the background and signal, but reach important conclusions regarding the tradeoffs between resolution and sensitivity as bore length and diameter and septal thickness are varied. Their modeling of the physical characteristics of the collimator is quite detailed, taking into account septal penetration and scattering and K x-ray production in the collimator material as well as the effects of multiple energy emissions from some isotopes. Though much further work is needed, the approach suggested by these workers is a model for the use of estimation tasks in system optimization.

17

Single-Photon Emission Computed Tomography

In the last chapter we considered two direct-imaging systems using high-energy radiation; in this chapter we discuss an indirect method called *single-photon emission computed tomography*, or *SPECT*. The modifier *single-photon* distinguishes it from *positron emission tomography*, or *PET*, in which two photons are generated simultaneously and the projection data are formed by coincident detection of both photons. In *SPECT*, a single gamma ray is emitted for each nuclear disintegration, and some sort of collimator is needed to form a projection image.

As in planar nuclear medicine, the object in *SPECT* is a self-luminous volume source. Unlike the planar case, however, the goal in *SPECT* is to provide a 3D map of the source, not a projection of it onto a 2D plane. We shall discuss *SPECT* in detail here because it is an important modality in its own right, but also because it serves as a vehicle for introducing many topics that are important in other kinds of tomography.

As with all digital imaging, *SPECT* systems are most accurately described as CD mappings from a continuous object function to a discrete data set. Much of the literature on *SPECT* and other forms of tomography, however, is based on CC formulations. This literature ignores data sampling (at least initially) and makes various other simplifying assumptions in order to find a linear integral transform, which we shall call the *forward tomographic transform*, that maps a continuous object to continuous mean data. Depending on the geometric model and assumptions made, this forward transform might be the 2D or 3D Radon transform (Sec. 4.4.5), the x-ray transform (Sec. 10.3.2), the cone-beam transform (Sec. 17.1.5), or attenuated versions of any of these.

The objective in this approach is to find another linear integral transform that, under various idealized assumptions, will allow recovery of the object function from the continuous data. We shall call this transform the *inverse tomographic transform*. This inverse transform is then discretized in some manner to get a discrete linear algorithm, which is applied to real, noisy, discrete data rather than to the ide-

alized, noise-free, continuous data assumed in the derivation. This approach works well, in the sense of giving useful images, in a surprisingly large number of cases.

There are two motivations for this emphasis on linear transforms and algorithms. First, there is the basic mathematical understanding that can be obtained from linear transforms. If we can see, based even on an idealized model, what information is contained in our data and how to extract it, we can perhaps use this understanding to improve the design of the imaging system and the algorithm. Second, there is a computational and economic motivation. We can use nonlinear iterative reconstruction algorithms (see Sec. 15.4) to account for factors such as blur, sampling and noise that are necessarily left out of the integral transforms, but iterative algorithms require more computation than one-step linear transforms. Computed tomography came of age at a time when computational power was very limited, and there was a strong motivation for noniterative linear algorithms. Of course, this computational power has grown exponentially, but so too has the ability of practical tomographic systems to acquire data. With 3D data acquisition and ever finer detector resolution, the demands on iterative algorithms have grown apace, and the motivation for linear algorithms remains. It will be interesting to see whether linear transforms or iterative algorithms win out in the decades to come.¹ (The authors of this book believe that the choice must be based on objective measures of image quality as well as on economics.)

Though this chapter is essentially about an inverse problem, we take seriously the maxim: If you want to solve an inverse problem, concentrate on the forward problem. Accordingly, Sec. 17.1 is devoted to analysis of the forward problem for several different data-acquisition geometries. The inverse problem is treated in Sec. 17.2, and issues of noise and image quality are in Sec. 17.3.

17.1 FORWARD PROBLEMS

Methods for the deterministic analysis of imaging systems were developed in Chaps. 6, 7 and 10, and in this section we apply those methods to the mathematical description of the forward problem in SPECT. Our goals are to provide concrete applications of the mathematics from earlier chapters and to lay the ground work for discussing image reconstruction and image quality later in this chapter.

Sections 17.1.1 – 17.1.4 are all devoted to one popular SPECT geometry, where a gamma camera and parallel-hole collimator are rotated around the object. The first three of these sections are based on CD models where a discrete set of projection angles is used, and the projection data at each angle are measured on a discrete array. In particular, Sec. 17.1.1 develops a formal operator theory so that we can see how the system operators \mathcal{H} , \mathcal{H}^\dagger and $\mathcal{H}^\dagger\mathcal{H}$ for SPECT are related to their counterparts for planar nuclear medicine as treated in Sec. 16.2. Then, in Sec. 17.1.2, we consider specifically equally spaced angles and see some of the implications of

¹The tension between linear transforms and iterative algorithms is seen historically as well. Some would argue that tomography could not have existed without the fundamental work of Radon, Bracewell and Cormack on integral transforms, but in fact it was an iterative algorithm implemented by Godfrey Hounsfield that was used in the first commercial CT scanner, and Cormack and Hounsfield shared the Nobel prize for tomography.

group theory; acquaintance with Chap. 6 is essential for this discussion, but the section can be skipped without loss of continuity.

In Sec. 17.1.3 we bring in a different mathematical tool and show how Fourier analysis, in the form of the Fourier crosstalk matrix introduced in Sec. 7.3.3, can be used to analyze practical SPECT systems. The interesting point here is that we can make good use of Fourier analysis without assuming shift-invariance.

In Sec. 17.1.4, we continue the discussion of SPECT systems with parallel-hole collimators, but now from a CC perspective. Our goal here is to relate the actual data-acquisition process to the commonly used idealization, the 2D Radon transform.

Continuing on the theme of forward problems, Sec. 17.1.5 considers 3D CC formulations applicable to pinhole imaging and focused collimators. The goal in this section is to relate the continuous data to the 3D Radon transform (Sec. 4.4.5) and the x-ray or cone-beam transform (Sec. 10.3.2), and also to relate these two apparently different transforms to each other. The effects of attenuation on the forward tomographic operators are discussed in Sec. 17.1.6.

17.1.1 CD formulations for parallel-beam SPECT

The simplest way to acquire data for SPECT is to use a parallel-hole collimator with any suitable gamma-ray detector, such as an Anger camera, and to rotate the collimator-detector assembly around the patient as shown in Fig. 17.1. We already know a great deal about this system from the discussion in Sec. 16.2 of planar nuclear medicine with a parallel-hole collimator, so our main goal here is to see how these planar results apply to rotating-camera SPECT. We shall discuss this problem in the language of CD mappings, where the detector array is a discrete set of elements and the data are acquired at discrete projection angles, but the same formalism will prove useful in a CC context in Sec. 17.2.1. Only the forward problem is discussed here; image reconstruction for this geometry is treated in Secs. 17.2.2 and 17.2.5.

Fig. 17.1 Configuration for acquiring SPECT data with a rotating gamma camera and a parallel-hole collimator. The collimator and camera are rotated as a unit around the patient.

Notation and conventions The formalism developed in Sec. 16.2 for planar imaging with parallel-hole collimators is applicable to parallel-beam SPECT with minor modifications. First, we need to add an index to denote the projection angle. One way to do so is just to consider the vector index on $\bar{g}_{\mathbf{m}}$ to have three components, two to index position on the detector as before and now a third, say j , to indicate projection angle. To avoid confusion with previous notation, we shall use gothic bold \mathbf{m} to denote the 3D index and retain \mathbf{m} as 2D; thus $\mathbf{m} = (m_x, m_y, j) = (\mathbf{m}, j)$.

We also have to be more careful about the specification of the object support now than we were in Sec. 16.2. There we considered the object support to extend to $\pm\infty$ in x and y and from 0 to ∞ in z (where z is normal to the collimator face), or we considered a slab of infinite lateral extent but finite thickness in z . Neither of these options is viable here—it is hard to rotate a camera around an infinite slab. We could consider a cube, but it is useful for the object support to have the same projection for all angles. Therefore we define the region \mathbf{S}_f as a cylinder whose axis coincides with the axis of rotation of the camera, and we define a support function $S_f(\mathbf{r})$ to be unity within this cylinder and zero outside. There is no loss of generality with this definition so long as all objects of interest fit entirely in the support.

With the cylindrical support, the projection operator at angle ϕ_j , denoted \mathcal{H}_j , appears to be just a rotated version of the operator for $\phi = 0$, which we denote \mathcal{H}_0 . This would be true if there were no attenuation, or if the attenuation coefficient were uniform within the cylinder of support, but with a general attenuation distribution, \mathcal{H}_j depends in a more complicated way on the projection angle. We shall come back to the subject of attenuation in Sec. 17.1.6, but for now we simply ignore it.

The forward operator With the cylindrical support and no attenuation, rotating the detector and collimator by ϕ_j is equivalent to rotating the object by $-\phi_j$. Either the object function or the kernel function is transformed according to (7.198), and the mean of the \mathbf{m}^{th} measurement can be written in two equivalent forms as

$$\bar{g}_{\mathbf{m}} = \int_{\mathbf{S}_f} d^3\mathbf{r} h_{\mathbf{m}}(\mathbf{r}) f(\mathbf{R}_j\mathbf{r}) = \int_{\mathbf{S}_f} d^3\mathbf{r} h_{\mathbf{m}}(\mathbf{R}_j^{-1}\mathbf{r}) f(\mathbf{r}), \quad (17.1)$$

where \mathbf{R}_j is a 3×3 rotation matrix,² corresponding to rotation of the detector about the x axis by an angle ϕ_j , and $h_{\mathbf{m}}(\mathbf{r})$ (with a 2D subscript) is the kernel for $\phi_j = 0$. When convenient, we shall also denote $\bar{g}_{\mathbf{m}}$ by $\bar{g}_{\mathbf{m}j}$, and if we wish to consider a fixed j and all \mathbf{m} , we can define a vector $\bar{\mathbf{g}}_j$ with M^2 elements.

We can also express (17.1) in terms of functional operators defined as in Secs. 6.6.1 and 7.2.9. We let \mathcal{T}_j be the functional transformation corresponding to the geometric rotation \mathbf{R}_j , so that

$$\mathcal{T}_j t(\mathbf{r}) = t(\mathbf{R}_j^{-1}\mathbf{r}) \quad (17.2)$$

for an arbitrary function $t(\mathbf{r})$. Then, since \mathcal{T}_j is unitary,

$$f(\mathbf{R}_j\mathbf{r}) = \mathcal{T}_j^\dagger f(\mathbf{r}), \quad (17.3)$$

and (17.1) becomes

$$\bar{\mathbf{g}}_j = \mathcal{H}_0 \mathcal{T}_j^\dagger \mathbf{f}. \quad (17.4)$$

Thus the operator for projection with the camera at angle ϕ_j is

$$\mathcal{H}_j = \mathcal{H}_0 \mathcal{T}_j^\dagger. \quad (17.5)$$

Note that it is not correct to write $\bar{\mathbf{g}}$ as $\sum_j \bar{\mathbf{g}}_j$ or \mathcal{H} as $\sum_j \mathcal{H}_j$; the vector $\bar{\mathbf{g}}_j$ has M^2 elements for an $M \times M$ detector array, but $\bar{\mathbf{g}}$ has JM^2 elements if there are J projection angles; the individual projections are stored separately, not summed. Mathematically speaking, the range of \mathcal{H} is the direct sum of the ranges of the \mathcal{H}_j .

²In Chaps. 6 and 7, rotation matrices were denoted by \mathcal{R} , but we reserve that symbol in this chapter for the Radon transform.

Adjoint operators Next we consider the adjoint or backprojection operator. From (17.5) and property (c) of Sec. 1.3.5, the adjoint operator for a single projection is given formally by

$$\mathcal{H}_j^\dagger = \mathcal{T}_j \mathcal{H}_0^\dagger. \tag{17.6}$$

The meaning of this operator was discussed in Sec. 16.2.2. If we think of \mathcal{H}_j as simple line-integral projection of the 3D object onto a 2D detector, then backprojection amounts to smearing the 2D projection back into the 3D volume defined by the support function. If there is blurring associated with the collimator or detector, then there is an additional blurring in the backprojection step.

When all projections are considered, the adjoint operator is given by

$$\mathcal{H}^\dagger = \sum_{j=0}^{J-1} \mathcal{T}_j \mathcal{H}_0^\dagger, \tag{17.7}$$

or in detail as³

$$[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) = \sum_{j=0}^{J-1} \sum_{\mathbf{m}=1}^M h_{\mathbf{m}}(\mathbf{R}_j^{-1} \mathbf{r}) g_{\mathbf{m}}. \tag{17.8}$$

Now we do have the sum over j ; all projections contribute to the backprojected image at each \mathbf{r} .

Projection-backprojection operator We can now write down expressions for the projection-backprojection operator $\mathcal{H}^\dagger \mathcal{H}$, which we know is fundamental to both SVD and inverse problems. Formally,

$$\mathcal{H}^\dagger \mathcal{H} = \sum_{j=0}^{J-1} \mathcal{H}_j^\dagger \mathcal{H}_j = \sum_{j=0}^{J-1} \mathcal{T}_j \mathcal{H}_0^\dagger \mathcal{H}_0 \mathcal{T}_j^\dagger. \tag{17.9}$$

Explicitly, the kernel of the CC operator $\mathcal{H}^\dagger \mathcal{H}$ is given by (7.238) and (17.1) as

$$k(\mathbf{r}, \mathbf{r}') = \sum_{j=0}^{J-1} \sum_{\mathbf{m}=1}^M h_{\mathbf{m}}(\mathbf{R}_j^{-1} \mathbf{r}) h_{\mathbf{m}}(\mathbf{R}_j^{-1} \mathbf{r}') = \sum_{j=0}^{J-1} k_0(\mathbf{R}_j^{-1} \mathbf{r}, \mathbf{R}_j^{-1} \mathbf{r}'), \tag{17.10}$$

where $k_0(\mathbf{r}, \mathbf{r}')$ is the kernel for $\mathcal{H}_0^\dagger \mathcal{H}_0$.

Weighted Hilbert spaces In the analysis above we have taken both \mathbb{U} and \mathbb{V} as simple Euclidean spaces, but in tomography it is often advantageous to use weighted Hilbert spaces. As in (1.12), we can define the object space by means of the weighted scalar product,

$$(\mathbf{f}_1, \mathbf{f}_2)_{\mathbb{U}} = \int_{\mathbf{S}_f} d^3 \mathbf{r} W(\mathbf{r}) f_1^*(\mathbf{r}) f_2(\mathbf{r}), \tag{17.11}$$

where $W(\mathbf{r})$ is an arbitrary real, nonnegative function; in the present problem it is useful to assume that $W(\mathbf{r})$ is invariant to rotations about the x axis. Similarly,

³Recall that the sum over the 2D multi-index \mathbf{m} means that both components m_x and m_y run from 1 to M , so we are considering an $M \times M$ detector array stepped to J angles.

the finite-dimensional image space can be defined via

$$(\mathbf{g}_1, \mathbf{g}_2)_V = \sum_{j=0}^{J-1} \sum_{\mathbf{m}=1}^M w_{\mathbf{m}} g_{1\mathbf{m}}^* g_{2\mathbf{m}}, \quad (17.12)$$

where $\{w_{\mathbf{m}}\}$ is a set of real, nonnegative weights. It is convenient to choose these weights to be independent of the angular index j .

Using the definition of the adjoint from Sec. 1.3.5, the reader may show that (17.8) now becomes

$$[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) = \frac{1}{W(\mathbf{r})} \sum_{j=0}^{J-1} \sum_{\mathbf{m}=1}^M w_{\mathbf{m}} h_{\mathbf{m}}(\mathbf{R}_j^{-1} \mathbf{r}) g_{\mathbf{m}}. \quad (17.13)$$

17.1.2 Equally spaced angles

So far we have not placed any restrictions on the J projection angles, but now we assume that they are equally spaced around 360° . We therefore let the angular index j run from 0 to $J-1$ and set $\phi_j = j\Delta\phi \equiv 2\pi j/J$. Our goal is to derive an SVD for this system; group theory (see Chap. 6) will prove useful in this endeavor.

Symmetry considerations For J equally spaced angles, the matrices $\{\mathbf{R}_j\}$ form a representation of the group \mathbf{C}_J (see Sec. 6.4.1). If the support functions are invariant under any rotation about the axis, as we have assumed above, then the transformation operators $\{\mathcal{T}_j\}$ also form a representation of \mathbf{C}_J , and each of these operators commutes with $\mathcal{H}^\dagger \mathcal{H}$ (see Sec. 6.7.3).

Mirror symmetries may also be present. If the detector array is invariant to reflection in a mirror plane passing through the axis of rotation, then the full symmetry group is the dihedral group \mathbf{D}_J , discussed in Sec. 6.4.2. The dihedral groups are significantly more complicated than the rotation groups since they are not Abelian. To avoid this complication, we can assume that the detector array is offset laterally by a fraction of a pixel so that the mirror symmetry is broken.

If there are no other symmetries, then, in the language of Sec. 6.7.3, the symmetry group of the system is the Abelian group \mathbf{C}_J . This simple statement allows us to say a great deal about the eigenfunctions of $\mathcal{H}^\dagger \mathcal{H}$, which are also the object-space singular functions in an SVD. We know from Secs. 6.7.5 and 7.2.9 that the eigenfunctions are nondegenerate (*i.e.*, all eigenvalues are distinct). Moreover, each eigenfunction transforms under rotation according to a specific irreducible representation of \mathbf{C}_J . Since all of these irreducible representations are 1D, that means that each eigenfunction of $\mathcal{H}^\dagger \mathcal{H}$ is also an eigenfunction of every \mathcal{T}_j .

These properties suggest that we denote the eigenfunctions with two indices n and k , where k specifies the irreducible representation, and write the eigenvalue equation for $\mathcal{H}^\dagger \mathcal{H}$ as

$$\mathcal{H}^\dagger \mathcal{H} \mathbf{u}_{nk} = \mu_{nk} \mathbf{u}_{nk}. \quad (17.14)$$

The eigenvalue equation for \mathcal{T}_j is

$$\mathcal{T}_j \mathbf{u}_{nk} = \chi_j^{(k)} \mathbf{u}_{nk}. \quad (17.15)$$

We have written the eigenvalue here as $\chi_j^{(k)}$, which is also the character (see Sec. 6.3.3) for \mathcal{T}_j in the k^{th} irreducible representation; since the representation is 1D,

matrix, character and eigenvalue are identical. Specifically, we know from (6.17) that

$$\chi_j^{(k)} = \exp(-2\pi i k j / J). \tag{17.16}$$

Singular-value decomposition Suppose we have solved the eigenvalue problem for a fixed projection angle, say $\phi_j = 0$. That is, we know the solutions to

$$\mathcal{H}_0^\dagger \mathcal{H}_0 \mathbf{u}_n = \mu_n \mathbf{u}_n. \tag{17.17}$$

We would like to use these single-view eigenfunctions to construct eigenfunctions of $\mathcal{H}^\dagger \mathcal{H}$ as given by (17.9).

As we have already noted, each of the eigenfunctions must transform under rotation according to a specific irreducible representation of \mathbf{C}_J , and we saw in Sec. 6.6.3 that we can construct functions with the desired transformation properties by starting with an arbitrary function and projecting it onto the k^{th} irreducible representation. From (6.36), we know that the form of this projection is

$$u_{nk}(\mathbf{r}) = \frac{1}{J} \sum_{j=0}^{J-1} [\chi_j^{(k)}]^* \mathcal{T}_j q_n(\mathbf{r}) = \frac{1}{J} \sum_{j=0}^{J-1} \exp\left(\frac{2\pi i k j}{J}\right) \mathcal{T}_j q_n(\mathbf{r}) \equiv \mathcal{P}_k q_n(\mathbf{r}), \tag{17.18}$$

where \mathcal{P}_k is the projection operator and $q_n(\mathbf{r})$ is yet to be determined. The reader can verify that this $u_{nk}(\mathbf{r})$ satisfies (17.15) as required, and also that \mathcal{P}_k is idempotent and Hermitian as required of all projection operators (see Sec. 1.3.6).

If we use (17.9) along with (17.18) and the spectral representation for $\mathcal{H}_0^\dagger \mathcal{H}_0$, the eigenvalue equation (17.14) becomes

$$\begin{aligned} \mathcal{H}^\dagger \mathcal{H} \mathbf{u}_{nk} &= \frac{1}{J} \sum_{n'=1}^R \sum_{j'=0}^{J-1} \sum_{j=0}^{J-1} \mu_{n'} \exp\left(\frac{2\pi i k j}{J}\right) \mathcal{T}_{j'} \mathbf{u}_{n'} \mathbf{u}_{n'}^\dagger \mathcal{T}_j^\dagger \mathcal{T}_j \mathbf{q}_n \\ &= \mu_{nk} \frac{1}{J} \sum_{j=0}^{J-1} \exp\left(\frac{2\pi i k j}{J}\right) \mathcal{T}_j \mathbf{q}_n, \end{aligned} \tag{17.19}$$

where R is the rank of $\mathcal{H}_0^\dagger \mathcal{H}_0$. If we make the change of variables $\ell = [j - j']$ (where the square brackets denote modulus- J arithmetic) and recognize that $\mathcal{T}_{j'}^\dagger \mathcal{T}_j = \mathcal{T}_\ell$, we can write the left-hand side of (17.19) as

$$\begin{aligned} \mathcal{H}^\dagger \mathcal{H} \mathbf{u}_{nk} &= \frac{1}{J} \sum_{n'=1}^R \sum_{j'=0}^{J-1} \sum_{\ell=0}^{J-1} \mu_{n'} \exp\left[\frac{2\pi i k (\ell + j')}{J}\right] \mathcal{T}_{j'} \mathbf{u}_{n'} \mathbf{u}_{n'}^\dagger \mathcal{T}_\ell \mathbf{q}_n \\ &= J \sum_{n'=1}^R \mu_{n'} [\mathbf{u}_{n'}^\dagger \mathcal{P}_k \mathbf{q}_n] \mathcal{P}_k \mathbf{u}_{n'}. \end{aligned} \tag{17.20}$$

Thus the eigenvalue equation becomes

$$J \sum_{n'=1}^R \mu_{n'} [\mathbf{u}_{n'}^\dagger \mathcal{P}_k \mathbf{q}_n] \mathcal{P}_k \mathbf{u}_{n'} = \mu_{nk} \mathcal{P}_k \mathbf{q}_n, \tag{17.21}$$

and the objective is to find \mathbf{q}_n . In most cases numerical methods are necessary, though we shall encounter a situation in Sec. 17.2.1 where a fully analytical solution

is possible. To gain further insight at this point, however, we shall describe an approximate analytic solution and argue qualitatively that the approximation is reasonable.

Approximate SVD A useful first approximation is $\mathbf{q}_n \propto \mathbf{u}_n$. This choice is based on numerical studies of parallel-hole collimators and multiple-pinhole systems⁴ that indicate that, for all ℓ ,

$$\mathbf{u}_{n'}^\dagger \mathcal{T}_\ell \mathbf{u}_n \approx 0 \quad \text{if } n \neq n'. \quad (17.22)$$

If $\ell = 0$, then $\mathbf{u}_{n'}^\dagger \mathcal{T}_\ell \mathbf{u}_n \equiv 0$ since \mathcal{T}_0 is the unit operator and \mathbf{u}_n and $\mathbf{u}_{n'}$ are both eigenvectors of the Hermitian operator $\mathcal{H}_0^\dagger \mathcal{H}_0$, hence orthogonal if $n \neq n'$. For $\ell \neq 0$, $\mathbf{u}_{n'}$ and $\mathcal{T}_\ell \mathbf{u}_n$ may not be exactly orthogonal, but, as we shall see in an example below, we expect their scalar product to be small.

If (17.22) is satisfied, it follows that $\mathbf{u}_{n'}^\dagger \mathcal{P}_k \mathbf{u}_n$ is approximately zero for $n \neq n'$, so we can dispense with the sum and set $n' = n$ in (17.21). By inspection, we then have

$$\mu_{nk} = J \mu_n \mathbf{u}_n^\dagger \mathcal{P}_k \mathbf{u}_n = \mu_n \sum_{\ell=0}^{J-1} \exp\left(\frac{2\pi i k \ell}{J}\right) \mathbf{u}_n^\dagger \mathcal{T}_\ell \mathbf{u}_n \quad (17.23)$$

and

$$\mathbf{u}_{nk} = N_{nk} \mathcal{P}_k \mathbf{u}_n = \frac{N_{nk}}{J} \sum_{j=0}^{J-1} \exp\left(\frac{2\pi i k j}{J}\right) \mathcal{T}_j \mathbf{u}_n, \quad (17.24)$$

where N_{nk} is a normalizing constant. Solution of the single-view eigenvalue problem thus gives us the solution of the J -view problem under \mathbf{C}_J symmetry in this approximation. As exercises, the reader may show that (a) μ_{nk} is real; (b) \mathbf{u}_{nk} and $\mathbf{u}_{n'k'}$ are orthogonal unless $n = n'$ and $k = k'$; and (c) (17.23) and (17.24) reproduce (17.9).

How good is the approximation? The essential step that led to (17.23) and (17.24) is the assumption that $\mathcal{P}_k \mathbf{u}_n$ is at least approximately orthogonal to $\mathbf{u}_{n'}$ (which follows from the stronger assumption that $\mathcal{T}_\ell \mathbf{u}_n$ is approximately orthogonal to $\mathbf{u}_{n'}$). To check these assumptions, we shall derive the single-view eigenfunctions for a simple model of the imaging system. The model we choose is one treated briefly in Sec. 16.2.3, where we considered a large detector element used with a fine collimator bore, so that the collimator blur was negligible and the system response function was a thin cylindrical ray. The key point of this model is that there is no overlap of the system response functions in a single view.

With this assumption, the eigenfunction \mathbf{u}_n is just the response function itself. To demonstrate this point, we first note that the response functions are indexed by detector elements, so we can replace the index n by the 2D multi-index \mathbf{m} that we customarily use in detector space. From (7.238) with $h_{\mathbf{m}}(\mathbf{r})$ real, we then have

$$\left[\mathcal{H}_0^\dagger \mathcal{H}_0\right] h_{\mathbf{m}}(\mathbf{r}) = \sum_{\mathbf{m}'=1}^M h_{\mathbf{m}'}(\mathbf{r}) \int_{\mathbf{S}_f} d^3 r' h_{\mathbf{m}'}(\mathbf{r}') h_{\mathbf{m}}(\mathbf{r}'). \quad (17.25)$$

⁴Numerical and analytic SVDs of pinhole systems can be found in Aarsvold (1993), and some of the results can be found in Barrett *et al.* (1991). Aarsvold has also done numerical studies of collimator systems but they are unpublished at this writing.

But if there is no overlap of the response functions, the integral is zero unless $\mathbf{m} = \mathbf{m}'$, so

$$\left[\mathcal{H}_0^\dagger \mathcal{H}_0 \right] h_{\mathbf{m}}(\mathbf{r}) = \mu_{\mathbf{m}} h_{\mathbf{m}}(\mathbf{r}), \quad (17.26)$$

where

$$\mu_{\mathbf{m}} = \int_{\mathbf{S}_f} d^3 r' [h_{\mathbf{m}}(\mathbf{r}')]^2. \quad (17.27)$$

The normalized single-view eigenfunctions are given by

$$u_{\mathbf{m}}(\mathbf{r}) = \frac{h_{\mathbf{m}}(\mathbf{r})}{\sqrt{\int_{\mathbf{S}_f} d^3 r h_{\mathbf{m}}^2(\mathbf{r})}}. \quad (17.28)$$

Thus, as expected, the single-view eigenfunctions are proportional to the response functions, provided only that the response functions are orthogonal. In particular, attenuation does not invalidate (17.28). As an exercise, the reader may show that (17.27) and (17.28) lead to the correct expression for $\mathcal{H}_0^\dagger \mathcal{H}_0$.

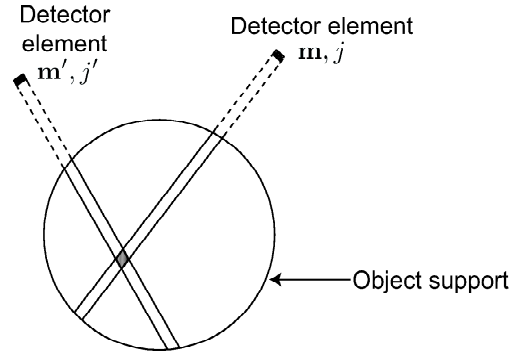

Fig. 17.2 Illustration of the overlap of two single-view response functions. The collimator is not shown, and only a single pixel of the detector is shown at each angular position. It is assumed that the bores of the collimator are very fine so that the response functions are defined by the width of the detector pixel at all points in the object support.

We can now use this overlap-free model to check on the accuracy of (17.22). With (17.28), we can write

$$\mathbf{u}_{\mathbf{m}}^\dagger \mathcal{T}_\ell \mathbf{u}_{\mathbf{m}'} = \frac{\int_{\mathbf{S}_f} d^3 r h_{\mathbf{m}}(\mathbf{r}) [\mathcal{T}_\ell h_{\mathbf{m}'}](\mathbf{r})}{\sqrt{\int_{\mathbf{S}_f} d^3 r h_{\mathbf{m}}^2(\mathbf{r}) \int_{\mathbf{S}_f} d^3 r h_{\mathbf{m}'}^2(\mathbf{r})}}. \quad (17.29)$$

For $\ell \neq 0$, the integrand in the numerator is nonzero only where the single-view response functions $h_{\mathbf{m}}(\mathbf{r})$ and $[\mathcal{T}_\ell h_{\mathbf{m}'}](\mathbf{r})$ overlap. The overlap is identically zero if \mathbf{m} and \mathbf{m}' refer to different x -planes (*i.e.*, $m_x \neq m'_x$), where the x -axis is the axis of rotation. For $m'_x = m_x$, the overlap is the shaded region of Fig. 17.2. For simplicity, we consider a square bore of side ϵ , and we see that

$$\mathbf{u}_{\mathbf{m}}^\dagger \mathcal{T}_\ell \mathbf{u}_{\mathbf{m}'} \approx \frac{\epsilon}{\sqrt{L_{\mathbf{m}} L_{\mathbf{m}'}} |\sin(2\pi\ell/J)|}, \quad \ell \neq 0, \quad m'_x = m_x, \quad (17.30)$$

where $L_{\mathbf{m}}$ is the length of the intersection of the response function $h_{\mathbf{m}}(\mathbf{r})$ and the object support, and we have assumed that $\epsilon/|\sin(2\pi\ell/J)|$ is less than either $L_{\mathbf{m}}$ or $L_{\mathbf{m}'}$. The important point to note about (17.30) is that it goes to zero as $\epsilon \rightarrow 0$ (for fixed J).

To summarize, $\mathbf{u}_{\mathbf{m}}^\dagger \mathcal{T}_\ell \mathbf{u}_{\mathbf{m}'}$ is always identically zero if $\ell = 0$ and $\mathbf{m} \neq \mathbf{m}'$. If there is no overlap of the single-view response functions, then the eigenfunctions are the response functions, and in that case $\mathbf{u}_{\mathbf{m}}^\dagger \mathcal{T}_\ell \mathbf{u}_{\mathbf{m}'} = 0$ if $m'_x \neq m_x$ (for rotation about the x -axis). If the single-view response functions do not overlap, the only case where $\mathbf{u}_{\mathbf{m}}^\dagger \mathcal{T}_\ell \mathbf{u}_{\mathbf{m}'}$ is nonzero is when $\ell \neq 0$, $m'_x = m_x$ and there is overlap of the rays from different views; even in that case $\mathbf{u}_{\mathbf{m}}^\dagger \mathcal{T}_\ell \mathbf{u}_{\mathbf{m}'}$ approaches zero when $\epsilon \rightarrow 0$.

We shall revisit this approximation in Sec. 17.2.1 and give a condition under which it is exact.

17.1.3 Fourier analysis in the CD formulation

Even though the system under consideration is not shift-invariant, we can nevertheless profitably use Fourier methods to describe it. We know from Sec. 7.3.3 that a Fourier *series* is a useful description for a function of compact support and that it leads to the Fourier crosstalk matrix as an exact description of the CD imaging system.

From (7.261) we know that the first step in determining the crosstalk matrix is to compute the response in the data to a single Fourier component, denoted by the vector index⁵ \mathbf{k} . In our present notation, this response is given by [cf. (17.1)]

$$\psi_{\mathbf{m}\mathbf{k}} = \int_{\mathbf{S}_f} d^3\mathbf{r} h_{\mathbf{m}}(\mathbf{r}) \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{R}_j \mathbf{r}) = \int_{\mathbf{S}_f} d^3\mathbf{r} h_{\mathbf{m}}(\mathbf{r}) \exp(2\pi i \mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}), \quad (17.31)$$

where the last form is valid since $\mathbf{R}_j^\dagger = \mathbf{R}_j^{-1}$. Note that we now have a total of six indices on $\psi_{\mathbf{m}\mathbf{k}}$. In the data domain, m_x and m_y specify location on the 2D detector and j specifies projection angle; recall that $\mathbf{m} = (m_x, m_y, j)$. In the object domain, the three components of \mathbf{k} are needed to specify the 3D spatial frequency.

To compute $\psi_{\mathbf{m}\mathbf{k}}$, we can use the same simple model as above where the response function $h_{\mathbf{m}}(\mathbf{r})$ is a thin cylinder of cross-sectional area ϵ^2 , with its axis normal to the detector plane at location \mathbf{m} . For this model and the coordinates we are using (with the origin on the axis of rotation),

$$\begin{aligned} \psi_{\mathbf{m}\mathbf{k}} &\approx \epsilon^2 \exp \left[2\pi i (\mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}})_\perp \cdot \mathbf{r}_{\mathbf{m}} \right] \int_{-L_{\mathbf{m}}/2}^{L_{\mathbf{m}}/2} dz \exp \left[2\pi i (\mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}})_z z \right] \\ &= \epsilon^2 L_{\mathbf{m}} \exp \left[2\pi i (\mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}})_\perp \cdot \mathbf{r}_{\mathbf{m}} \right] \operatorname{sinc} \left[L_{\mathbf{m}} (\mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}})_z \right], \end{aligned} \quad (17.32)$$

where subscript \perp denotes the projection of the 3D vector onto the x - y plane.

We know from (7.263) that the crosstalk matrix \mathbf{B} has elements given by

$$\beta_{\mathbf{k}\mathbf{k}'} = \sum_{\mathbf{m}=1}^M \sum_{j=0}^{J-1} \psi_{\mathbf{m}\mathbf{k}}^* \psi_{\mathbf{m}\mathbf{k}'}. \quad (17.33)$$

⁵The reader should not confuse the index \mathbf{k} used here with the k used above; both denote Fourier series coefficients, but in different senses.

The diagonal elements, which tell us how strongly particular Fourier components are transferred into the data, are given by

$$\beta_{\mathbf{k}\mathbf{k}} = \epsilon^4 \sum_{\mathbf{m}=1}^M \sum_{j=0}^{J-1} L_{\mathbf{m}}^2 \operatorname{sinc}^2 \left[L_{\mathbf{m}} (\mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}})_z \right]. \quad (17.34)$$

This equation is the CD counterpart of the central-slice theorem (see Sec. 4.4.2). It says that the only Fourier components that contribute to the data, for each j , are the ones for which the crests of the wave are nearly parallel to the z axis, so that $(\mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}})_z$ is near zero.

The sum over \mathbf{m} in (17.34) doesn't do much since the summand depends only weakly on that index. For the off-diagonal elements, however, the sum over detector locations is critical. These elements are given by

$$\begin{aligned} \beta_{\mathbf{k}\mathbf{k}'} = \epsilon^4 \sum_{\mathbf{m}=1}^M \sum_{j=0}^{J-1} L_{\mathbf{m}}^2 \operatorname{sinc} \left[L_{\mathbf{m}} (\mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}})_z \right] \operatorname{sinc} \left[L_{\mathbf{m}} (\mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}'})_z \right] \\ \times \exp \left[-2\pi i (\mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}} - \mathbf{R}_j^{-1} \boldsymbol{\rho}_{\mathbf{k}'})_{\perp} \cdot \mathbf{r}_{\mathbf{m}} \right]. \end{aligned} \quad (17.35)$$

Now the summand varies rapidly with the detector index \mathbf{m} , and the sum exhibits complicated aliasing behavior, as we shall see below.

Numerical study of the crosstalk matrix In Fig. 17.3 we show a sequence of crosstalk matrices, generated by D. W. Wilson for various SPECT systems. The figure is a plot of $\beta_{\mathbf{k}\mathbf{k}'}$ as the gray level, with k_x and k'_x as the axes. All of the systems used a detector with 64 elements in one dimension, and it acquired 64 projection at equally spaced angles. The first figure (upper left) shows a nearly ideal system with a parallel-hole collimator but no detector blur, no attenuation and no scatter. In this limit the crosstalk matrix is nearly diagonal, indicating that $\mathcal{H}^{\dagger} \mathcal{H}$ is nearly shift invariant and that image reconstruction should be very easy. Then we progressively add these various degrading effects, moving steadily away from the diagonal condition.

Fig. 17.3 Crosstalk matrices for various SPECT systems, courtesy of D. W. Wilson. *Upper left:* near-ideal system with no attenuation or scatter in the patient. *Upper right:* near-ideal system with attenuation. *Lower left:* same system with attenuation and detector blur. *Lower right:* same system with attenuation, detector blur and scatter.

17.1.4 2D Radon transform and parallel-beam SPECT

There are two ways we can pass to the limit of continuous data in SPECT or other kinds of tomography. First, we can consider very fine sampling by the collimator and detector, so that the discrete detector positions \mathbf{r}_m are replaced by the continuous 2D vector \mathbf{r}_d on the detector plane. Second, we can consider a very large number of projection angles, so that $J \rightarrow \infty$ and the discrete projection angle ϕ_j is replaced by an arbitrary angle ϕ . If we take both of these limits, the mean data can be denoted $\bar{g}(\mathbf{r}_d, \phi)$.

It is also common in the literature to consider only one of the two continuous limits, treating \mathbf{r}_d as continuous but still considering a discrete set of angles. From an engineering perspective, this approach is really backwards: if we want to collect more angles in a rotating-camera system, we can just do so, without any physical or engineering limitation except that more storage space is required for the data. If we want more detector elements, however, it is a major engineering effort, and if we want finer collimators, not only must we be able to fabricate them, we must also accept the inevitable loss of photon collection efficiency. Nevertheless, the hybrid model of discrete angles and continuous detectors has been well studied, and like the fully CC model, it often leads to useful linear algorithms.

Just formally passing to the limit of fine sampling is not sufficient if we want to find a simple forward transform, and hence to have a chance of finding the inverse transform. We must also ignore many physical effects such as detector and collimator blur, attenuation and scatter. In this section we shall specify in detail what assumptions and approximations are needed if we want to reduce the parallel-beam SPECT problem to the 2D Radon transform.

2D Radon transform As discussed in Sec. 4.4.1, the 2D Radon transform consists of 1D line-integral projections of a 2D function. Specifically, the definition is given in (4.139) as

$$\lambda(p, \phi) = [\mathcal{R}_2 \mathbf{f}](p, \phi) = \int_{-\infty}^{\infty} d^2 r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}), \quad (17.36)$$

or simply as $\lambda = \mathcal{R}_2 \mathbf{f}$, where \mathcal{R}_2 is the 2D Radon-transform operator. Recall that $p = \mathbf{r} \cdot \hat{\mathbf{n}}$ is the equation of a line normal to the 2D unit vector $\hat{\mathbf{n}}$ and a distance p from the origin (see Fig. 2.7) and that the origin coincides with the center of rotation.

From irradiance to Radon We shall now build on the discussion in Sec. 16.2.2 to show that the 2D Radon transform is applicable to rotating-camera SPECT if we ignore attenuation in the object and blur from the detector and collimator. A useful starting point for making the connection is (16.82); if we set $\mu_{tot} = 0$ in that equation, we can write the photon irradiance on the detector face as

$$I_p(\mathbf{r}) = \frac{1}{4\pi} \int_{2\pi} d\Omega T(\mathbf{r}, \hat{\mathbf{s}}) \int_0^{\infty} dl f(\mathbf{r} - \hat{\mathbf{s}}l). \quad (17.37)$$

In this expression, $T(\mathbf{r}, \hat{\mathbf{s}})$ is the transmission of the collimator, defined by (16.80) as

$$T(\mathbf{r}, \hat{\mathbf{s}}) = \sum_{\mathbf{n}} \beta(\mathbf{r} - \mathbf{r}_n) \beta\left(\mathbf{r} - \mathbf{s}_{\perp} \frac{L_b}{s_z} - \mathbf{r}_n\right), \quad (17.38)$$

where the sum is over all bores in the collimator, $\beta(\mathbf{r} - \mathbf{r}_n)$ is a 2D function that is unity within the open area of the n^{th} bore and zero otherwise, and $\mathbf{s}_\perp = (s_x, s_y)$ if $\hat{\mathbf{s}} = (s_x, s_y, s_z)$ and the detector plane is normal to the z axis.

We pass to the limit of a very fine collimator by letting

$$\beta(\mathbf{r} - \mathbf{r}_n) \rightarrow A_{bore} \delta(\mathbf{r} - \mathbf{r}_n), \quad \sum_n \cdots \rightarrow \frac{\alpha_{pf}}{A_{bore}} \int_\infty d^2r_n \cdots, \quad (17.39)$$

where A_{bore} is the open area of the collimator bore and α_{pf} is the packing fraction as defined above (16.91). In this limit, we have

$$T(\mathbf{r}, \hat{\mathbf{s}}) \rightarrow \alpha_{pf} A_{bore} \int_\infty d^2r_n \delta(\mathbf{r} - \mathbf{r}_n) \delta\left(\mathbf{r} - \mathbf{s}_\perp \frac{L_b}{s_z} - \mathbf{r}_n\right) = \frac{\alpha_{pf} A_{bore}}{L_b^2} \delta(\mathbf{s}_\perp), \quad (17.40)$$

since $s_z = 1$ if $\mathbf{s}_\perp = 0$. The factor $\delta(\mathbf{s}_\perp)$ indicates that the collimator accepts only the photons that travel normal to the detector face, in a direction that we can denote by $\hat{\mathbf{s}}_d$ (d for detector). As a nontrivial exercise in delta functions, the reader may show that

$$\int_{2\pi} d\Omega \delta(\mathbf{s}_\perp) = 1, \quad (17.41)$$

so (17.37) becomes

$$I_p(\mathbf{r}) \rightarrow \frac{\alpha_{pf} A_{bore}}{4\pi L_b^2} \int_0^\infty dl f(\mathbf{r} - \hat{\mathbf{s}}_d l). \quad (17.42)$$

The factor in front of the integral is recognized from (16.98) as the point-source sensitivity, which is independent of distance from the collimator face with a parallel-hole collimator; it is this fact that makes the Radon transform useful for describing projection data obtained with such collimators.

If there is no detector blur, then the detector measures the photon irradiance directly, but we are not interested in the full 2D photon distribution in this discussion. Instead, we consider a thin stripe of height ϵ_x (where the camera rotation is about the x axis). Photons detected in this stripe originate from a thin slab parallel to the y - z plane. If we denote the coordinates in the detector plane as (x_d, y_d) , we can choose the origin so that the center of this slab is at $x_d = 0$. Then we can define a linear photon density $g_\phi(y_d)$ at projection angle ϕ by

$$g_\phi(y_d) \equiv \int_{-\epsilon_x/2}^{\epsilon_x/2} dx_d I_p(x_d, y_d) \rightarrow \epsilon_x I_p(0, y_d), \quad (17.43)$$

where the last form holds in the limit as $\epsilon_x \rightarrow 0$.

To finish forcing the data to look like a 2D Radon transform, we define a 2D function $f_0(y, z) = f(0, y, z)$ and we let \mathbf{r} now be (y, z) . Then we see that

$$g_\phi(y_d) = \frac{\alpha_{pf} A_{bore} \epsilon_x}{4\pi L_b^2} \int_\infty d^2r f(\mathbf{r}) \delta(y_d - \mathbf{r} \cdot \hat{\mathbf{n}}), \quad (17.44)$$

where $\hat{\mathbf{n}}$ is a 2D unit vector in the y - z plane perpendicular to $\hat{\mathbf{s}}_d$. Thus, finally, we have something that looks like (17.36).

To summarize the assumptions and approximations needed to get (17.44), we had to pass to the limit of vanishingly small collimator bores, we had to neglect

detector blur and sampling, and we had to consider a thin stripe of the photon irradiance on the detector plane. We also implicitly ignored septal penetration in the collimator since (17.38) was derived earlier on the assumption that all photons striking the collimator material were absorbed.

There are many obvious difficulties in these assumptions. Very fine collimators have very little efficiency, as indicated by the factor of A_{bore} in (17.44), and if we chose to make a collimator with fine bores, we would run into problems of septal penetration, invalidating (17.38). Moreover, selecting out a thin stripe of height ϵ_x reduces the photon count further. Finally, we know from the discussions in Chap. 12 that gamma-ray detectors such as the Anger scintillation camera have fundamental limitations on their spatial resolution.

17.1.5 3D transforms and cone-beam SPECT

One consequence of the collimator and detector blur in SPECT is that we cannot really treat the problem as 2D, even with a parallel-hole collimator. When we integrate over a stripe of the data, we are necessarily including contributions from portions of the object outside the corresponding slab in object space. For realistic systems, there is no good substitute for a fully 3D treatment.

For a fully 3D analysis of tomographic systems in CC terms, we have two candidates for the idealized tomographic transform: the 3D Radon transform and the x-ray transform. In this section we shall discuss each of them and show how they relate to practical acquisition geometries. Then we shall show a way in which they relate to each other.

3D Radon transform The 3D Radon transform is very similar in form to the 2D version, (17.36). The definition of the 3D Radon transform is (4.173), but for clarity we modify the notation slightly and write it here as

$$\lambda(p, \hat{\mathbf{n}}) = [\mathcal{R}_3 \mathbf{f}](p, \hat{\mathbf{n}}) = \int_{\infty} d^3 \mathbf{r} f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}), \quad (17.45)$$

where \mathbf{r} and $\hat{\mathbf{n}}$ are 3D vectors (the latter a unit vector). In pure operator form, $\lambda = \mathcal{R}_3 \mathbf{f}$.

In spite of the mathematical similarity of (17.36) and (17.45), they describe rather different physical systems. The equation $p = \mathbf{r} \cdot \mathbf{n}$ describes a line in 2D, but $p = \mathbf{r} \cdot \hat{\mathbf{n}}$ is the equation of a *plane* in 3D. Thus the 2D Radon transform is a useful description for systems where the data consist of integrals of the object over thin tubes, approximating lines, while the 3D Radon transform is useful when the data consist of integrals of the object over thin slabs, approximating planes.

One way to obtain data related to the 3D Radon transform is to acquire 2D line-integral-like projections with a parallel-hole collimator and then to sum over stripes in the 2D image. This is what we did in (17.43) to get to the 2D Radon transform, but in that case the stripe of integration was perpendicular to the rotation axis (x), and the corresponding slab of integration in object space reduced to the plane $x = 0$ as ϵ_x vanished. If we consider more general stripes, we can obtain integrals over other planes. For example, if we integrate the 2D projection at angle $\phi = 0$ over stripes at all angles in the 2D data plane, we obtain the 3D Radon transform for all $\hat{\mathbf{n}}$ lying in the x - y plane. If we then repeat the process for all projection angles, we get the full 3D Radon transform of the object (neglecting attenuation and blur).

A more direct way of acquiring the 3D Radon transform (and collecting more photons in the process) is to use a slat collimator, as shown in Fig. 17.4. This “collimator” actually collimates in only one direction, allowing photons travelling near a plane defined by one of the openings to pass through unimpeded. Thus the detector need not have any spatial resolution in the direction parallel to the slats, and something approximating planar integrals of the object are obtained immediately. It is an interesting exercise in radiometry to work out the precise relation between object and image in this case.

Fig. 17.4 Slat collimator viewing a 3D radioactive object.

3D x-ray transform The x-ray transform, denoted by the operator \mathcal{X} , was defined in Chap. 10 by (10.136) and (10.137). For simplicity, we drop the factor $1/c_m$ used in Chap. 10 and define

$$[\mathcal{X}f](\mathbf{r}, \hat{\mathbf{s}}) = \int_0^\infty dl f(\mathbf{r} - \hat{\mathbf{s}}l), \quad (17.46)$$

where $\hat{\mathbf{s}}$ is a 3D unit vector. (Note that we use $\hat{\mathbf{n}}$ or $\hat{\mathbf{u}}$ for a unit vector normal to a line or plane, but $\hat{\mathbf{s}}$ for a unit vector in a ray direction.)

It is also useful to recast (17.46) into our standard form for a 3D integral transform. By the change of variables $\mathbf{r}' = \mathbf{r} - \hat{\mathbf{s}}l$ and some algebra, or more directly by use of the identity (10.159), we can write

$$[\mathcal{X}f](\mathbf{r}, \hat{\mathbf{s}}) = \int_{-\infty}^{\infty} d^3\mathbf{r}' f(\mathbf{r}') \frac{\delta\left(\hat{\mathbf{s}} - \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|}\right)}{|\mathbf{r} - \mathbf{r}'|^2}. \quad (17.47)$$

In this form, \mathcal{X} appears to map a function of three variables to a function of five variables (x , y , z and two angles), but in practice some subset of these variables will be addressed in any particular measurement geometry.

Like the 2D Radon transform, the x-ray transform involves line integrals. Within the approximations that led to (17.42), each measurement taken with a parallel-hole collimator is one sample of the 3D x-ray transform of the object (as well as one sample of the 2D Radon transform). The difference is that the 2D Radon transform involves lines in the plane of a 2D object, while the 3D x-ray transform involves lines through a volume object. The 3D Radon transform, on the other hand, appears rather different since it involves integrals over planes in the object, but in fact there is an important relation between these two 3D transforms, as we shall see below.

Cone-beam geometries So far the 2D projection systems we have discussed have all used parallel-hole collimators rotated in a circle around the object. An alternative data-acquisition scheme is to acquire each 2D data set with a pinhole rather than a collimator (see Sec. 10.4.2), and to attempt to acquire enough data for 3D reconstruction by moving the pinhole-detector assembly through a sequence of positions. The locus of all positions of the pinhole is called the *trajectory* or *vertex path*, and data are usually acquired at a discrete set of positions along the trajectory (though continuous acquisition is also possible). Many authors argue that a simple circular trajectory is inadequate for 3D reconstruction and advocate more complicated trajectories such as a spiral or a circle plus a line segment.

SPECT data can also be acquired with focused collimators. With both pinholes and focused collimators, the rays involved in each 2D projection of the 3D object pass approximately through a point and hence form a cone. A similar situation occurs in x-ray computed tomography where the rays all emanate from a point (the focal spot on the x-ray tube). The term *cone-beam tomography* is used to describe all of these situations, and the point of the cone is often called the *vertex*.

The idealized CC description of the data in cone-beam tomography in all of these geometries is the 3D x-ray transform (17.46) when we interpret the variable \mathbf{r} as the vertex position \mathbf{r}_v and $\hat{\mathbf{s}}$ as a unit vector along the line from the vertex to a position on the detector.⁶ Since location of the vertex along the trajectory can be specified by a single parameter (distance along the trajectory, say), the 3D x-ray transform maps a function of three variables to another function of three variables in this case.

Many authors refer to (17.46) as the *cone-beam transform*, reserving the term x-ray transform for the special case where the unit vectors $\hat{\mathbf{s}}$ are all parallel. Physically, this would be appropriate if the vertex point \mathbf{r}_v were at an infinite distance from the object support. We prefer not to make this distinction since we often want to consider situations where the object support can be unbounded.

Relation to the Boltzmann transport equation Fundamentally, it is the law of conservation of radiance that makes the x-ray transform so widely applicable. In Sec. 10.3.2 we used the Boltzmann transport equation to show that radiance was conserved at all points along a geometric ray in a non-attenuating medium. By properly defining the source function, we showed in (10.136) that the radiance ($c_m w$) was just a line integral of the source distribution.

This result is exact and holds at all points in space for a non-attenuating medium, but it takes no account of the effects of the detector and image-forming aperture. For a pinhole of finite diameter, a conical set of rays through the object reaches each point on the detector, as illustrated in Fig. 10.9. The *irradiance* at that point is obtained from the *radiance* by integrating it over a range of angles defined by the pinhole (see Sec. 10.4.2). Thus the irradiance at a point is an an-

⁶A minor difference between the pinhole and focused-collimator geometries concerns the direction of $\hat{\mathbf{s}}$. In (17.46), $\mathbf{r}_v - \hat{\mathbf{s}}\ell$ describes a point displaced from the vertex by an amount ℓ in the direction $-\hat{\mathbf{s}}$. If we think of $\hat{\mathbf{s}}$ as pointing generally to the right, that means that the source is to the left of the vertex. Since the detector is to the right of the vertex for pinhole imaging, (17.46) is correct in that case. With a focused collimator, on the other hand, the source is to the right of the vertex, and $\mathbf{r}_v - \hat{\mathbf{s}}\ell$ would describe a point to the left, hence never passing through the source. We can fix that problem either by regarding $-\hat{\mathbf{s}}$ as the ray direction or by changing $\mathbf{r}_v - \hat{\mathbf{s}}\ell$ to $\mathbf{r}_v + \hat{\mathbf{s}}\ell$ in (17.46).

gular integral of line integrals through the object. This cone must not, however, be confused with the cone in cone-beam tomography. Even an ideal point detector *integrates* the radiance over a cone of rays defined by the pinhole, but it is assumed in cone-beam tomography that we can *measure separately* the radiance associated with each ray. The only way to reconcile these views is to assume that the pinhole diameter goes to zero, so that each point on an ideal detector is uniquely associated with a single ray.

Relation between the 3D Radon and x-ray transforms Most approaches to reconstruction from cone-beam data start with a mathematical relation between the 3D Radon and x-ray transforms. That there should be such a relation is perhaps not surprising since we can integrate a single 2D cone-beam projection over a stripe in data space as shown in Fig. 17.5, and when we do, we see that the integral is sensitive to source points on a slab, approximating a plane through the object.

Fig. 17.5 Integration of a single 2D cone-beam projection over a stripe in data space.

One might think that we have, in fact, estimated one sample of the 3D Radon transform in this way, just as we did when we integrated over a stripe in a parallel-beam projection. The key difference, however, is that there is a Jacobian of the form $1/|\mathbf{r} - \mathbf{r}'|^2$ in the integral over the plane in the cone-beam case [see (17.47)], but no such factor with parallel projections. We encountered a similar Jacobian in (16.63) when discussing another form of cone-beam imaging, transmission radiography, and we noted there that we can get an unweighted integral over the object only if the vertex is far away and/or the object is small, so that the cone-beam rays through the object are approximately parallel. Since the vertex is usually placed close to the object in SPECT in order to collect many photons, this is seldom a useful approximation.

Nevertheless, it is possible to recover the 3D Radon transform of a function from knowledge of an appropriate set of values of the x-ray transform. In fact, many different formulas for making this conversion appear in the literature; for an excellent survey, see Natterer and Wübbeling (2001). As this reference emphasizes, all of these formulas can be derived from a single formula originally obtained by Hamaker *et al.*, (1980). In our notation, Hamaker's result can be written as

$$\int_{4\pi} d\Omega_{\hat{\mathbf{s}}} [\mathcal{X}\mathbf{f}](\mathbf{r}, \hat{\mathbf{s}}) h(\hat{\mathbf{s}} \cdot \hat{\mathbf{n}}) = \int_{-\infty}^{\infty} dp [\mathcal{R}_3\mathbf{f}](p, \hat{\mathbf{n}}) h(p - \mathbf{r} \cdot \hat{\mathbf{n}}), \quad (17.48)$$

where $h(\cdot)$ is any function of one variable that is homogeneous of degree -2 , *i.e.*,

$$h(\alpha x) = \frac{1}{\alpha^2} h(x). \quad (17.49)$$

To derive (17.48), we substitute (17.46) into the left-hand side and use our favorite change of variables, $\mathbf{r}' = \mathbf{r} - \hat{\mathbf{s}}\ell$, yielding

$$\int_{4\pi} d\Omega_{\hat{\mathbf{s}}} [\mathcal{X}\mathbf{f}](\mathbf{r}, \hat{\mathbf{s}}) h(\hat{\mathbf{s}} \cdot \hat{\mathbf{n}}) = \int_{\infty} d^3\mathbf{r}' f(\mathbf{r}') \frac{1}{|\mathbf{r} - \mathbf{r}'|^2} h\left(\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \cdot \hat{\mathbf{n}}\right), \quad (17.50)$$

which, with the use of (17.45) and (17.49), gives the right-hand side of (17.48).

A derivative formula An important special case of Hamaker's formula is where $h(x)$ is the derivative of a delta function, $h(x) = \delta'(x)$. This function satisfies the homogeneity condition (17.49) for $\alpha > 0$, which is all we need. With this choice and (2.57), (17.48) becomes

$$\begin{aligned} \int_{4\pi} d\Omega_{\hat{\mathbf{s}}} [\mathcal{X}\mathbf{f}](\mathbf{r}, \hat{\mathbf{s}}) \delta'(\hat{\mathbf{s}} \cdot \hat{\mathbf{n}}) &= \int_{-\infty}^{\infty} dp [\mathcal{R}_3\mathbf{f}](p, \hat{\mathbf{n}}) \delta'(p - \mathbf{r} \cdot \hat{\mathbf{n}}) \\ &= - \left\{ \frac{\partial}{\partial p} [\mathcal{R}_3\mathbf{f}](p, \hat{\mathbf{n}}) \right\}_{p=\mathbf{r} \cdot \hat{\mathbf{n}}}. \end{aligned} \quad (17.51)$$

Geometrically, all three forms in (17.51) involve the neighborhood of the same plane, namely the plane $p = \mathbf{r} \cdot \hat{\mathbf{n}}$. Since $[\mathcal{X}\mathbf{f}](\mathbf{r}, \hat{\mathbf{s}})$ is measured only for $\mathbf{r} = \mathbf{r}_v$, where \mathbf{r}_v is one of the vertex positions, we must have $p = \mathbf{r}_v \cdot \hat{\mathbf{n}}$, so the equation of the plane of interest can also be written as $(\mathbf{r} - \mathbf{r}_v) \cdot \hat{\mathbf{n}} = 0$. The derivative on the right-hand side in (17.51) can be computed just from values of $\mathcal{R}_3\mathbf{f}$ arbitrarily close to this plane. The delta derivative on the left-hand side then requires that $\hat{\mathbf{s}} \cdot \hat{\mathbf{n}} = 0$, which means that the only rays of interest are ones that travel in the plane from \mathbf{r}_v toward the detector.

The derivative of a delta function in the middle form of (17.51) is essentially the basis function for the dipole-sheet transform, introduced in Sec. 4.4.5.

17.1.6 Attenuation

Our discussion of ECT so far has consistently neglected attenuation of the radiation in the object, but in practice attenuation can lead to serious image degradation. Ways of compensating for attenuation during reconstruction are discussed in Sec. 17.2.4, but here we collect some mathematical properties of the forward transforms.

Attenuated x-ray transform The attenuated x-ray transform was originally defined in (10.151), but we write it slightly differently here. We drop the factor of $1/c_m$, which was handy in the radiometry discussion but superfluous here, and we drop the subscript on the total attenuation coefficient μ_{tot} . Thus we define

$$[\mathcal{X}_{\mu}\mathbf{f}](\mathbf{r}, \hat{\mathbf{s}}) = \int_0^{\infty} d\ell f(\mathbf{r} - \hat{\mathbf{s}}\ell) \exp\left[-\int_0^{\ell} d\ell' \mu(\mathbf{r} - \hat{\mathbf{s}}\ell')\right]. \quad (17.52)$$

With the same manipulation as in (17.47), we can also write

$$[\mathcal{X}_{\mu}\mathbf{f}](\mathbf{r}, \hat{\mathbf{s}}) = \int_{\infty} d^3\mathbf{r}' f(\mathbf{r}') \frac{\delta\left(\hat{\mathbf{s}} - \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|}\right)}{|\mathbf{r} - \mathbf{r}'|^2} \exp\left[-\int_0^{|\mathbf{r} - \mathbf{r}'|} d\ell' \mu(\mathbf{r} - \hat{\mathbf{s}}\ell')\right]. \quad (17.53)$$

Thus, if we let \mathbf{r} be the vertex position \mathbf{r}_v , radiation originating at point \mathbf{r}' and travelling toward the vertex is attenuated by a factor determined by the line integral of μ along the line from \mathbf{r}' to \mathbf{r}_v .

Attenuated 2D Radon transform Since the 2D Radon transform is really the same thing as the x-ray transform with rays confined to a plane, we can regard (17.52) as also defining the 2D attenuated Radon transform if we simply treat \mathbf{r} and $\hat{\mathbf{s}}$ as 2D vectors. To make the transform look like (17.36), however, we write

$$\lambda_\mu(p, \phi) = [\mathcal{R}_{2,\mu}\mathbf{f}](p, \phi) = \int_\infty d^2r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) \exp \left[- \int_0^\infty d\ell' \mu(\mathbf{r} + \hat{\mathbf{n}}_\perp \ell') \right], \tag{17.54}$$

where $\hat{\mathbf{n}}_\perp$ is normal to $\hat{\mathbf{n}}$ and in the 2D plane where $f(\mathbf{r})$ is defined (see Fig. 17.6). Since the delta function selects out a line perpendicular to $\hat{\mathbf{n}}$, it follows that $\hat{\mathbf{n}}_\perp$ is the ray direction. Specifically, if $\hat{\mathbf{n}}$ makes an angle ϕ with the y axis, then $\hat{\mathbf{n}}_\perp$ makes an angle ϕ with the z axis in the 3D coordinate system where the axis of rotation is the x axis. Now the line integral runs from the source point \mathbf{r} to infinity, but that really means to the boundary of the attenuating medium since $\mu(\mathbf{r})$ is zero beyond that point.

Fig. 17.6 Geometry used in discussing the attenuated 2D Radon transform.

Exponential 2D Radon transform Sometimes it is useful to assume that the attenuation coefficient is constant within the object of interest. For example, in SPECT imaging of the abdomen, the attenuating material is mostly soft tissue. Differences in attenuation among different soft tissues are small, so little error is made by replacing the actual attenuation distribution $\mu(\mathbf{r})$ with a constant μ . Then the attenuation factor in (17.54) becomes

$$\exp \left[- \int_0^\infty d\ell' \mu(\mathbf{r} + \hat{\mathbf{n}}_\perp \ell') \right] \approx \exp [-\mu L(\mathbf{r}, \phi)], \tag{17.55}$$

where $L(\mathbf{r}, \phi)$ is the total length of attenuating medium between point \mathbf{r} and the detector in direction $\hat{\mathbf{n}}_\perp$. If we assume that the boundary of the attenuating medium is convex, we can decompose this length further as (see Fig. 17.6)

$$L(\mathbf{r}, \phi) = L_0(p, \phi) - \mathbf{r} \cdot \hat{\mathbf{n}}_\perp, \tag{17.56}$$

where $L_0(p, \phi)$ is the distance to the boundary of the medium in direction $\hat{\mathbf{n}}_\perp$ from a point on the line running through the center of rotation. Since $L_0(p, \phi)$ is independent of \mathbf{r} , it can be taken out of the integral, and the attenuated 2D Radon

transform becomes

$$\lambda_\mu(p, \phi) = \exp[-\mu L_0(p, \phi)] \int_{-\infty}^{\infty} d^2r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) \exp(\mu \mathbf{r} \cdot \hat{\mathbf{n}}_\perp). \quad (17.57)$$

The first exponential factor is known if the object contour is specified, so we can move it to the other side of the equation and define a modified projection,

$$g_\mu(p, \phi) \equiv \exp[\mu L_0(p, \phi)] \lambda_\mu(p, \phi) = \int_{-\infty}^{\infty} d^2r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) \exp(\mu \mathbf{r} \cdot \hat{\mathbf{n}}_\perp). \quad (17.58)$$

The right-hand side defines the *2D exponential Radon transform* $\mathcal{R}_{2e, \mu}$. The reader is cautioned that this transform is often seen with a minus sign in the exponent, but that comes about when $\hat{\mathbf{n}}_\perp$ is taken to be antiparallel to the ray direction instead of parallel.

Why not a 3D attenuated Radon? Since the 3D Radon transform involves integrals of the activity distribution $f(\mathbf{r})$ over planes and the attenuation factors involve integrals of the attenuation distribution $\mu(\mathbf{r})$ along lines, there is no unique way to define an attenuated 3D Radon transform. We noted in Sec. 17.1.5 that we could get 3D Radon data by starting with line-integral projections taken with a parallel-hole collimator and then integrating over a stripe in the 2D data space; in this case the attenuation factors would be determined by lines of sight through the collimator bores. Many different combinations of projection angles and stripes of integration would, however, integrate the activity over the same plane, but with different attenuation factors. For example, if we want to know the integral of $f(\mathbf{r})$ over the plane $x = 0$, we can get it by integrating the photon irradiance $I_p(x_d, y_d)$ over $-\frac{1}{2} < x_d \leq \frac{1}{2}$ and over all y_d in the detector plane [cf. (17.43)]. This procedure gives the same answer for all projection angles ϕ in the absence of attenuation, but the attenuation factors are different for different ϕ .

Similarly, if we consider other detection geometries such as the slit collimator of Fig. 17.4, or if we derive the 3D Radon data by mathematical manipulation of cone-beam data as suggested by (17.51), still other attenuation factors arise. In short, as soon as we combine planar integrals of the activity with line integrals of the attenuation, then many different versions of the attenuated transform can occur; very few of them have been explored in the literature.

17.2 INVERSE PROBLEMS

Having catalogued the various formulations of the forward problem in SPECT, we can now discuss inverse problems. The discussion will range from purely theoretical inversion formulas based on idealized models of the forward problem, through practical issues of how the idealized expressions are discretized for computation, to comprehensive iterative algorithms that make essentially no assumptions about the data-acquisition process.

We begin in Secs. 17.2.1–17.2.3 by discussing the SVD of some specific CC forward operators. The operator formalism from Sec. 17.1.1 and the group-theoretic considerations from Sec. 17.1.2 recur in this discussion. In particular, Sec. 17.2.1 derives SVDs for the 2D Radon operator, first with infinite object support and continuous angular sampling, then with finite support and a finite number of projection

angles. In Sec. 17.2.2, the SVD results are used to derive analytic inverses of the full 2D Radon transform and pseudoinverses in the case of finite angular sampling. In Sec. 17.2.3, we discuss inversion formulas for the 3D x-ray transform, and in Sec. 17.2.4 we consider transforms with attenuation factors.

In Secs. 17.2.5 and 17.2.6, we turn, at last, to practical reconstruction algorithms that can be applied to discrete data. Linear algorithms obtained by discretizing analytic inverses are discussed in Sec. 17.2.5, and ways of forming system matrices for iterative nonlinear algorithms are discussed in Sec. 17.2.6. The algorithms themselves have previously been treated in Sec. 15.4.

17.2.1 SVD of the 2D Radon transform

Study of the properties of tomographic transforms is sometimes referred to as *integral geometry*. The ultimate goal of research in this field is the full singular-value decomposition of each transform, from which one can discuss inversion formulas, null functions, data-consistency conditions and ill-posedness. This goal represents a rich source of papers since there are many different transforms, many specific geometries for each transform (*e.g.*, many trajectories in cone-beam tomography) and many ways to define scalar products and hence Hilbert spaces.

In this section we look in some detail at SVD of the 2D Radon transform and its close relatives; in the following section we shall use these SVDs to discuss inverses and pseudoinverses in various 2D problems.

Radon transform on the infinite plane With what we have learned in previous chapters, it is straightforward to give a singular-value decomposition of the 2D Radon transform, so long as we do not impose any constraints on the object support. That is, we use the Hilbert spaces defined as in Sec. 4.4.1, where the object is square-integrable over the infinite plane⁷ and the scalar product in data space is defined by the measure $dp d\phi$; neither space involves any weighting function. We shall discuss this SVD problem first and then address finite object support, finite angular sampling and weighted Hilbert spaces.

With infinite support and no weights, we know from (4.167) that the operator $\mathcal{R}_2^\dagger \mathcal{R}_2$ is a 2D convolution:

$$\left[\mathcal{R}_2^\dagger \mathcal{R}_2 \mathbf{f} \right] (\mathbf{r}) = \int_{\infty} d^2 r' \frac{f(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}. \quad (17.59)$$

We know also from Sec. 7.2.4 that the eigenfunctions of convolution operators are complex exponentials and that the eigenvalues are given by the transfer function; see (7.140) and (7.141). For the 2D Radon transform, the relevant eigenvalue equation is

$$\mathcal{R}_2^\dagger \mathcal{R}_2 \mathbf{u}_\rho = \mu_\rho \mathbf{u}_\rho. \quad (17.60)$$

⁷Use of this Hilbert space does not imply that any actual object has infinite extent; objects with finite support and finite values are, of course, square-integrable over the plane, hence members of the space. The fact that some members of the space are not realizable objects should not concern us. Any Hilbert space we choose will contain functions that cannot be objects, if for no other reason than that objects in tomography are nonnegative.

From (7.140), the Hilbert-space eigenvector \mathbf{u}_ρ corresponds to the eigenfunction

$$u_\rho(\mathbf{r}) = \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}), \quad (17.61)$$

where $\boldsymbol{\rho}$ is a 2D spatial-frequency vector. The operator is not compact (see Sec. 1.3.3), so a continuous index $\boldsymbol{\rho}$ is needed, and the eigenfunctions span the space $\mathbb{L}_2(\mathbb{R}^2)$ but are not themselves square-integrable; see Sec. 1.4.4 for further discussion of these subtleties.

From (7.141) and (4.169), the continuous eigenvalue spectrum is given by

$$\mu_\rho = \mathcal{F}_2 \left\{ \frac{1}{r} \right\} = \frac{1}{|\rho|}, \quad (17.62)$$

where the absolute-value signs are needed if we allow ρ to be signed, so that $\rho = \pm|\boldsymbol{\rho}|$. Eigenfunctions of the Hermitian operator $\mathcal{R}_2^\dagger \mathcal{R}_2$ are the same as the object-space singular functions of \mathcal{R}_2 , but we still need to determine the image-space singular functions to complete the SVD.

To get the image-space singular functions corresponding to nonzero singular values, we can use (7.122), which in the present case is written

$$v_\rho(p, \phi) = \frac{1}{\sqrt{\mu_\rho}} [\mathcal{R}_2 \mathbf{u}_\rho](p, \phi). \quad (17.63)$$

The reader with some degree of virtuosity in delta functions can show that

$$v_\rho(p, \phi) = \sqrt{|\rho|} \exp(2\pi i p \rho) \delta(\boldsymbol{\rho} \cdot \hat{\mathbf{n}}_\perp) = \frac{1}{\sqrt{|\rho|}} \exp(2\pi i p \rho) \delta(\hat{\boldsymbol{\rho}} \cdot \hat{\mathbf{n}}_\perp), \quad (17.64)$$

where $\hat{\boldsymbol{\rho}}$ is the unit vector parallel to $\boldsymbol{\rho}$. A similar exercise shows that both sets of singular functions are orthonormal, in the sense that

$$\mathbf{u}_\rho^\dagger \mathbf{u}_{\rho'} = \delta(\boldsymbol{\rho} - \boldsymbol{\rho}'), \quad \mathbf{v}_\rho^\dagger \mathbf{v}_{\rho'} = \delta(\rho - \rho'), \quad (17.65)$$

and that both sets of functions are complete,⁸ so that

$$\int_\infty d^2\rho \, u_\rho(\mathbf{r}) u_\rho^*(\mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}'), \quad \int_\infty d^2\rho \, v_\rho(p, \phi) v_\rho^*(p', \phi') = \delta(p - p') \delta(\phi - \phi'). \quad (17.66)$$

Another interesting exercise is to show that (17.64)–(17.66) are dimensionally correct.

Note that the delta function in (17.64) is 1D, since its argument is a scalar product. For fixed $\boldsymbol{\rho}$, this delta function shows that the image-space singular function is zero unless $\boldsymbol{\rho}$ is normal to $\hat{\mathbf{n}}_\perp$, which means that the line of integration is parallel to the crests of the function $\exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r})$. If we integrate in any other direction, the line of integration will cut across positive and negative portions of the function, giving a zero integral.

Since both sets of singular functions are complete, neither \mathcal{R}_2 nor \mathcal{R}_2^\dagger has null functions for the present choice of Hilbert spaces. We shall soon see, however, that \mathcal{R}_2 does have null functions if we consider a finite set of angles, and \mathcal{R}_2^\dagger has null functions if we impose a finite object support.

⁸Completeness of the image-space functions requires that ρ be allowed to take on positive and negative values.

Finite set of angles Suppose we acquire J 2D projections at the angles $\{\phi_j, j = 0, \dots, J-1\}$ (not necessarily equally spaced), so that we have a mixed CC/CD problem: the projection data are functions of the continuous p variable and the discrete angular index j . Then we can define a new Radon operator \mathcal{R}_{2J} by

$$[\mathcal{R}_{2J}\mathbf{f}](p, \phi_j) = \int_{-\infty}^{\infty} d^2r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}_j) \quad j = 0, \dots, J-1, \quad (17.67)$$

where $\hat{\mathbf{n}}_j$ makes angle ϕ_j with the x axis.

The projection-backprojection operator is given by

$$[\mathcal{R}_{2J}^\dagger \mathcal{R}_{2J}\mathbf{f}](\mathbf{r}) = \sum_{j=0}^{J-1} \int_{-\infty}^{\infty} dp \int_{-\infty}^{\infty} d^2r' f(\mathbf{r}') \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}_j) \delta(p - \mathbf{r}' \cdot \hat{\mathbf{n}}_j). \quad (17.68)$$

Using one of the delta functions to perform the p integral, we obtain

$$[\mathcal{R}_{2J}^\dagger \mathcal{R}_{2J}\mathbf{f}](\mathbf{r}) = \int_{-\infty}^{\infty} d^2r' f(\mathbf{r}') \left\{ \sum_{j=0}^{J-1} \delta[(\mathbf{r} - \mathbf{r}') \cdot \hat{\mathbf{n}}_j] \right\}. \quad (17.69)$$

The key point here is that the kernel (the quantity in large curly brackets) is a function of $\mathbf{r} - \mathbf{r}'$, so this operator is still a convolution. The PSF is a radial spoke pattern that limits to a $1/r$ function as $J \rightarrow \infty$.

Since $\mathcal{R}_{2J}^\dagger \mathcal{R}_{2J}$ is a convolution, its eigenfunctions are still given by the complex exponentials (17.61), and its eigenvalues are given by the Fourier transform of the PSF as

$$\mu_{\boldsymbol{\rho}} = \mathcal{F}_2 \left\{ \sum_{j=0}^{J-1} \delta(\mathbf{r} \cdot \hat{\mathbf{n}}_j) \right\} = \sum_{j=0}^{J-1} \int_{-\infty}^{\infty} d^2r \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) \delta(\mathbf{r} \cdot \hat{\mathbf{n}}_j), \quad (17.70)$$

where the delta function is 1D since its argument is a scalar. The integral can be evaluated in a Cartesian coordinate system where $\mathbf{r} \cdot \hat{\mathbf{n}}_j = x$, and the result is

$$\mu_{\boldsymbol{\rho}} = \sum_{j=0}^{J-1} \delta(\boldsymbol{\rho} \cdot \hat{\mathbf{n}}_{\perp j}) = \frac{1}{\rho} \sum_{j=0}^{J-1} \delta[\sin(\theta_{\boldsymbol{\rho}} - \phi_j)], \quad (17.71)$$

where $\hat{\mathbf{n}}_{\perp j}$ is the unit vector normal to $\hat{\mathbf{n}}_j$. The delta function vanishes unless $\boldsymbol{\rho}$ is perpendicular to one of the directions $\hat{\mathbf{n}}_{\perp j}$, hence parallel to one of the $\hat{\mathbf{n}}_j$. As we would expect from the central-slice theorem (4.150), the eigenvalues $\mu_{\boldsymbol{\rho}}$ are zero except for values of $\boldsymbol{\rho}$ along a set of radial spokes in the 2D frequency plane. Frequencies not on these spokes correspond to null functions of \mathcal{R}_{2J} .

As a check on this formalism, we can compute the spectral representation of the projection-backprojection operator, which is given abstractly by

$$\mathcal{R}_{2J}^\dagger \mathcal{R}_{2J} = \int_{-\infty}^{\infty} d^2\rho \mu_{\boldsymbol{\rho}} \mathbf{u}_{\boldsymbol{\rho}} \mathbf{u}_{\boldsymbol{\rho}}^\dagger = \sum_{j=0}^{J-1} \int_{-\infty}^{\infty} d^2\rho \delta(\boldsymbol{\rho} \cdot \hat{\mathbf{n}}_{\perp j}) \mathbf{u}_{\boldsymbol{\rho}} \mathbf{u}_{\boldsymbol{\rho}}^\dagger. \quad (17.72)$$

Explicitly,

$$[\mathcal{R}_{2J}^\dagger \mathcal{R}_{2J}\mathbf{f}](\mathbf{r}) = \sum_{j=0}^{J-1} \int_{-\infty}^{\infty} d^2\rho \delta(\boldsymbol{\rho} \cdot \hat{\mathbf{n}}_{\perp j}) \exp(2\pi i \mathbf{r} \cdot \boldsymbol{\rho}) \int_{-\infty}^{\infty} d^2r' \exp(-2\pi i \mathbf{r}' \cdot \boldsymbol{\rho}) f(\mathbf{r}'). \quad (17.73)$$

The integral over $\boldsymbol{\rho}$ can be performed in Cartesian coordinates with axes defined by $\hat{\mathbf{n}}_j$ and $\hat{\mathbf{n}}_{\perp j}$, and we obtain

$$\left[\mathcal{R}_{2J}^\dagger \mathcal{R}_{2J} \mathbf{f}\right](\mathbf{r}) = \sum_{j=0}^{J-1} \int_{-\infty}^{\infty} d^2 r' \delta[(\mathbf{r} - \mathbf{r}') \cdot \hat{\mathbf{n}}_j] f(\mathbf{r}'), \quad (17.74)$$

in accord with (17.69).

To complete the SVD of \mathcal{R}_{2J} , we need the image-space eigenfunctions. These functions are given by (17.63), but there is a complication since μ_ρ involves a delta function, and we don't know how to take the square root of a delta function. We might solve this problem with limiting representations, but we can avoid it altogether by going directly to the SVD representation of \mathcal{R}_{2J} . From (1.120) (as extended to continuous indices) and (17.63),

$$\mathcal{R}_{2J} = \int_{-\infty}^{\infty} d^2 \rho \sqrt{\mu_\rho} \mathbf{v}_\rho \mathbf{u}_\rho^\dagger = \int_{-\infty}^{\infty} d^2 \rho \sqrt{\mu_\rho} \left[\frac{1}{\sqrt{\mu_\rho}} \mathcal{R}_{2J} \mathbf{u}_\rho \right] \mathbf{u}_\rho^\dagger = \int_{-\infty}^{\infty} d^2 \rho [\mathcal{R}_{2J} \mathbf{u}_\rho] \mathbf{u}_\rho^\dagger. \quad (17.75)$$

Now the awkward square-root factor has cancelled,⁹ and we need only compute $\mathcal{R}_{2J} \mathbf{u}_\rho$, which is given by

$$[\mathcal{R}_{2J} \mathbf{u}_\rho](p, \phi_j) = \int_{-\infty}^{\infty} d^2 r \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}_j) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) = \exp(2\pi i \rho p) \delta(\boldsymbol{\rho} \cdot \hat{\mathbf{n}}_{j\perp}). \quad (17.76)$$

The reader should verify that (17.75) gives the right answer when applied to an arbitrary $f(\mathbf{r})$.

Finite support and finite angular sampling Next we consider the case of finite object support and J equally spaced angles around 2π (\mathbf{C}_J symmetry). We laid much of the groundwork for this problem in Secs. 17.1.1 and 17.1.2, and we now apply that treatment to the 2D Radon transform.

Specifically, the operator \mathcal{H} used in those sections is now to be identified with \mathcal{R}_{2J} , and the single-view projection operator \mathcal{H}_0 is defined by

$$\lambda_0(p) = [\mathcal{H}_0 \mathbf{f}](p) = \int_{\mathbf{S}_f} d^2 r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}_0), \quad (17.77)$$

where $\hat{\mathbf{n}}_0$ is parallel to the x axis if \mathbf{r} is chosen to lie in the x - y plane.

As in Sec. 17.1.2, we suppose that we have solved the eigenvalue problem for \mathcal{H}_0 , so we know the solutions to

$$\mathcal{H}_0^\dagger \mathcal{H}_0 \mathbf{u}_n = \mu_n \mathbf{u}_n. \quad (17.78)$$

We would like to use these single-view eigenfunctions to solve the eigenvalue problem for $\mathcal{H}^\dagger \mathcal{H}$, which is now the same as $\mathcal{R}_{2J}^\dagger \mathcal{R}_{2J}$. The solution is given by (17.23) and (17.24), but these results were based on the approximation in (17.22) that $\mathbf{u}_n^\dagger \mathcal{T}_\ell \mathbf{u}_n \approx 0$ if $n \neq n'$. We shall now show how this approximation can be made exact in the Radon problem.

⁹Equivalently, we could have derived the final form of (17.75) immediately by writing $\mathcal{R}_{2J} = \mathcal{R}_{2J} \mathbf{I}$ and using the completeness of the object-space eigenfunctions to express the unit operator \mathbf{I} .

Weighted Hilbert spaces Weighted Hilbert spaces, which we first mentioned in a CD context in Sec. 17.1.1, are a great help in finding an SVD of \mathcal{R}_{2J} . If the object support \mathbf{S}_f is the disk of radius R , a general weighted scalar product is defined similarly to (17.11) as

$$(\mathbf{f}_1, \mathbf{f}_2)_U = \int_{\mathbf{S}_f} d^2r W(r) f_1^*(\mathbf{r}) f_2(\mathbf{r}), \tag{17.79}$$

where $W(r) > 0$ for all $r < R$.

For a finite set of angles $\{\phi_j, j = 0, \dots, J - 1\}$, the scalar product in 2D Radon space can be defined by

$$(\lambda_1, \lambda_2)_V = \sum_{j=0}^{J-1} \int_{-R}^R dp w(p) \lambda_1^*(p, \phi_j) \lambda_2(p, \phi_j). \tag{17.80}$$

(Note that we have maintained the rotational symmetry by making the weighting functions independent of angle.) With these scalar products, the single-view adjoint operator is given by [cf. (17.13)]

$$[\mathcal{H}_0^\dagger \lambda_0](\mathbf{r}) = \frac{1}{W(\mathbf{r})} \int_{-R}^R dp w(p) \lambda_0(p) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}_0) = \frac{w(\mathbf{r} \cdot \hat{\mathbf{n}}_0)}{W(\mathbf{r})} \lambda_0(\mathbf{r} \cdot \hat{\mathbf{n}}_0). \tag{17.81}$$

Davison and Grunbaum (1981) suggest that the weights be chosen such that

$$\frac{1}{w(p)} = \int_{\mathbf{S}_f} d^2r \frac{1}{W(r)} \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) \tag{17.82}$$

for all $\hat{\mathbf{n}}$. The beauty of this condition is that it turns the single-view operator $\mathcal{H}_0 \mathcal{H}_0^\dagger$ into the unit operator, as we can see by calculating the kernel:

$$\begin{aligned} [\mathcal{H}_0 \mathcal{H}_0^\dagger](p, p') &= \int_{\mathbf{S}_f} d^2r \frac{w(p')}{W(r)} \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}_0) \delta(p' - \mathbf{r} \cdot \hat{\mathbf{n}}_0) \\ &= \delta(p - p') w(p') \int_{\mathbf{S}_f} d^2r \frac{1}{W(r)} \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}_0) = \delta(p - p'). \end{aligned} \tag{17.83}$$

Thus *any* function of p is an eigenfunction of $\mathcal{H}_0 \mathcal{H}_0^\dagger$, and if we want the full set of single-view image-space eigenfunctions, we need only pick a complete set of functions that are orthonormal on $-R < p < R$ with respect to the weight $w(p)$, *i.e.*,

$$\int_{-R}^R dp w(p) v_n^*(p) v_{n'}(p) = \delta_{nn'}. \tag{17.84}$$

An important example, treated by Logan and Shepp (1975) and Hamaker and Solmon (1978), is $W(r) = 1$ over the support disk. In this case, $w(p) = [2\sqrt{R^2 - p^2}]^{-1}$, a weighting function that we encountered in connection with Chebyshev polynomials in Sec. 4.1.4 [see (4.60) and (4.61)].

A commuting family Weights satisfying (17.82) have a second salutary effect; in addition to converting $\mathcal{H}_0\mathcal{H}_0^\dagger$ to the unit operator, they simplify the entire family of operators of the form $\mathcal{H}_0\mathcal{I}_\ell\mathcal{H}_0^\dagger$. With these weights, Davison and Grunbaum have shown that each member of this family commutes with every other member. As we shall now show, this is precisely what we need in order to make the approximate SVD expressions from Sec. 17.1.2 exact.

If every member of the family commutes with every other member, then it is possible to find a set of vectors \mathbf{v}_n in data space that are simultaneously eigenvectors for each member of the family, including $\mathcal{H}_0\mathcal{H}_0^\dagger$. The eigenvalue equation is

$$\mathcal{H}_0\mathcal{I}_\ell\mathcal{H}_0^\dagger\mathbf{v}_n = \mu_n^{(\ell)}\mathbf{v}_n. \quad (17.85)$$

Note that $\mu_n^{(0)}$ is what we called μ_n above, and note also that there is no index ℓ on \mathbf{v}_n . We shall verify (17.85) for one choice of weights below, but for now we simply assume it is true.

From Sec. 1.5.1 we know that the eigenvectors of $\mathcal{H}_0^\dagger\mathcal{H}_0$ with nonzero singular values are given by

$$\mathbf{u}_n = \frac{1}{\sqrt{\mu_n^{(0)}}}\mathcal{H}_0^\dagger\mathbf{v}_n, \quad (17.86)$$

but $\mu_n^{(0)} = 1$ here since $\mathcal{H}_0\mathcal{H}_0^\dagger$ is the unit operator in the single-view data space. Thus

$$\mathbf{u}_n^\dagger\mathcal{I}_\ell\mathbf{u}_{n'} = \left[\mathcal{H}_0^\dagger\mathbf{v}_n\right]^\dagger\mathcal{I}_\ell\mathcal{H}_0^\dagger\mathbf{v}_{n'}. \quad (17.87)$$

By an elementary property of the adjoint (see Sec. 1.3.5) and (17.85), we have

$$\mathbf{u}_n^\dagger\mathcal{I}_\ell\mathbf{u}_{n'} = \mathbf{v}_n^\dagger\mathcal{H}_0\mathcal{I}_\ell\mathcal{H}_0^\dagger\mathbf{v}_{n'} = \mu_n^{(\ell)}\mathbf{v}_n^\dagger\mathbf{v}_{n'} = \mu_n^{(\ell)}\delta_{nn'}, \quad (17.88)$$

which is just the condition we needed in Sec. 17.1.2 to derive (17.23) and (17.24).

Computation of eigenfunctions Next we need to find the eigenfunctions that satisfy (17.85). For simplicity, we take $W(r) = 1$ on the object support, so that $w(p) = [2\sqrt{R^2 - p^2}]^{-1}$. With this choice of weights, one might think we should take $v_n(p)$ to be a Chebyshev polynomial of the first kind [see (4.60)], but there is a less-obvious choice that is needed if we want to satisfy (17.85) for all ℓ . Following Davison and Grunbaum, we take

$$v_n(p) = \frac{2}{R\sqrt{\pi}}\sqrt{R^2 - p^2} U_n\left(\frac{p}{R}\right), \quad (17.89)$$

where $U_n(p/R)$ is the Chebyshev polynomial of the *second* kind. With (4.61) and a change of variables, we can see that these functions are orthonormal with respect to the weight $[2\sqrt{R^2 - p^2}]^{-1}$ on $(-R, R)$; in essence, we have artificially introduced a factor of $\sqrt{R^2 - p^2}$ in each of the functions, and one of these factors cancels the weight, leaving an orthogonality integral with weight $\sqrt{R^2 - p^2}$ rather than its reciprocal.

To verify that these eigenfunctions satisfy (17.85), we shall apply each of the three operators in that expression in turn. The first of these operators is \mathcal{H}_0^\dagger , which is defined by (17.81). Since $\mu_n^{(0)} = 1$ in (17.86), application of this operator gives

the single-view, object-space eigenfunctions $u_n(\mathbf{r})$; thus

$$u_n(\mathbf{r}) = [\mathcal{H}_0^\dagger \mathbf{v}_n](\mathbf{r}) = \frac{1}{R\sqrt{\pi}} U_n\left(\frac{\mathbf{r} \cdot \hat{\mathbf{n}}_0}{R}\right). \quad (17.90)$$

The rotation operator \mathcal{T}_ℓ simply replaces $\hat{\mathbf{n}}_0$ with $\hat{\mathbf{n}}_\ell$, so the left-hand side of (17.85) becomes

$$[\mathcal{H}_0 \mathcal{T}_\ell \mathcal{H}_0^\dagger \mathbf{v}_n](p) = \frac{1}{R\sqrt{\pi}} \int_{\mathbf{S}} d^2r \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}_0) U_n\left(\frac{\mathbf{r} \cdot \hat{\mathbf{n}}_\ell}{R}\right). \quad (17.91)$$

To perform the integral, we take \mathbf{r} in the x - y plane and choose the x axis parallel to $\hat{\mathbf{n}}_0$, so that $\mathbf{r} \cdot \hat{\mathbf{n}}_0 = x$ and $\mathbf{r} \cdot \hat{\mathbf{n}}_\ell = x \cos \phi_\ell + y \sin \phi_\ell$. The delta function takes care of one integral, and we see that

$$[\mathcal{H}_0 \mathcal{T}_\ell \mathcal{H}_0^\dagger \mathbf{v}_n](p) = \frac{1}{R\sqrt{\pi}} \int_{-\sqrt{R^2-p^2}}^{\sqrt{R^2-p^2}} dy U_n\left(\frac{p \cos \phi_\ell + y \sin \phi_\ell}{R}\right). \quad (17.92)$$

Next we define $\cos \theta_p \equiv p/R$ and

$$\alpha \equiv \frac{p \cos \phi_\ell + y \sin \phi_\ell}{R}, \quad (17.93)$$

so that

$$[\mathcal{H}_0 \mathcal{T}_\ell \mathcal{H}_0^\dagger \mathbf{v}_n](p) = \frac{1}{\sqrt{\pi}} \frac{1}{\sin \phi_\ell} \int_{\cos(\phi_\ell - \theta_p)}^{\cos(\phi_\ell + \theta_p)} d\alpha U_n(\alpha). \quad (17.94)$$

With the definition of the Chebyshev polynomial from (4.63) and some trigonometry, we obtain

$$[\mathcal{H}_0 \mathcal{T}_\ell \mathcal{H}_0^\dagger \mathbf{v}_n](p) = \frac{\sin[(n+1)\phi_\ell]}{(n+1) \sin \phi_\ell} v_n(p). \quad (17.95)$$

This result confirms (17.85) and shows that

$$\mu_n^{(\ell)} = \frac{\sin[(n+1)\phi_\ell]}{(n+1) \sin \phi_\ell}. \quad (17.96)$$

The limit $\phi_\ell \rightarrow 0$ shows that $\mu_n^{(0)} = 1$ as expected.

The eigenvalue spectrum Now we can put the pieces together and compute the eigenvalues and eigenfunctions needed in the full SVD of \mathcal{R}_{2J} with circular support and the chosen weights.

The eigenvalue spectrum is found from (17.23), which contains the factor $\mathbf{u}_n^\dagger \mathcal{T}_\ell \mathbf{u}_n$. From (17.88), this factor is just $\mu_n^{(\ell)}$ in the present problem, so we have

$$\mu_{nk} = \sum_{\ell=0}^{J-1} \exp\left(\frac{2\pi i k \ell}{J}\right) \frac{\sin[2\pi(n+1)\ell/J]}{(n+1) \sin(2\pi\ell/J)}. \quad (17.97)$$

This sum can be performed numerically by an inverse DFT, but special attention must be given to the points where the denominator vanishes ($\ell = 0$ for any J and

also $\ell = J/2$ for J even). The eigenvalue $\mu_n^{(\ell)}$ limits to 1 at these points.

Davison and Grunbaum (1981) point out that μ_{nk} can also be expressed as

$$\mu_{nk} = \frac{J}{n+1} \sum_{\ell=0}^n \delta[n-k, 2\ell]_J, \quad (17.98)$$

where the delta function is a modulo- J Kronecker function, *i.e.*, it equals one when the modulo- J difference of the two arguments is zero, and zero otherwise. This form can be verified by taking the DFT of both sides and summing a geometric series.

Several features of the spectrum can be seen without numerics. First, as noted in Sec. 17.1.2, all μ_{nk} must be real and nonnegative, though some can be zero. Next, if $k = 0$, then the Fourier kernel is always 1, and if $n = 0$, the ratio of sines is also 1, so μ_{00} is equal to the number of projections J .

We can also get an analytic result if n and k are nonzero but $J > n + k$. As ℓ ranges from n to 0 in (17.98), the difference of arguments $n - k - 2\ell$ ranges from $-(n+k)$ to $n-k$. If $J > n+k$, the negative values can never be brought back to zero by addition of a multiple of J , so the modulo- J condition never comes into play. We need only consider $n - k \geq 0$, and the Kronecker delta takes the value unity exactly once in the range of summation if $n - k$ is even, and never if $n - k$ is odd. Thus, for $J > n + k$,

$$\mu_{nk} = \begin{cases} \frac{J}{n+1} & \text{if } n \geq k, \quad n - k \text{ even} \\ 0 & \text{if } n \geq k, \quad n - k \text{ odd} \\ 0 & \text{if } n < k \end{cases}. \quad (17.99)$$

This form is useful in regularized pseudoinverses where the sums over n and k are truncated so that $n + k < J$. It will also prove useful in Sec. 17.2.2 when we discuss the limit $J \rightarrow \infty$.

At the opposite extreme, if $n \gg J$ and J is odd, then only the $\ell = 0$ term contributes much to the sum [*cf.* (2.47)], and this term limits to 1 as $\frac{n}{J} \rightarrow \infty$. Thus $\mu_{nk} \rightarrow 1$ in this limit for all k . If J is even, then there is also a contribution from $\ell = J/2$, so $\mu_{nk} \rightarrow 2$ as $\frac{n}{J} \rightarrow \infty$. (The 2 comes in since the list of angles is redundant for J even.)

Eigenfunctions We get the multiple-view, object-space eigenfunctions from (17.24) and (17.90) as

$$u_{nk}(\mathbf{r}) = \frac{1}{R\sqrt{\pi}} \frac{N_{nk}}{J} \sum_{j=0}^{J-1} \exp\left(\frac{2\pi i k j}{J}\right) U_n\left(\frac{\mathbf{r} \cdot \hat{\mathbf{n}}_j}{R}\right). \quad (17.100)$$

Calculation of the normalizing constant N_{nk} follows the same lines that led to (17.97); when $\mu_{nk} \neq 0$, the result is

$$N_{nk} = \sqrt{\frac{J}{\mu_{nk}}}. \quad (17.101)$$

Each multiple-view, image-space eigenvector \mathbf{v}_{nk} comprises a set of projections of the corresponding object-space eigenvector \mathbf{u}_{nk} ; the j^{th} member of the set is given

by

$$v_{nkj}(p) = \sqrt{\frac{1}{\mu_{nk}}} \left[\mathcal{H}_0 \mathcal{T}_j^\dagger \mathbf{u}_{nk} \right] (p) = \sqrt{\frac{1}{\mu_{nk}}} \int_{\mathbf{S}_f} d^2r \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}_j) u_{nk}(\mathbf{r}), \quad (\mu_{nk} \neq 0). \quad (17.102)$$

By use of (17.24), (17.85) (with the recognition that $\mathcal{H}_0^\dagger \mathbf{v}_n = \mathbf{u}_n$) and a change of variables, we find

$$v_{nkj}(p) = \frac{1}{\sqrt{J}} \exp(2\pi i k j / J) v_n(p). \quad (17.103)$$

This remarkably simple result is actually mandated by group theory. Since the projection data are stored separately rather than summed (see Sec. 17.1.1), the effect of a rotation is to permute the projections cyclically, and any function that transforms according to the k^{th} irreducible representation must have the form of (17.103).

Null functions of the adjoint With continuous angular sampling, the forward operator \mathcal{R}_2 is nonsingular, but the adjoint may nevertheless have null functions. The procedure used in (17.63) gives only the image-space singular functions corresponding to nonzero singular values. To complete the analysis, we must also find the null functions of the adjoint. This task is sometimes referred to as *characterizing the range* of the operator, since the null space of the adjoint (inconsistency space) is the orthogonal complement of the range of the forward operator (consistency space) as discussed in Sec. 1.5.2 (see especially Fig. 1.5).

Group theory provides us some assistance in finding null functions of the adjoint operator (Clarkson and Barrett, 1998b). From representation theory, it is known (Naimark and Stern, 1982) that any subspace of \mathbb{V} invariant under all rotations and dilations must have basis functions of the form

$$\tilde{v}_{mk} \propto p^m \exp(ik\phi). \quad (17.104)$$

Applying the adjoint operator to these functions, we see that

$$\left[\mathcal{R}_2^\dagger p^m \exp(ik\phi) \right] (\mathbf{r}) = \int_{-\infty}^{\infty} dp \int_0^\pi d\phi p^m \exp(ik\phi) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) = \int_0^\pi d\phi (\mathbf{r} \cdot \hat{\mathbf{n}})^m \exp(ik\phi). \quad (17.105)$$

The integral is invariant to the orientation of \mathbf{r} in the x - y plane, so we may as well take \mathbf{r} to be parallel to the x axis (from which ϕ is measured). Then we have

$$\int_0^\pi d\phi (\mathbf{r} \cdot \hat{\mathbf{n}})^m \exp(ik\phi) = r^m \int_0^\pi d\phi (\cos \phi)^m \exp(ik\phi). \quad (17.106)$$

This integral vanishes if $m + |k|$ is even and $0 \leq m < |k|$, so functions $\tilde{v}_{mk}(p, \phi)$ with m and k satisfying this condition are null functions of \mathcal{R}_2^\dagger .

The existence of these null functions does not contradict the earlier claim that the image-space eigenfunctions given in (17.64) form a complete set if we define the Hilbert spaces without an object support. Functions proportional to p^m are not square-integrable over the infinite line, so are not part of the Hilbert space \mathbb{V} if we impose no support limitation. If we limit the object support to the disk of radius R , then the projection is restricted to $-R < p < R$, so p^m becomes integrable. The math leading to (17.106) is still the same (so long as $r < R$) and the functions $\tilde{v}_{mk}(p, \phi)$ are still null functions, but now part of the data space.

Consistency conditions We saw in Sec. 15.2.5 that any null function of the adjoint leads to a data-consistency condition. In the present problem, we have

$$\left(\mathcal{R}_2^\dagger \tilde{\mathbf{v}}_{mk}, \mathbf{f}\right) = 0 = (\tilde{\mathbf{v}}_{mk}, \mathcal{R}_2 \mathbf{f}), \quad (17.107)$$

provided $m + |k|$ is even and $0 \leq m < |k|$. Thus any vector in consistency space (*i.e.*, one that can be written as $\mathcal{R}_2 \mathbf{f}$ for some \mathbf{f}) must be orthogonal to $p^m \exp(ik\phi)$ under the stated conditions on m and k . Noisy data will generally not lie entirely in consistency space.

For finite support and equally spaced angles (\mathbf{C}_J symmetry), the consistency conditions are derived by Clarkson and Barrett (1998b) using group-theoretic considerations. They show that the null functions of the adjoint $\mathcal{R}_{2,J}^\dagger$ are $\tilde{v}_{mk}(p, \phi_j) \propto p^m \exp(ik\phi_j)$, but now the restrictions on m and k must be stated differently for J even or odd; see Clarkson and Barrett for the details. Again, any consistent data vector must be orthogonal to these functions.

17.2.2 Inverses and pseudoinverses in 2D

Some of the 2D transforms treated in Sec. 17.2.1 are singular and some are nonsingular. Our goal in this section is to show how SVD methods can be used to find inverses of the nonsingular transforms and pseudoinverses of the singular ones.

Inverse 2D Radon transform From Sec. 4.4, we already know various forms of the inverse 2D Radon transform with infinite object support, but we shall now show how some of them are related to the SVD expressions above. We begin by rederiving (4.155).

Since \mathcal{R}_2 is nonsingular, its inverse is the same as its pseudoinverse; one operator form is found from (1.131) with the discrete index k replaced by the continuous vector index $\boldsymbol{\rho}$:

$$\mathcal{R}_2^{-1} = \int_{-\infty}^{\infty} d^2\rho \frac{1}{\sqrt{\mu_\rho}} \mathbf{u}_\rho \mathbf{v}_\rho^\dagger. \quad (17.108)$$

With (17.61)–(17.64), we obtain the explicit expression,

$$\begin{aligned} f(\mathbf{r}) &= [\mathcal{R}_2^{-1} \boldsymbol{\lambda}](\mathbf{r}) \\ &= \int_{-\infty}^{\infty} |\rho| d\rho \int_0^\pi d\theta_\rho \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) \int_0^\pi d\phi \delta(\boldsymbol{\rho} \cdot \hat{\mathbf{n}}_\perp) \int_{-\infty}^{\infty} dp \exp(-2\pi i p \rho) \lambda(p, \phi). \end{aligned} \quad (17.109)$$

The integral over p yields the 1D Fourier transform of the projection, $\Lambda(\rho, \phi)$, and the integral over $d\theta_\rho$ can be performed by using (4.166), resulting in

$$f(\mathbf{r}) = \int_0^\pi d\phi \int_{-\infty}^{\infty} |\rho| d\rho \exp(2\pi i \mathbf{r} \cdot \hat{\mathbf{n}}_\rho) \Lambda(\rho, \phi). \quad (17.110)$$

This expression is equivalent to (4.155).

Filtered backprojection We can also express the inverse 2D Radon transform in the filtered-backprojection form of (4.161). To derive this form from the SVD, we write the inverse Radon operator as

$$\mathcal{R}_2^{-1} = \mathcal{R}_2^\dagger \left(\mathcal{R}_2 \mathcal{R}_2^\dagger \right)^{-1}. \quad (17.111)$$

In this expression, \mathcal{R}_2^\dagger is the backprojection operator, and $(\mathcal{R}_2\mathcal{R}_2^\dagger)^{-1}$ is the filter applied to the projections before backprojection.

The filtering operator is given in SVD form as

$$(\mathcal{R}_2\mathcal{R}_2^\dagger)^{-1} = \int_{-\infty}^{\infty} d^2\rho \frac{1}{\mu_\rho} \mathbf{v}_\rho \mathbf{v}_\rho^\dagger. \tag{17.112}$$

The kernel of this operator is

$$\left[(\mathcal{R}_2\mathcal{R}_2^\dagger)^{-1} \right] (p, \phi; p' \phi') = \int_{-\infty}^{\infty} d^2\rho \frac{1}{\mu_\rho} v_\rho(p, \phi) v_\rho^*(p', \phi'). \tag{17.113}$$

With (17.62) and (17.64), we see that

$$\begin{aligned} & \left[(\mathcal{R}_2\mathcal{R}_2^\dagger)^{-1} \right] (p, \phi; p' \phi') \\ &= \int_{-\infty}^{\infty} |\rho| d\rho \exp[2\pi i(p - p')\rho] \int_0^\pi d\theta_\rho \delta[\cos(\phi - \theta_\rho)] \delta[\cos(\phi' - \theta_\rho)]. \end{aligned} \tag{17.114}$$

Performing the angular integral as in (4.166) and using (3.169) for the integral over ρ , we get

$$\left[(\mathcal{R}_2\mathcal{R}_2^\dagger)^{-1} \right] (p, \phi; p' \phi') = -\frac{1}{2\pi^2} \frac{1}{(p - p')^2} \delta(\phi - \phi'), \tag{17.115}$$

where $1/p^2$ is the strange generalized function discussed in detail in Sec. 2.3.3. Thus the filtered projection is given by

$$\left[(\mathcal{R}_2\mathcal{R}_2^\dagger)^{-1} \lambda \right] (p, \phi) = -\frac{1}{2\pi^2} \int_{-\infty}^{\infty} dp' \frac{\lambda(p', \phi)}{(p - p')^2}, \tag{17.116}$$

and application of the backprojection operator \mathcal{R}_2^\dagger then yields (4.161).

Apodization Though the inverse 2D Radon transform exists, it involves dividing by singular values that tend to zero as $\rho \rightarrow \infty$, leading to a large noise amplification for image components associated with small singular values. As we know from Sec. 15.2.6, this amplification can be controlled — at the expense of spatial resolution — by regularization in the SVD domain [see (15.114)]. Such regularization is also called *apodization*, especially in a tomographic context.

Since the singular values in the 2D Radon transform with infinite object support are indexed by the spatial frequency ρ , apodization amounts to weighting each component with a function that tends to 0 as the frequency gets large. For example, (17.110) can be modified to

$$\hat{f}(\mathbf{r}) = \int_0^\pi d\phi \int_{-\infty}^{\infty} |\rho| d\rho \exp(2\pi i \mathbf{r} \cdot \hat{\mathbf{n}}\rho) A(\rho) \Lambda(\rho, \phi), \tag{17.117}$$

where the apodizing function $A(\rho)$ is typically unity at $\rho = 0$. Note that this expression is no longer an exact inverse, hence the hat on $\hat{f}(\mathbf{r})$.

Pseudoinverses with finite angular sampling? In Sec. 17.2.1, we derived the SVD for a 2D Radon transform with infinite object support and J angular samples, but it is not obvious whether a pseudoinverse exists in this case. The difficulty is that the eigenvalues μ_ρ are angular delta functions. They vanish unless ρ is parallel to one of the projection directions $\hat{\mathbf{n}}_j$, but in a sense they are infinite along these directions. This problem prevented us from defining properly normalized singular functions in the image space; an expression like (17.63) does not work since the eigenvalues involve delta functions. This same problem comes up again in trying to define a pseudoinverse, which necessarily involves dividing by μ_ρ or its square root.

There is no theorem that says a pseudoinverse has to exist in this problem. We noted in Sec. 1.6.1 that a pseudoinverse exists for any bounded linear operator with closed range, and in particular when the range is a finite-dimensional space. The operator \mathcal{R}_{2J} has an infinite-dimensional range, however, and with infinite support \mathcal{R}_{2J}^\dagger is unbounded; backprojection of any function into the infinite plane yields a function of infinite \mathbb{L}_2 norm. (Of course, both of these problems apply also to the full 2D Radon operator \mathcal{R} , and in that case there is not only a pseudoinverse but even a true inverse.)

If a Moore-Penrose pseudoinverse of \mathcal{R}_{2J} exists, it must also be a 1-inverse and satisfy the first Penrose equation, $\mathcal{R}_{2J}\mathcal{R}_{2J}^+\mathcal{R}_{2J} = \mathcal{R}_{2J}$ (see Sec. 1.6.1). To check this equation, consider first the operator $\mathcal{R}_{2J}^+\mathcal{R}_{2J}$, which is the projector onto the measurement space of \mathcal{R}_{2J} . Measurement space in this problem is defined by the radial spokes parallel to $\hat{\mathbf{n}}_k$ in the 2D Fourier plane, so the projection operator must have the form,

$$\begin{aligned} [\mathcal{R}_{2J}^+\mathcal{R}_{2J}\mathbf{f}](\mathbf{r}) &= \sum_{k=0}^{J-1} \int_{-\infty}^{\infty} d^2\rho C(\rho) \delta(\rho \cdot \hat{\mathbf{n}}_{\perp k}) \exp(2\pi i \rho \cdot \mathbf{r}) \int_{-\infty}^{\infty} d^2r' \exp(-2\pi i \rho \cdot \mathbf{r}') f(\mathbf{r}') \\ &= \sum_{k=0}^{J-1} \int_0^{\infty} d\rho C(\rho) \exp(2\pi i \rho \hat{\mathbf{n}}_k \cdot \mathbf{r}) F(\rho \hat{\mathbf{n}}_k). \end{aligned} \quad (17.118)$$

Applying \mathcal{R}_{2J} to both sides, we obtain

$$[\mathcal{R}_{2J}\mathcal{R}_{2J}^+\mathcal{R}_{2J}\mathbf{f}](p, \phi_j) = \sum_{k=0}^{J-1} \int_{-\infty}^{\infty} d^2r \delta(p - \hat{\mathbf{n}}_j \cdot \mathbf{r}) \int_0^{\infty} d\rho C(\rho) \exp(2\pi i \rho \hat{\mathbf{n}}_k \cdot \mathbf{r}) F(\rho \hat{\mathbf{n}}_k). \quad (17.119)$$

Next we interchange the order of integration,¹⁰ so that

$$[\mathcal{R}_{2J}\mathcal{R}_{2J}^+\mathcal{R}_{2J}\mathbf{f}](p, \phi_j) = \sum_{k=0}^{J-1} \int_0^{\infty} d\rho C(\rho) \exp(2\pi i \rho \hat{\mathbf{n}}_k \cdot \mathbf{r}) \delta(\rho \hat{\mathbf{n}}_k \cdot \hat{\mathbf{n}}_{\perp j}) F(\rho \hat{\mathbf{n}}_k). \quad (17.120)$$

What we would like to get this way is

$$\begin{aligned} [\mathcal{R}_{2J}\mathbf{f}](p, \phi_j) &= \int_{-\infty}^{\infty} d^2\rho \exp(2\pi i \rho \hat{\mathbf{n}}_j \cdot \mathbf{r}) \delta(\rho \cdot \hat{\mathbf{n}}_{\perp j}) F(\rho \hat{\mathbf{n}}_j) \\ &= \int_0^{\infty} d\rho \exp(2\pi i \rho \hat{\mathbf{n}}_j \cdot \mathbf{r}) F(\rho \hat{\mathbf{n}}_j). \end{aligned} \quad (17.121)$$

¹⁰If this step is not legal, then the projection operator did not exist in the first place.

To make (17.120) the same as (17.121), we would have to make $C(\rho) \delta(\rho \hat{\mathbf{n}}_k \cdot \hat{\mathbf{n}}_{\perp j})$ be the Kronecker delta δ_{kj} , which isn't possible. Hence no 1-inverse of \mathcal{R}_{2J} exists.

It is instructive to repeat this exercise with \mathcal{R}_2 instead of \mathcal{R}_{2J} and to find $C(\rho)$ in that case.

Finite support, finite angular sampling The issue of existence of a pseudoinverse disappears if we consider a finite object support. In Sec. 17.2.1, we derived an SVD for J angles equally spaced around 2π , objects supported on a disc of radius R , and weighted Hilbert spaces with $W(r) = 1$ on the object support and $w(p) = [2\sqrt{R^2 - p^2}]^{-1}$ in the projection data. With these choices, the singular functions in object and image space are given by (17.100) and (17.103), respectively, and the singular values are found by taking the square root of (17.98). Using these pieces in (1.138) (again extended to continuous indices), we can write the pseudoinverse as

$$\begin{aligned}
 & [\mathcal{R}_{2J}^+ \boldsymbol{\lambda}](\mathbf{r}) \\
 = & \lim_{\eta \rightarrow 0^+} \frac{1}{\pi R^2} \sum_{n=0}^{\infty} \sum_{k=0}^{J-1} \frac{1}{\mu_{nk} + \eta} \left[\frac{1}{J} \sum_{j=0}^{J-1} \exp(2\pi i k j / J) U_n \left(\frac{\mathbf{r} \cdot \hat{\mathbf{n}}_j}{R} \right) \right] \int_{-R}^R dp U_n \left(\frac{p}{R} \right) \lambda_k(p),
 \end{aligned} \tag{17.122}$$

where

$$\lambda_k(p) \equiv \sum_{j'=0}^{J-1} \exp(-2\pi i k j' / J) \lambda(p, \phi_{j'}). \tag{17.123}$$

Thus SVD inversion in this problem begins by performing a DFT in the angular variable to yield a function of the index k , then using a Chebyshev polynomial of the second kind to transform from the resulting function of p to a function of order number n . Filtering takes place in this n - k domain, and transformation back to the object domain is performed by multiplying by a Chebyshev polynomial with $\mathbf{r} \cdot \hat{\mathbf{n}}_j$ in its argument, doing an inverse DFT on the j index, and summing over n and k .

Limit of infinite angular sampling More insight into (17.122) can be obtained by considering the limit of very fine angular sampling ($J \rightarrow \infty$). In this limit, the eigenvalues are given by (17.99), and we can write

$$\begin{aligned}
 & [\mathcal{R}_{2J}^+ \boldsymbol{\lambda}](\mathbf{r}) \\
 = & \frac{1}{\pi R^2} \sum_{n=0}^{\infty} \sum_{k=0}^{J-1} \frac{n+1}{J} \left[\frac{1}{J} \sum_{j=0}^{J-1} \exp(2\pi i k j / J) U_n \left(\frac{\mathbf{r} \cdot \hat{\mathbf{n}}_j}{R} \right) \right] \int_{-R}^R dp U_n \left(\frac{p}{R} \right) \lambda_k(p).
 \end{aligned} \tag{17.124}$$

One might think it would be necessary to modify the summation limits here since, according to (17.99), the sum includes only the terms for which $n \geq k$ and $n - k$ is even, but in fact no modification is needed; in the absence of noise, the consistency condition (17.107) causes the integral over p to vanish for the terms we would like to leave out. (Recall that $U_n(p/R)$ is a polynomial of degree n , containing terms in p^n, p^{n-2} , and so on.)

We can now reinsert (17.123) and do the sum over k , yielding $J\delta_{jj'}$, and we can use this delta function to do the sum over j' . We then take advantage of the limit

$J \rightarrow \infty$, where the discrete angle ϕ_j (or $2\pi j/J$) becomes the continuous variable ϕ , to replace the sum over j with an integral: $\sum_{j=0}^{J-1} \rightarrow \frac{J}{2\pi} \int_0^{2\pi} d\phi$. Thus

$$[\mathcal{R}_{2J}^+ \lambda](\mathbf{r}) = \frac{1}{\pi R^2} \sum_{n=0}^{\infty} (n+1) \frac{1}{2\pi} \int_0^{2\pi} d\phi U_n\left(\frac{\mathbf{r} \cdot \hat{\mathbf{n}}}{R}\right) \int_{-\infty}^{\infty} dp U_n\left(\frac{p}{R}\right) \lambda(p, \phi). \quad (17.125)$$

To put this expression into a more familiar form, we write

$$[\mathcal{R}_{2J}^+ \lambda](\mathbf{r}) = \int_0^{2\pi} d\phi \int_{-\infty}^{\infty} dp h(\mathbf{r} \cdot \hat{\mathbf{n}}, p) \lambda(p, \phi), \quad (17.126)$$

where

$$h(\mathbf{r} \cdot \hat{\mathbf{n}}, p) \equiv \frac{1}{\pi R^2} \frac{1}{2\pi} \sum_{n=0}^{\infty} (n+1) U_n\left(\frac{\mathbf{r} \cdot \hat{\mathbf{n}}}{R}\right) U_n\left(\frac{p}{R}\right). \quad (17.127)$$

Comparing these expressions to (4.159) and (4.160), we see that (17.126) is the shift-variant, finite-support counterpart of filtered backprojection. The order n of the Chebyshev polynomial is the counterpart of spatial frequency, and the factor $(n+1)$ is the counterpart of the factor $|\nu|$ that occurs in ordinary filtered backprojection.

Large object support To make further contact with filtered backprojection, consider what happens when R gets large. Intuitively, the inverse operator should become shift-invariant in this limit.

Recall the definition of the Chebyshev polynomial from (4.63):

$$U_n\left(\frac{p}{R}\right) \equiv \frac{\sin[(n+1)\cos^{-1}(p/R)]}{\sin[\cos^{-1}(p/R)]}. \quad (17.128)$$

If $R \gg p$, then

$$\cos^{-1}\left(\frac{p}{R}\right) \approx \frac{\pi}{2} - \frac{p}{R}. \quad (17.129)$$

Thus the denominator in (17.128) is approximately unity, and

$$U_n\left(\frac{p}{R}\right) \approx \sin\left[(n+1)\frac{\pi}{2}\right] \cos\left[(n+1)\frac{p}{R}\right] - \cos\left[(n+1)\frac{\pi}{2}\right] \sin\left[(n+1)\frac{p}{R}\right]. \quad (17.130)$$

With this approximation and a little trigonometry, the sum in (17.127) becomes

$$\begin{aligned} \sum_{n=0}^{\infty} (n+1) U_n\left(\frac{p'}{R}\right) U_n\left(\frac{p}{R}\right) &= \sum_{n \text{ even}}^{\infty} (n+1) \cos\left[(n+1)\frac{p}{R}\right] \cos\left[(n+1)\frac{p'}{R}\right] \\ &+ \sum_{n \text{ odd}}^{\infty} (n+1) \sin\left[(n+1)\frac{p}{R}\right] \sin\left[(n+1)\frac{p'}{R}\right]. \end{aligned} \quad (17.131)$$

If p and p' are both small compared to R , the sines and cosines vary slowly with n , and it is valid to replace the sums with integrals. If we define $2\pi\nu = (n+1)/R$ and note that n changes in steps of 2 in each sum, then $\Delta\nu = 1/(\pi R)$. With some more trig, the filter function is given in the limit by

$$\begin{aligned}
 h(p', p) &= \lim_{R \rightarrow \infty} \frac{1}{2\pi^2 R^2} \sum_{n=0}^{\infty} (n+1) U_n\left(\frac{p'}{R}\right) U_n\left(\frac{p}{R}\right) \\
 &= \int_0^{\infty} \nu d\nu \cos[2\pi\nu(p' - p)] = \frac{1}{2} \int_{-\infty}^{\infty} |\nu| d\nu \exp[2\pi i\nu(p' - p)]. \quad (17.132)
 \end{aligned}$$

As expected, the filter function is now a function of only $p' - p$. Moreover, we recognize the integral as the 1D Fourier transform of $|\nu|$, so it is precisely the filter function that always occurs in filtered backprojection. We have succeeded in reproducing the results from Sec. 4.4.3 by a very round-about route,¹¹ but along the way we also found an expression for the pseudoinverse of the 2D Radon transform with J equally spaced angles and finite object support.

17.2.3 Inversion of the 3D x-ray transform

The 3D x-ray transform is defined in (17.46), and an equivalent form is given in (17.47). As we discussed in Sec. 17.1.5, the main application of this transform is in cone-beam tomography, where the vector \mathbf{r} in the transform is interpreted as the position of the vertex of the cone. In most data-collection geometries, this vertex moves along a path called the trajectory, and position along the trajectory can be specified by a scalar parameter τ . Thus the vertex position can be written as $\mathbf{r}_v(\tau)$, and the continuous data can be expressed by a slight modification of (17.46) and (17.47) as

$$g(\tau, \hat{\mathbf{s}}) = \int_0^{\infty} d\ell f[\mathbf{r}_v(\tau) - \hat{\mathbf{s}}\ell] = \int_S d^3\mathbf{r}' f(\mathbf{r}') \frac{\delta\left[\hat{\mathbf{s}} - \frac{\mathbf{r}_v(\tau) - \mathbf{r}'}{|\mathbf{r}_v(\tau) - \mathbf{r}'|}\right]}{|\mathbf{r}_v(\tau) - \mathbf{r}'|^2}, \quad (17.133)$$

where S is the object support.

Our goal in this section is to discuss conditions under which the object $f(\mathbf{r}')$ can be recovered from the continuous, noise-free data $g(\tau, \hat{\mathbf{s}})$ and then to find explicit inversion formulas. Key to this effort will be the Hamaker formulas (17.48) and (17.51); these formulas establish a close relation between the 3D x-ray transform and the 3D Radon transform, and all known inversion formulas exploit this relation in some way.

Completeness conditions An excellent historical and mathematical account of data completeness in cone-beam tomography is presented by Defrise and Clack (1994). As these authors point out, the literature on this subject begins with the pioneering mathematical investigations of A. A. Kirillov (1961). If we translate his work into the language of cone-beam tomography, he concludes basically that any object can be recovered from cone-beam data if all planes in space pass through a trajectory point. This condition takes no account of finite object support and therefore leads to the impractical conclusion that the trajectory must be unbounded. B. D. Smith

¹¹The sharp-eyed reader will note that there is an extra factor of $\frac{1}{2}$ in the final form of (17.132) that does not appear in Sec. 4.4.3. It arises since the integral over ϕ in (17.126) runs from 0 to 2π , while the corresponding integral in (4.155) runs from 0 to π .

(1985a) showed that any object of finite support could be reconstructed if all planes through the support contain at least one trajectory point.

Chen (1992) gave a completeness condition applicable when the object has finite support but we are interested in recovering the object only within some region of interest (ROI) contained in the support. This condition was improved by Tuy (1983) who showed that the object could be recovered within the ROI if all planes passing through the ROI contain at least one trajectory point. Another condition, given by Grangeat (1987, 1990), allows for the possibility that projections from some of the trajectory points are truncated by a finite detector size. We shall not make use of these alternative conditions here. Instead, we assume, following Smith, that all planes through the object contain at least one trajectory point.

General approach to inversion formulas Many papers on cone-beam reconstruction adhere to a four-step paradigm originated by Smith (1985b). The steps can be enumerated as:

1. Transform to the 3D Radon domain;
2. Reparameterize;
3. Filter;
4. Perform Radon backprojection.

Each of these steps can be formulated as a linear integral transform, so the overall sequence is another linear transform, mapping $g(\tau, \hat{\mathbf{s}})$ to a continuous object estimate $\hat{f}(\mathbf{r})$. For noise-free continuous data satisfying the completeness condition discussed above, we arrive at $\hat{f}(\mathbf{r}) = f(\mathbf{r})$. This inverse tomographic transform can then be used as a starting point to derive practical reconstruction algorithms to be applied to noisy, discrete data.

Step 1: Transformation to the Radon domain The first step is application of the Hamaker formula (17.48). Following the notation of Smith, we denote the result of this step as $G(\tau, \hat{\mathbf{n}})$ (where here the capital letter does *not* denote a Fourier transform) and write

$$G(\tau, \hat{\mathbf{n}}) = \int_{4\pi} d\Omega_{\hat{\mathbf{s}}} g(\tau, \hat{\mathbf{s}}) h(\hat{\mathbf{s}} \cdot \hat{\mathbf{n}}). \quad (17.134)$$

As in Sec. 17.1.5 we require that $h(\cdot)$ be a function of one variable that is homogeneous of degree -2 , *i.e.*, $h(\alpha x) = \frac{1}{\alpha^2} h(x)$. Candidate functions are the derivative of a delta function and the generalized function $-1/x^2$, which we know from (3.169) to be the 1D inverse Fourier transform of the ramp function $2\pi^2|\nu|$.

The usefulness of homogeneous functions of degree -2 becomes apparent when we substitute the final form of (17.133) into (17.134), obtaining

$$G(\tau, \hat{\mathbf{n}}) = \int_{4\pi} d\Omega_{\hat{\mathbf{s}}} \int_S d^3\mathbf{r}' f(\mathbf{r}') \frac{\delta \left[\hat{\mathbf{s}} - \frac{\mathbf{r}_v(\tau) - \mathbf{r}'}{|\mathbf{r}_v(\tau) - \mathbf{r}'|} \right]}{|\mathbf{r}_v(\tau) - \mathbf{r}'|^2} h(\hat{\mathbf{s}} \cdot \hat{\mathbf{n}}). \quad (17.135)$$

With a wave to Fubini, we interchange the order of integration and use the definition of the angular delta function, (2.155), to see that

$$G(\tau, \hat{\mathbf{n}}) = \int_S d^3\mathbf{r}' f(\mathbf{r}') \frac{h \left[\frac{\mathbf{r}_v(\tau) - \mathbf{r}'}{|\mathbf{r}_v(\tau) - \mathbf{r}'|} \cdot \hat{\mathbf{n}} \right]}{|\mathbf{r}_v(\tau) - \mathbf{r}'|^2}. \tag{17.136}$$

Now, because of the homogeneity, we can write

$$G(\tau, \hat{\mathbf{n}}) = \int_S d^3\mathbf{r}' f(\mathbf{r}') h \{ [\mathbf{r}_v(\tau) - \mathbf{r}'] \cdot \hat{\mathbf{n}} \}. \tag{17.137}$$

In particular, if $h(x)$ is the derivative of a delta function, then

$$G(\tau, \hat{\mathbf{n}}) = \left\{ \frac{\partial}{\partial p} [\mathcal{R}_3 \mathbf{f}](p, \hat{\mathbf{n}}) \right\}_{p=\mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}}. \tag{17.138}$$

Thus we have related the cone-beam data to the derivative of the 3D Radon transform by using the homogeneity of the delta derivative to get rid of the $1/r^2$ Jacobian factor inherent in cone-beam projections. We recall that the plane of integration for the Radon transform has normal $\hat{\mathbf{n}}$ and is a distance p from the origin; the vertex point must lie on this plane since $p = \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}$.

We note also that (17.138) is essentially the dipole-sheet transform of the object (see Sec. 4.4.5), so recovery of the object from this stage amounts to implementing the inverse dipole-sheet transform. To do so, however, we must express $G(\tau, \hat{\mathbf{n}})$ in terms of the Radon parameter p rather than the trajectory parameter τ .

Step 2: Reparameterization If Smith's data-completeness condition is satisfied, it is always possible to find one or more values of τ such that $p = \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}$ for any plane through the object defined by p and $\hat{\mathbf{n}}$. Many papers then simply define a new function $F(p, \hat{\mathbf{n}})$ (where the capital letter again does *not* denote Fourier transform) by writing

$$F(p, \hat{\mathbf{n}}) \equiv G(\tau, \hat{\mathbf{n}}), \tag{17.139}$$

with the side condition that τ signifies one of the solutions of $p = \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}$. This step is often called *rebinning*, even though neither $F(p, \hat{\mathbf{n}})$ nor $G(\tau, \hat{\mathbf{n}})$ refers to binned data in any way.

Semantic issues aside, (17.139) presents both mathematical and practical difficulties. The practical problem is that several different values of τ correspond to the same p and $\hat{\mathbf{n}}$ if the plane intersects the trajectory in several places. In that case it is at best arbitrary to choose one such point, and when we consider noisy data there may be a noise advantage to averaging over the trajectory points. Mathematically, there are two difficulties. First, we would like to obtain an overall integral transformation that maps the data (a function of τ) to the final image, so we need an integral over τ . Second, it is not just the isolated point τ that is important with continuous data, but rather some infinitesimal neighborhood of that point; in other words, we must consider the Jacobian of the transformation from a function of τ to a function of p .

One way we might consider defining the required function of p is by

$$F(p, \hat{\mathbf{n}}) \stackrel{?}{=} \int d\tau G(\tau, \hat{\mathbf{n}}) \delta[p - \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}]. \tag{17.140}$$

By (2.33), the result of this integral is

$$F(p, \hat{\mathbf{n}}) = \sum_{k=1}^{K(p, \hat{\mathbf{n}})} \frac{G(\tau_k, \hat{\mathbf{n}})}{\left| \frac{\partial}{\partial \tau} \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}} \right|_{\tau=\tau_k}}, \tag{17.141}$$

where $\{\tau_k, k = 1, \dots, K(p, \hat{\mathbf{n}})\}$ are the solutions to $p = \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}$. This formula properly includes the Jacobians (the denominators in the summand), but it is awkward and unaesthetic.

A cleaner definition, and the one we shall adopt, is

$$F(p, \hat{\mathbf{n}}) \equiv \frac{1}{K(p, \hat{\mathbf{n}})} \int d\tau G(\tau, \hat{\mathbf{n}}) \left| \frac{\partial}{\partial \tau} \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}} \right| \delta[p - \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}]. \tag{17.142}$$

The integral now gives

$$F(p, \hat{\mathbf{n}}) = \frac{1}{K(p, \hat{\mathbf{n}})} \sum_{k=1}^{K(p, \hat{\mathbf{n}})} G(\tau_k, \hat{\mathbf{n}}). \tag{17.143}$$

Though (17.143) looks like (17.139) except for the averaging over equivalent trajectory points, we have the advantage from (17.142) that we now know how to express the reparameterization as an integral transform. The Jacobians have not been neglected but instead have been cancelled out by a judicious definition of the kernel of this transform.

Steps 3 and 4: Filtering and backprojection If we choose $h(x)$ as the derivative of a delta function, then (17.138) applies, and we see that

$$F(p, \hat{\mathbf{n}}) = \frac{\partial}{\partial p} [\mathcal{R}_3 \mathbf{f}](p, \hat{\mathbf{n}}). \tag{17.144}$$

We know from (4.186) how to go from the derivative of the 3D Radon transform back to the original function; we need only differentiate again and backproject. 3D Radon backprojection can be conceptualized as smearing back over the plane of integration and integrating over all orientations of the plane. Since the plane is defined by $p = \mathbf{r} \cdot \hat{\mathbf{n}}$, backprojection is realized mathematically by substituting $\mathbf{r} \cdot \hat{\mathbf{n}}$ for p and then performing an angular integral. Thus we have [cf. (4.186)]

$$\hat{f}(\mathbf{r}) = -\frac{1}{4\pi^2} \int_{2\pi} d\Omega_{\hat{\mathbf{n}}} \left[\frac{\partial}{\partial p} F(p, \hat{\mathbf{n}}) \right]_{p=\mathbf{r} \cdot \hat{\mathbf{n}}}. \tag{17.145}$$

If the data are given by (17.133), then $\hat{f}(\mathbf{r}) = f(\mathbf{r})$. This formula was first derived by Grangeat (1987).

Reconstruction operator Since we performed a sequence of linear transformations to get from the continuous data $g(\tau, \hat{\mathbf{s}})$ to the reconstruction $\hat{f}(\mathbf{r})$, there must be a single linear operator that performs the same task. In abstract form, there is an operator \mathcal{O} such that $\hat{\mathbf{f}} = \mathcal{O}\mathbf{g}$. We shall now work out the kernel of that operator.

For generality, we let the filter used in Step 3 be denoted by $\tilde{h}(\cdot)$, which could be different from the filter $h(\cdot)$ used in Step 1. With this notation, (17.142) can be merged with the more general form of (17.145) to yield

$$\begin{aligned}\hat{f}(\mathbf{r}) &= \int_{2\pi} d\Omega_{\hat{\mathbf{n}}} \int_{-\infty}^{\infty} dp' \tilde{h}(\mathbf{r} \cdot \hat{\mathbf{n}} - p') \frac{1}{K(p', \hat{\mathbf{n}})} \int d\tau G(\tau, \hat{\mathbf{n}}) \left| \frac{\partial}{\partial \tau} \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}} \right| \delta[p' - \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}] \\ &= \int_{2\pi} d\Omega_{\hat{\mathbf{n}}} \int d\tau \tilde{h}[\mathbf{r} \cdot \hat{\mathbf{n}} - \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}] \frac{1}{K[\mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}, \hat{\mathbf{n}}]} G(\tau, \hat{\mathbf{n}}) \left| \frac{\partial}{\partial \tau} \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}} \right|. \quad (17.146)\end{aligned}$$

Inserting the definition of $G(\tau, \hat{\mathbf{n}})$ from (17.134) gives

$$\hat{f}(\mathbf{r}) = \int d\tau \int_{4\pi} d\Omega_{\hat{\mathbf{s}}} \int_{2\pi} d\Omega_{\hat{\mathbf{n}}} \tilde{h}[\mathbf{r} \cdot \hat{\mathbf{n}} - \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}] h(\hat{\mathbf{s}} \cdot \hat{\mathbf{n}}) \frac{\left| \frac{\partial}{\partial \tau} \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}} \right|}{K[\mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}, \hat{\mathbf{n}}]} g(\tau, \hat{\mathbf{s}}). \quad (17.147)$$

Thus, if we write

$$\hat{f}(\mathbf{r}) = \int d\tau \int_{4\pi} d\Omega_{\hat{\mathbf{s}}} o(\mathbf{r}; \tau, \hat{\mathbf{s}}) g(\tau, \hat{\mathbf{s}}), \quad (17.148)$$

the kernel must be given by

$$o(\mathbf{r}; \tau, \hat{\mathbf{s}}) = \int_{2\pi} d\Omega_{\hat{\mathbf{n}}} \tilde{h}[\mathbf{r} \cdot \hat{\mathbf{n}} - \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}] h(\hat{\mathbf{s}} \cdot \hat{\mathbf{n}}) \frac{\left| \frac{\partial}{\partial \tau} \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}} \right|}{K[\mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}, \hat{\mathbf{n}}]}. \quad (17.149)$$

Choice of filter functions We still need to determine what filter functions can be used if we wish to have an exact inversion formula, where $\hat{f}(\mathbf{r}) = f(\mathbf{r})$. To this end, we look at the overall transformation from object to reconstruction. Writing this transformation as

$$\hat{f}(\mathbf{r}) = \int_{\infty} d^3\mathbf{r}' k(\mathbf{r}, \mathbf{r}') f(\mathbf{r}'), \quad (17.150)$$

we see from (17.133) and (17.148) that

$$k(\mathbf{r}, \mathbf{r}') = \int d\tau \int_{4\pi} d\Omega_{\hat{\mathbf{s}}} o(\mathbf{r}; \tau, \hat{\mathbf{s}}) \frac{\delta\left[\hat{\mathbf{s}} - \frac{\mathbf{r}_v(\tau) - \mathbf{r}'}{|\mathbf{r}_v(\tau) - \mathbf{r}'|}\right]}{|\mathbf{r}_v(\tau) - \mathbf{r}'|^2} = \int d\tau \frac{o\left[\mathbf{r}; \tau, \frac{\mathbf{r}_v(\tau) - \mathbf{r}'}{|\mathbf{r}_v(\tau) - \mathbf{r}'|}\right]}{|\mathbf{r}_v(\tau) - \mathbf{r}'|^2}. \quad (17.151)$$

Inserting (17.149) and using the homogeneity of $h(\cdot)$, we find

$$k(\mathbf{r}, \mathbf{r}') = \int d\tau \int_{2\pi} d\Omega_{\hat{\mathbf{n}}} \tilde{h}[\mathbf{r} \cdot \hat{\mathbf{n}} - \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}] h[\mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}} - \mathbf{r}' \cdot \hat{\mathbf{n}}] \frac{\left| \frac{\partial}{\partial \tau} \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}} \right|}{K[\mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}, \hat{\mathbf{n}}]}. \quad (17.152)$$

Now we make the change of variables $p = \mathbf{r}_v(\tau) \cdot \hat{\mathbf{n}}$. Recognizing the last factor in (17.152) as the Jacobian of this transformation, we see that

$$k(\mathbf{r}, \mathbf{r}') = \int_{-\infty}^{\infty} dp \int_{2\pi} d\Omega_{\hat{\mathbf{n}}} \tilde{h}(\mathbf{r} \cdot \hat{\mathbf{n}} - p) h(p - \mathbf{r}' \cdot \hat{\mathbf{n}}). \quad (17.153)$$

As an exercise, the reader can show that $k(\mathbf{r}, \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}')$, yielding an exact inversion formula, if the Fourier transforms of the filter functions satisfy

$$H(\nu) \tilde{H}(\nu) = \nu^2. \quad (17.154)$$

This condition is satisfied if $h(x) = \delta'(x)$ and $\tilde{h}(x) = -\delta'(x)/(4\pi^2)$, and it is this choice that gives (17.145). Another choice is ramp filters, $H(\nu) = \tilde{H}(\nu) = |\nu|$. Clack and Defrise (1994) have shown that the filters can also be certain linear combinations of derivatives and ramp filters. (Cross-terms in $\nu|\nu|$ cancel out by symmetry arguments.)

17.2.4 Inversion of attenuated transforms

We have encountered several tomographic transforms that include an exponential factor in the integrand. These *attenuated transforms* include the 2D attenuated Radon transform, the 2D exponential Radon transform and the 3D attenuated x-ray transform. (The 2D attenuated x-ray transform is the same as the 2D attenuated Radon transform, and the 3D attenuated and exponential Radon transforms are of little interest for reasons discussed in Sec. 17.1.6.)

As we saw in Sec. 17.1.6, the 2D exponential Radon transform, (17.58), applies when the attenuation coefficient is constant over a convex region. Inversion formulas for this case were found by Bellini *et al.* (1979) and Tretiak and Metz (1980). Over the next fifteen years, several other inversion formulas were found, and eventually Metz and Pan (1995) showed that all of them were special cases of a general formalism. (see also Pan and Metz, 1995).

Inversion formulas for the more general attenuated Radon transform, (17.54), were much more difficult to find, and many observers (including one author of this book) had thought they might not exist. Finally, however, an approach to a solution was suggested by Arbizov (1998), and Novikov (2002a, 2002b) developed an explicit inversion formula. Implementations of this formula were presented by Kuniyansky (2001) and Natterer (2001), and the latter author also presented a simpler derivation and an alternative inversion formula.

The key problem that remains unsolved at this writing is the attenuated x-ray transform. We know from Sec. 17.2.3 that inversion of the unattenuated x-ray transform is all about dealing with a weighting factor in the integrand, namely the factor $1/|\mathbf{r}_v(\tau) - \mathbf{r}'|^2$ in (17.133). Similarly, any attenuated transform brings in another weighting factor, the exponential attenuation factor. Real cone-beam data must necessarily involve both weighting — inverse-square and exponential attenuation — so it would be of some importance to devise continuous inversion formulas that include both.

Inversion of the 2D exponential Radon transform Because the inversion formulas for nonconstant attenuation are complex (in both senses of the word), we shall concentrate here on the 2D exponential Radon transform. For notational simplicity in what follows, we denote the operator for this transform as \mathcal{R}_μ rather than $\mathcal{R}_{2e,\mu}$ as used in (17.58); thus

$$g_\mu(p, \phi) = [\mathcal{R}_\mu \mathbf{f}](p, \phi) = \int_{-\infty}^{\infty} d^2r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) \exp(\mu \mathbf{r} \cdot \hat{\mathbf{n}}_\perp). \quad (17.155)$$

It turns out to be useful to include $\mathcal{R}_{-\mu}$ in our theory along with \mathcal{R}_μ . In particular, as we shall see below, the operator $\mathcal{R}_{-\mu}^\dagger \mathcal{R}_\mu$ turns out to be shift-invariant in spite of the fact that both the attenuating medium and the axis of rotation establish a preferred origin in object space. Moreover, the convolutional relation (4.194), which we derived in a signal-processing context in Sec. 4.4.6, generalizes to (Natterer, 1986)

$$\left(\mathcal{R}_{-\mu}^\dagger \mathbf{h}\right) * \mathbf{f} = \mathcal{R}_{-\mu}^\dagger [\mathbf{h} * (\mathcal{R}_\mu \mathbf{f})], \quad (17.156)$$

where \mathbf{h} denotes an arbitrary function in data space, $h(p, \phi)$. Thus the asterisk on the left denotes 2D convolution but the one on the right denotes 1D convolution with respect to p for each ϕ . Derivation of (17.156) is left as an exercise.

Unfiltered backprojection Let us first examine the case $h(p, \phi) = \delta(p)$, so that the right-hand side of (17.156) becomes simply $\mathcal{R}_{-\mu}^\dagger \mathcal{R}_\mu \mathbf{f}$. Explicitly, from (17.155) and the definition of the adjoint [cf. (4.144)], we have

$$\left[\mathcal{R}_{-\mu}^\dagger \mathcal{R}_\mu \mathbf{f} \right] (\mathbf{r}) = \int_{-\infty}^{\infty} d^2 r' f(\mathbf{r}') \int_0^{2\pi} d\phi \delta[(\mathbf{r}-\mathbf{r}') \cdot \hat{\mathbf{n}}] \exp[-\mu(\mathbf{r}-\mathbf{r}') \cdot \hat{\mathbf{n}}_\perp] = [\mathbf{f} * (\mathcal{R}_{-\mu}^\dagger \mathbf{h})](\mathbf{r}). \quad (17.157)$$

Since the integral over ϕ covers a full circle, we can without loss of generality choose \mathbf{r} to lie along the x axis and write

$$\left[\mathcal{R}_{-\mu}^\dagger \mathbf{h} \right] (\mathbf{r}) = \int_0^{2\pi} d\phi \delta(r \cos \phi) \exp(-\mu r \sin \phi). \quad (17.158)$$

The integral can be performed with the help of (2.33), and we find

$$\left[\mathcal{R}_{-\mu}^\dagger \mathbf{h} \right] (\mathbf{r}) = \frac{\cosh \mu r}{r}, \quad (17.159)$$

where $r = |\mathbf{r}|$. Note that this expression reduces to $1/r$ if $\mu \rightarrow 0$, and we know that $1/r$ is the PSF for unfiltered backprojection with the ordinary 2D Radon transform [see (4.167)].

We might think about performing a deconvolution in the 2D Fourier domain, but the exponential growth of $\cosh \mu r$ means that the Fourier transform of (17.159) cannot be defined in conventional terms, or even in terms of tempered distributions (see Sec. 3.3.4).

Exact filter function Another way to use (17.156) is to try to find the function $h(p, \phi)$ that yields a 2D delta function when backprojected with $\mathcal{R}_{-\mu}^\dagger$; that is,

$$\left[\mathcal{R}_{-\mu}^\dagger \mathbf{h} \right] (\mathbf{r}) = \delta(\mathbf{r}). \quad (17.160)$$

With this function, (17.156) becomes

$$\mathbf{f} = \mathcal{R}_{-\mu}^\dagger [\mathbf{h} * (\mathcal{R}_\mu \mathbf{f})]. \quad (17.161)$$

If the filter function is independent of ϕ , it can be written as $h(p)$; the function $[\mathcal{R}_{-\mu}^\dagger \mathbf{h}](\mathbf{r})$ is rotationally symmetric in this case, and the left-hand side of (17.160) becomes [cf. (17.158)]

$$\left[\mathcal{R}_{-\mu}^\dagger \mathbf{h} \right] (\mathbf{r}) = \int_0^{2\pi} d\phi h(r \cos \phi) \exp(-\mu r \sin \phi). \quad (17.162)$$

Representing $h(p)$ in terms of its 1D Fourier transform $H(\nu)$, we obtain

$$\left[\mathcal{R}_{-\mu}^\dagger \mathbf{h} \right] (\mathbf{r}) = \int_{-\infty}^{\infty} d\nu H(\nu) \int_0^{2\pi} d\phi \exp(-\mu r \sin \phi + 2\pi i r \cos \phi). \quad (17.163)$$

A tabulated integral (Gradshteyn and Ryzhik, 1980, formula 3.937) yields

$$\left[\mathcal{R}_{-\mu}^\dagger \mathbf{h} \right] (\mathbf{r}) = 2\pi \int_{-\infty}^{\infty} d\nu H(\nu) J_0 \left[2\pi r \sqrt{\nu^2 - (\mu/2\pi)^2} \right]. \quad (17.164)$$

This form immediately suggests the change of variables $\rho = \sqrt{\nu^2 - (\mu/2\pi)^2}$. If we take $H(\nu)$ to be zero for $|\nu| < \mu/2\pi$, then there is no worry about the argument of the Bessel function becoming imaginary. Since the integrand is even, we can write

$$\left[\mathcal{R}_{-\mu}^\dagger \mathbf{h} \right] (\mathbf{r}) = 4\pi \int_0^\infty d\rho H \left[\sqrt{\rho^2 + (\mu/2\pi)^2} \right] J_0(2\pi\rho r). \quad (17.165)$$

We can now satisfy (17.160) almost by inspection. We know from (3.248) and (3.254) that

$$2\pi \int_0^\infty \rho d\rho J_0(2\pi\rho r) = \delta(\mathbf{r}), \quad (17.166)$$

so (17.160) holds if we take

$$H(\nu) = \begin{cases} \frac{1}{2}|\nu| & \text{if } |\nu| > \mu/2\pi \\ 0 & \text{if } |\nu| \leq \mu/2\pi \end{cases}. \quad (17.167)$$

This function, the familiar ramp filter with the center portion deleted, is plotted in Fig. 17.7. It was first derived by Tretiak and Metz (1980).

Fig. 17.7 The Tretiak-Metz filter function, expressed in the 1D frequency domain.

Neumann-series approach Yet another use of (17.156) was suggested, in a slightly different context, by Wagner *et al.* (2001). They inquired what would happen if one applied the filter function for the ordinary 2D Radon transform (*i.e.*, a ramp filter) to data from the exponential Radon transform and then followed it with the exponentially weighted backprojection $\mathcal{R}_{-\mu}^\dagger$. If we denote the ramp filter by \mathbf{h}_0 (the subscript indicating $\mu = 0$), then we can define

$$\hat{\mathbf{f}}_0 \equiv \mathcal{R}_{-\mu}^\dagger [\mathbf{h}_0 * \mathbf{g}_\mu], \quad (17.168)$$

where $\mathbf{g}_\mu = \mathcal{R}_\mu \mathbf{f}$ is the (noise-free) exponential-Radon data.

Since (17.156) holds for any filter function, we see that

$$\hat{\mathbf{f}}_0 = (\mathcal{R}_{-\mu}^\dagger \mathbf{h}_0) * \mathbf{f} = \left[(\mathcal{R}_{-\mu}^\dagger \mathbf{h}_0) - \delta \right] * \mathbf{f} + \mathbf{f} \equiv -\mathcal{K}\mathbf{f} + \mathbf{f}, \quad (17.169)$$

where δ represents the 2D delta function $\delta(\mathbf{r})$ and \mathcal{K} is the operator defined by the next-to-last term of (17.169).

Since (17.169) is in the form of (A.59), we can apply the Neumann series to write

$$\mathbf{f} = \hat{\mathbf{f}}_0 + \mathcal{K}\hat{\mathbf{f}}_0 + \mathcal{K}^2\hat{\mathbf{f}}_0 \dots \quad (17.170)$$

Thus, if the series converges, we can find the actual object \mathbf{f} from $\hat{\mathbf{f}}_0$ in spite of having used the wrong filter function. Convergence is problematical since $\mathcal{R}_{-\mu}^\dagger$ is an unbounded operator if the object has infinite support, but Wagner *et al.* suggest that the problem can be avoided by assuming a sufficiently small support.

Fourier-series approach An elegant general approach to the exponential Radon transform was presented by Metz and Pan (1995). This approach begins by expanding $g_\mu(p, \phi)$ in an angular Fourier series as

$$g_\mu(p, \phi) = \sum_{k=-\infty}^{\infty} g_{\mu k}(p) e^{ik\phi} \tag{17.171}$$

and then further expands the coefficients in terms of their 1D Fourier transforms, so that

$$g_\mu(p, \phi) = \sum_{k=-\infty}^{\infty} e^{ik\phi} \int_{-\infty}^{\infty} d\nu G_{\mu k}(\nu) e^{2\pi i\nu p}. \tag{17.172}$$

Thus the projection data are represented in a hybrid manner by a Fourier transform on the p variable and a Fourier-series expansion in the angular variable ϕ . Explicitly,

$$G_{\mu k}(\nu) = \frac{1}{2\pi} \int_0^{2\pi} d\phi \int_{-\infty}^{\infty} dp g_\mu(p, \phi) e^{-ik\phi} e^{-2\pi i\nu p}. \tag{17.173}$$

We can also represent the Fourier transform of $f(\mathbf{r})$ in an angular Fourier series as

$$F(\boldsymbol{\rho}) = \sum_{k=-\infty}^{\infty} F_k(\rho) \exp(ik\theta_\rho), \tag{17.174}$$

where the spatial frequency vector $\boldsymbol{\rho}$ has polar coordinates (ρ, θ_ρ) .

Following Tretiak and Metz (1980) and Metz and Pan (1995), we now seek a relation between $G_{\mu k}(\nu)$ and $F_k(\rho)$. For consistent (noise-free) data, we can express $g_\mu(p, \phi)$ by (17.155) and represent $f(\mathbf{r})$ by its inverse Fourier transform, which is expressed by (17.174). Then (17.173) becomes

$$\begin{aligned} G_{\mu k}(\nu) &= \frac{1}{2\pi} \int_0^{2\pi} d\phi \int_{-\infty}^{\infty} dp \int_{\infty}^{d^2r} \int_{\infty}^{d^2\rho} \sum_{k'=-\infty}^{\infty} F_{k'}(\rho) \exp(ik'\theta_\rho) \exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r}) \\ &\times \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) \exp(\mu\mathbf{r} \cdot \hat{\mathbf{n}}_\perp) \exp(-ik\phi) \exp(-2\pi i\nu p). \end{aligned} \tag{17.175}$$

The p integral can be performed by use of the delta function, and we recognize that $d^2r = r dr d\theta$ and $d^2\rho = \rho d\rho d\theta_\rho$, so we have

$$\begin{aligned} G_{\mu k}(\nu) &= \frac{1}{2\pi} \int_0^{2\pi} d\phi \int_0^{\infty} r dr \int_0^{2\pi} d\theta \int_0^{\infty} \rho d\rho \int_0^{2\pi} d\theta_\rho \sum_{k'=-\infty}^{\infty} F_{k'}(\rho) \exp(ik'\theta_\rho) \\ &\times \exp[2\pi i\rho r \cos(\theta - \theta_\rho)] \exp[\mu r \sin(\theta - \phi)] \exp(-ik\phi) \exp[-2\pi i\nu r \cos(\theta - \phi)]. \end{aligned} \tag{17.176}$$

With the variable changes $\phi' = \theta - \phi$ and $\theta' = \theta - \theta_\rho$, the integral over θ_ρ yields $2\pi \delta_{kk'}$, so

$$\begin{aligned}
 G_{\mu k}(\nu) &= \int_0^\infty r dr \int_0^\infty \rho d\rho F_k(\rho) \int_0^{2\pi} d\theta' \exp(2\pi i \rho r \cos \theta') \exp(-ik\theta') \\
 &\quad \times \int_0^{2\pi} d\phi' \exp(\mu r \sin \phi') \exp(ik\phi') \exp(-2\pi i \nu r \cos \phi'). \quad (17.177)
 \end{aligned}$$

Using two tabulated integrals (Gradshteyn and Ryzhik, 1980, formulas 3.715 and 3.937), we find

$$G_{\mu k}(\nu) = 4\pi^2 \left[\frac{\nu + \frac{\mu}{2\pi}}{\sqrt{\nu^2 - \left(\frac{\mu}{2\pi}\right)^2}} \right]^k \int_0^\infty r dr \int_0^\infty \rho d\rho F_k(\rho) J_k(2\pi\rho r) J_k\left[2\pi r \sqrt{\nu^2 - \left(\frac{\mu}{2\pi}\right)^2}\right]. \quad (17.178)$$

Finally, we use the Fourier-Bessel theorem (Morse and Feshbach, 1953),

$$4\pi^2 \int_0^\infty r dr \int_0^\infty \rho d\rho F_k(\rho) J_k(2\pi\rho r) J_k(2\pi\zeta r) = F_k(\zeta), \quad (17.179)$$

to obtain (for $\nu \geq \frac{\mu}{2\pi}$)

$$G_{\mu k}(\nu) = \left[\frac{\frac{\mu}{2\pi} + \nu}{\sqrt{\nu^2 - \left(\frac{\mu}{2\pi}\right)^2}} \right]^k F_k \left[\sqrt{\nu^2 - \left(\frac{\mu}{2\pi}\right)^2} \right]. \quad (17.180)$$

This is the desired relation between the mixed Fourier series-transform representation of the ERT data and the corresponding representation of the object. For $\mu = 0$, this relation is just a restatement of the central-slice theorem. An equivalent relation is

$$G_{\mu k}(-\nu) = \left[\frac{\frac{\mu}{2\pi} - \nu}{\sqrt{\nu^2 - \left(\frac{\mu}{2\pi}\right)^2}} \right]^k F_k \left[\sqrt{\nu^2 - \left(\frac{\mu}{2\pi}\right)^2} \right]. \quad (17.181)$$

We can use either of these relations to find the object coefficients $F_k(\rho)$. From (17.180) and a change of variables, we find

$$F_k(\rho) = \left[\frac{\rho}{\frac{\mu}{2\pi} + \sqrt{\rho^2 + \left(\frac{\mu}{2\pi}\right)^2}} \right]^k G_{\mu k} \left[\sqrt{\rho^2 + \left(\frac{\mu}{2\pi}\right)^2} \right], \quad (17.182)$$

and from (17.181) we find

$$F_k(\rho) = \left[\frac{\rho}{\frac{\mu}{2\pi} - \sqrt{\rho^2 + \left(\frac{\mu}{2\pi}\right)^2}} \right]^k G_{\mu k} \left[-\sqrt{\rho^2 + \left(\frac{\mu}{2\pi}\right)^2} \right]. \quad (17.183)$$

With noise-free, continuous data, we can use either (17.182) or (17.183) to reconstruct the object exactly via (17.174) and an inverse Fourier transform.

Noisy, continuous data The derivation of (17.182) and (17.183) used the defining relation (17.155) for $g_\mu(p, \phi)$, and it was at that point that ideal, continuous, noise-free data were assumed. As we shall discuss in more detail in Secs. 17.2.5 and 17.2.6,

real data are both noisy and discrete. It is of some theoretical interest, however, to imagine that the data are noisy but not discrete, in which case $g_\mu(p, \phi)$ is not given by (17.155) but instead by

$$g_\mu(p, \phi) = \int_{-\infty}^{\infty} d^2r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) \exp(\mu \mathbf{r} \cdot \hat{\mathbf{n}}_\perp) + \Delta g(p, \phi), \quad (17.184)$$

where $\Delta g(p, \phi)$ is some random process.

The immediate consequence of (17.184) is that $g_\mu(p, \phi)$ is not in consistency space (the range of \mathcal{R}_μ) since there is no reason to believe that $\Delta g(p, \phi)$ is the projection of some object. Nevertheless, we can still apply all of the manipulations used above. That is, we can use the noisy, continuous data to compute the Fourier coefficients $G_{\mu k}(\nu)$ by means of (17.173), and we can then compute the right-hand sides of (17.182) and (17.183). What we cannot do, however, is claim that we have thereby found the actual object coefficient $F_k(\rho)$. Instead, we have found noisy estimates, denoted $\hat{F}_k^{(1)}(\rho)$ when (17.182) is used and $\hat{F}_k^{(2)}(\rho)$ when (17.183) is used. Because of the noise, these two estimates will not be identical.

Metz and Pan (1995) showed that different linear combinations of $\hat{F}_k^{(1)}(\rho)$ and $\hat{F}_k^{(2)}(\rho)$ reproduced different ERT inversion formulas previously found in the literature and also led to many new formulas. Clarkson (1999) showed how the different formulas correspond to different ways of projecting the inconsistent data onto consistency space.

17.2.5 Discretization of analytic reconstruction algorithms

So far in this chapter we have discussed the forward problem for SPECT in both CD and CC formulations, and we have discussed several analytic inversion formulas applicable to the CC case. We have not yet introduced any practical reconstruction algorithms that can be applied to discrete SPECT data, though general considerations on this issue were given in Chap. 15. Our goal in this section and the next is to show how the principles developed in Chap. 15 can be applied specifically to SPECT. The focus in this section is one-step linear algorithms obtained by discretizing analytic transforms. In Sec. 17.2.6 we turn to iterative algorithms, and in particular to formulating the requisite system matrix.

Discretization of analytic inverses In Sec. 15.2.4 we began with a CC operator \mathcal{L} with a known left inverse \mathcal{L}^{-1} and investigated how it could be applied to noisy, discrete data. The data model was assumed in (15.84) to be

$$\mathbf{g} = C \mathcal{D}_w \mathcal{L} \mathbf{f} + \mathbf{n}, \quad (17.185)$$

where C is a constant related to system sensitivity and exposure time, and \mathcal{D}_w is a CD operator that acts on the continuous data and produces discrete measurements. The goal was to reconstruct the coefficients in some approximate object expansion; these coefficients (*e.g.*, pixel values) were assumed to be related to the object by (15.85):

$$\boldsymbol{\theta} = \mathcal{D}_\chi \mathbf{f} \quad \text{or} \quad \theta_n = \int_{-\infty}^{\infty} d^2r \chi_n(\mathbf{r}) f(\mathbf{r}). \quad (17.186)$$

For more discussion of this equation, see Sec. 7.1.3.

It was suggested in Sec. 15.2.4 that a reasonable (not necessarily optimal) way of estimating $\boldsymbol{\theta}$ is to define the matrix \mathbf{O} by (15.88),

$$\mathbf{O} = \mathcal{D}_\chi \mathcal{L}^{-1} \mathcal{D}_w^\dagger, \quad (17.187)$$

and use it to reconstruct the object coefficients as in (15.90):

$$\hat{\boldsymbol{\theta}} = \frac{1}{C} \mathbf{O} \mathbf{g}. \quad (17.188)$$

Discretization of the 2D inverse Radon transform To see how to apply these formulas to SPECT, consider first the situation where collimator blur and attenuation are neglected, so the irradiance on the detector plane is assumed to be described by the 2D Radon transform of the object, $\lambda(p, \phi)$. We further assume point sampling at uniform intervals in both p and ϕ , so we can index the discrete measurements with one index j for the ϕ variable and a second index k for the p variable. A convenient way to normalize the sampling operator \mathcal{D}_w is to take $w_{jk}(p, \phi) = [\Delta p \Delta \phi]^{1/2} \delta(p - p_k) \delta(\phi - \phi_j)$, where Δp and $\Delta \phi$ are the sampling intervals in p and ϕ , respectively. With these definitions, the mean value of the $(jk)^{th}$ measurement is given by

$$\bar{g}_{jk} = C' \int_{-\infty}^{\infty} dp \int_0^\pi d\phi \delta(p - p_k) \delta(\phi - \phi_j) \lambda(p, \phi) = C' \lambda(p_k, \phi_j) = C[\mathcal{D}_w \mathcal{R}_2 \mathbf{f}]_{jk}, \quad (17.189)$$

where C' is a constant related to the system and exposure time but independent of the definition of \mathcal{D}_w , and $C \equiv C'[\Delta p \Delta \phi]^{-1/2}$.

With this data model and the inverse Radon transform as given in (4.161), the reconstruction matrix \mathbf{O} has elements given by

$$\begin{aligned} O_{njk} &= \int_{-\infty}^{\infty} d^2 r \chi_n(\mathbf{r}) \int_0^\pi d\phi \int_{-\infty}^{\infty} dp h(\mathbf{r} \cdot \hat{\mathbf{n}} - p) \delta(p - p_k) \delta(\phi - \phi_j) \\ &= \int_{-\infty}^{\infty} d^2 r \chi_n(\mathbf{r}) h(\mathbf{r} \cdot \hat{\mathbf{n}}_j - p_k), \end{aligned} \quad (17.190)$$

where $h(p)$ is the generalized function $-1/(2\pi^2 p^2)$, *i.e.*, the inverse Fourier transform of a ramp filter. Thus, with point sampling, we need only evaluate the shifted filter function at the sample points in data space, backproject, and then compute its scalar product in object space with (say) a pixel function.

By expressing $h(p)$ in terms of its Fourier transform, we can also write

$$\begin{aligned} O_{njk} &= \int_{-\infty}^{\infty} d^2 r \chi_n(\mathbf{r}) \int_{-\infty}^{\infty} |\nu| d\nu \exp[2\pi i(\mathbf{r} \cdot \hat{\mathbf{n}}_j - p_k)\nu] \\ &= \int_{-\infty}^{\infty} |\nu| d\nu X_n^*(\hat{\mathbf{n}}_j \nu) \exp(-2\pi i \nu p_k), \end{aligned} \quad (17.191)$$

where $X_n(\boldsymbol{\rho})$ is the 2D Fourier transform of $\chi_n(\mathbf{r})$. We can include apodization in this form by inserting into the integrand a factor $A(\nu)$ that goes to zero as ν increases [*cf.* (17.117)]. On the other hand, choice of $\chi_n(\mathbf{r})$ itself is a kind of apodization or regularization since $X_n(\hat{\mathbf{n}}_j \nu) \rightarrow 0$ as $\nu \rightarrow \infty$. The rolloff is more rapid if $\chi_n(\mathbf{r})$ is smoother or wider.

If we choose $\chi_n(\mathbf{r})$ to be the delta function $\delta(\mathbf{r} - \mathbf{r}_n)$, then $X_n(\hat{\mathbf{n}}_j\nu) = \exp(-2\pi i \mathbf{r}_n \cdot \hat{\mathbf{n}}_j\nu)$. In that case, it is imperative that we include an apodizing factor to control noise amplification, and the matrix elements are given by

$$O_{nj k} = \int_{-\infty}^{\infty} |\nu| d\nu A(\nu) \exp(2\pi i \mathbf{r}_n \cdot \hat{\mathbf{n}}_j\nu) \exp(-2\pi i \nu p_k) = h_A(\mathbf{r}_n \cdot \hat{\mathbf{n}}_j - p_k), \quad (17.192)$$

where $h_A(p) = \mathcal{F}_1^{-1}\{|\nu|A(\nu)\}$. Application of this matrix implements the commonly used filtered-backprojection algorithm.

Result of applying the discretized inverse If the data model (17.185) were accurate, $\hat{\boldsymbol{\theta}}$ would be expressed by [cf. (15.91)]

$$\hat{\boldsymbol{\theta}} = \mathcal{D}_\chi \mathcal{R}_2^{-1} \mathcal{D}_w^\dagger \mathcal{D}_w \mathcal{R}_2 \mathbf{f} + \frac{1}{C} \mathcal{D}_\chi \mathcal{R}_2^{-1} \mathcal{D}_w^\dagger \mathbf{n}. \quad (17.193)$$

The first term is the mean of $\boldsymbol{\theta}$ since the mean of \mathbf{n} is, by definition, zero. To be explicit, we can write the mean of the n^{th} component of $\boldsymbol{\theta}$ as

$$\bar{\theta}_n = \int_{\infty} d^2r \int_{\infty} d^2r' \chi_n(\mathbf{r}) p(\mathbf{r}, \mathbf{r}') f(\mathbf{r}'), \quad (17.194)$$

where $p(\mathbf{r}, \mathbf{r}')$ is the kernel of the CC operator $\mathcal{R}_2^{-1} \mathcal{D}_w^\dagger \mathcal{D}_w \mathcal{R}_2$, given by

$$p(\mathbf{r}, \mathbf{r}') = \Delta p \Delta \phi \sum_{j,k} h_A(\mathbf{r} \cdot \hat{\mathbf{n}}_j - p_k) \delta(p_k - \mathbf{r}' \cdot \hat{\mathbf{n}}_j). \quad (17.195)$$

With the normalization we have adopted here, $p(\mathbf{r}, \mathbf{r}') \rightarrow \delta(\mathbf{r} - \mathbf{r}')$ in the limit that $A(\nu) \rightarrow 1$ and the number of samples in both p and ϕ goes to infinity so that the sums can be replaced by integrals. Thus, if our data model is correct and there is no noise, the discretized operator yields perfect reconstruction in that limit.

More realistically, however, we must recognize that the system operator \mathcal{H} is not simply $C \mathcal{D}_w \mathcal{R}_2$; there are other effects such as collimator blur and attenuation, so we must write

$$\hat{\boldsymbol{\theta}} = \frac{1}{C} \mathcal{D}_\chi \mathcal{R}_2^{-1} \mathcal{D}_w^\dagger \mathcal{H} \mathbf{f} + \frac{1}{C} \mathcal{D}_\chi \mathcal{R}_2^{-1} \mathcal{D}_w^\dagger \mathbf{n}. \quad (17.196)$$

The general form (17.195) still applies, but now $p(\mathbf{r}, \mathbf{r}')$ is the kernel of the CC operator $\frac{1}{C} \mathcal{R}_2^{-1} \mathcal{D}_w^\dagger \mathcal{H}$. Explicitly,

$$p(\mathbf{r}, \mathbf{r}') = \frac{1}{C} \sum_{j,k} h_A(\mathbf{r} \cdot \hat{\mathbf{n}}_j - p_k) h_{jk}(\mathbf{r}'), \quad (17.197)$$

where $h_{jk}(\mathbf{r}')$ is what we usually call $h_m(\mathbf{r}')$, namely the kernel of the system operator \mathcal{H} . [The reader should not confuse $h_{jk}(\mathbf{r}')$ with the filter functions $h(p)$ or $h_A(p)$.]

Bias and estimability If $p(\mathbf{r}, \mathbf{r}')$ can be approximated by a delta function in (17.194), then the estimate of θ_n is unbiased. Unfortunately, this happy condition almost never occurs, for two reasons. First, there is no unbiased estimator for all true values of θ_n unless that parameter is estimable, as defined in Sec. 15.1.3, and we know from that section that it is estimable if and only if $\chi_n(\mathbf{r})$ can be written as

a linear superposition of the sensitivity functions. For the data model of (17.185), that means that $\chi_n(\mathbf{r})$ is a superposition of line delta functions—not something one would ever be very interested in estimating. Second, even if θ_n is estimable, the specific estimate obtained by applying the discretized inverse Radon transform will still be biased in essentially every case since the discretized inverse Radon transform is not the pseudoinverse of the discretized Radon forward operator of (17.185), and that operator is not an accurate description of the real system in the first place. In short, filtered backprojection will inevitably lead to biased estimates of the parameters.

For any choice of $\chi_n(\mathbf{r})$ and any assumed object $f(\mathbf{r})$, one can numerically compute the bias in the estimate of θ_n , but the authors would discourage the readers from following that route, at least if $\chi_n(\mathbf{r})$ represents a pixel or voxel. As we have argued in Sec. 13.3.2, bias or mean-square error in pixel values is a virtually meaningless measure of image quality. Instead, the values computed by (17.188) should be regarded as merely a linear transformation of the raw data, and the transformed data will then be used by some observer to perform some practical task. We shall return in Sec. 17.3.4 to the question of how well the transformed vector $\hat{\boldsymbol{\theta}}$ captures the information content (in terms of task performance) of the data \mathbf{g} .

17.2.6 Matrices for iterative methods

The analytic inverses described above require discretization of a known inverse operator \mathcal{L}^{-1} ; iterative methods, on the other hand, require discretization of an often poorly known forward operator \mathcal{H} . To discretize \mathcal{L}^{-1} in (17.187), we needed two discretization operators, \mathcal{D}_χ and \mathcal{D}_w . The first served to map the continuous output of the inverse into the desired reconstruction functionals, while the second, in its adjoint form, served to convert the actual discrete data into a continuous form where we could apply \mathcal{L}^{-1} . For modeling a forward problem as a DD or matrix equation, the actual CD operator \mathcal{H} already has the desired discrete output, so all we need is a discrete representation of the object. Methods for constructing such representations were introduced in Chap. 7 and used extensively in Chap. 15; we shall review this material briefly here and transcribe it into the notation of Sec. 17.1.1.

We represent the 3D object $f(\mathbf{r})$ approximately by

$$f_a(\mathbf{r}) = \sum_{\mathbf{n}=1}^N \theta_{\mathbf{n}} \phi_{\mathbf{n}}(\mathbf{r}), \quad (17.198)$$

where subscript a denotes approximate and subscript \mathbf{n} is a multi-index, a 3D vector with integer components specifying location in a 3D array. The summation limits run from 1 to N on each component, so we are here considering an $N \times N \times N$ object representation, but the formalism is easily generalized to other arrays. It will be convenient to think of $\phi_{\mathbf{n}}(\mathbf{r})$ as a voxel function, which is uniform within a cube of side ϵ centered on point $\mathbf{r}_{\mathbf{n}}$, but of course the math is more general.

The approximate object function $f_a(\mathbf{r})$ can be regarded as a vector in an N^3 -dimensional Hilbert space which we call representation space (see Sec. 7.1.2); when we take this view, (17.198) is written in operator form as

$$\mathbf{f}_a = \mathcal{D}_\phi^\dagger \boldsymbol{\theta}. \quad (17.199)$$

The system matrix \mathbf{H} is defined by (7.307) or (15.13) as

$$\mathbf{H} \equiv \mathcal{H}\mathcal{D}_\phi^\dagger, \quad (17.200)$$

with elements given by (7.304) or (15.14). In the present notation, the elements are expressed as

$$H_{\mathbf{m}\mathbf{n}} = \int_\infty d^3r h_{\mathbf{m}}(\mathbf{r}) \phi_{\mathbf{n}}(\mathbf{r}), \quad (17.201)$$

where \mathbf{m} is the 3D multi-index defined in Sec. 17.1.2; it specifies the 2D location on the detector face as well as the projection angle. This equation shows that a column of \mathbf{H} is the image of $\phi_{\mathbf{n}}(\mathbf{r})$ for all projection directions. Note that the functions $\{\chi_{\mathbf{n}}(\mathbf{r})\}$ do not appear in \mathbf{H} and that there is no need to introduce a data-space discretization operator \mathcal{D}_w since the data are already discrete.

Matrices specific to SPECT The great advantage of iterative algorithms is that one can put all of one's effort into accurate modeling of the forward problem, with no worry about having to solve the corresponding inverse problem analytically. In the case of SPECT imaging with an Anger camera, accurate forward modeling requires accounting for attenuation and scatter of the radiation in the patient's body, radiometric factors (inverse-square and obliquity), depth-dependent blur by the collimator or pinhole, septal penetration, blurring associated with position estimation, and binning the position estimates into a discrete data vector \mathbf{g} . As we shall see below, these effects can be taken into account by theoretical analysis, direct measurement, Monte Carlo simulation or some combination of these methods.

All of these methods of determining the system matrix are facilitated by thinking of the matrix in terms of probabilities. We know that $H_{\mathbf{m}\mathbf{n}}\theta_{\mathbf{n}}$ is the mean number of photons detected in bin \mathbf{m} of the data array when the object strength in voxel \mathbf{n} is $\theta_{\mathbf{n}}$. If we define $\theta_{\mathbf{n}}$ to be the mean number of photons emitted by voxel \mathbf{n} during some exposure time, then $H_{\mathbf{m}\mathbf{n}}$ is directly the probability that a photon emitted from voxel \mathbf{n} is detected in bin \mathbf{m} .

This probabilistic viewpoint leads to several useful decompositions of the \mathbf{H} matrix. For example, if a photon is recorded in bin \mathbf{m} , it may have arrived at the detector without any scattering, or it may have been scattered one or more times. Since these events are mutually exclusive, the probabilities add, and we can write

$$\mathbf{H} = \mathbf{H}^{(sc)} + \mathbf{H}^{(un)}, \quad (17.202)$$

where the superscript *sc* denotes *scattered* and *un* denotes *unscattered*. Both matrices are $M^2J \times N^3$ if we consider an $M \times M$ detector array stepped to J angles and an object decomposed via (17.198) into N^3 expansion functions such as voxels.

Analytic approaches to the \mathbf{H} matrix The unscattered component of \mathbf{H} was studied in detail in Sec. 16.2.2 for the case of a parallel-hole collimator, but in a CC formulation rather than the matrix formulation we seek here. The main result from that section was (16.82), which expressed the photon irradiance on the detector plane. We can adapt that expression to SPECT by adding an index j (specifying projection angle) to the photon irradiance $I_p(\mathbf{r})$ and to the collimator transmission $T(\mathbf{r}, \hat{\mathbf{s}})$. For simplicity, we drop the subscript p (which stood for *photon*), but, by some sort of perverted conservation law, we add a superscript as a reminder that

we are dealing only with unscattered photons. Thus we rewrite (16.82) as

$$I_j^{(un)}(\mathbf{r}) = \frac{1}{4\pi} \int_{2\pi} d\Omega T_j(\mathbf{r}, \hat{\mathbf{s}}) \int_0^\infty d\ell f(\mathbf{r} - \hat{\mathbf{s}}\ell) \exp \left[- \int_0^\ell d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell', \mathcal{E}_0) \right]. \quad (17.203)$$

The reader should recall our convention that the 2D vector \mathbf{r} and the 3D vector \mathbf{r} refer to the same physical location.

The relation between the photon irradiance and the discrete detector output is discussed in detail in Sec. 16.2.3. For an Anger camera, the key result is (16.1047), which in the present notation becomes

$$\bar{g}_{\mathbf{m}}^{(un)} = \tau \eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0) \int_{\mathbf{m}} d^2\hat{r} \int_\infty d^2r \text{pr}(\hat{\mathbf{r}}|\mathbf{r}, \mathcal{E}_0) I_j^{(un)}(\mathbf{r}), \quad (17.204)$$

where the range of the $\hat{\mathbf{r}}$ integral is over the 2D extent of the detector pixel indexed by $\mathbf{m} = (m_x, m_y)$. Continuing our probabilistic interpretation, we note that $\int_{\mathbf{m}} d^2\hat{r} \text{pr}(\hat{\mathbf{r}}|\mathbf{r}, \mathcal{E}_0)$ is the probability that a photon of energy \mathcal{E}_0 striking the detector face at point \mathbf{r} is estimated to fall in data bin \mathbf{m} , provided that it is absorbed [probability $\eta(\mathcal{E}_0)$] and that its estimated energy falls in the window [probability $P_{acc}(\mathcal{E}_0)$]. Combining (17.203) and (17.204) with (17.201) yields a complicated expression for the elements of $\mathbf{H}^{(un)}$:

$$H_{\mathbf{m}\mathbf{n}}^{(un)} = \frac{\tau \eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0)}{4\pi} \int_{\mathbf{m}} d^2\hat{r} \int_\infty d^2r \text{pr}(\hat{\mathbf{r}}|\mathbf{r}, \mathcal{E}_0) \int_{2\pi} d\Omega T_j(\mathbf{r}, \hat{\mathbf{s}}) \times \int_0^\infty d\ell \phi_{\mathbf{n}}(\mathbf{r} - \hat{\mathbf{s}}\ell) \exp \left[- \int_0^\ell d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell', \mathcal{E}_0) \right]. \quad (17.205)$$

We can put this expression into a more useful form by also adopting a discrete model for the detector. If we imagine that there is a pixel grid on the camera face, we can replace the integral over \mathbf{r} with a discrete sum over points $\{\mathbf{r}_{\mathbf{m}'}\}$. For simplicity we assume that these points have the same spacing ϵ_d as in the final image array. Then we can define a block-diagonal $M^2J \times M^2J$ matrix $\mathbf{H}^{(det)}$ representing the detector; its elements are given by

$$H_{\mathbf{m}\mathbf{m}'}^{(det)} = \delta_{jj'} \eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0) \int_{\mathbf{m}} d^2\hat{r} \text{pr}(\hat{\mathbf{r}}|\mathbf{r}_{\mathbf{m}'}, \mathcal{E}_0), \quad (17.206)$$

where $\mathbf{m} = (\mathbf{m}, j)$ and $\mathbf{m}' = (\mathbf{m}', j')$. Thus $H_{\mathbf{m}\mathbf{m}'}^{(det)}$ is the probability that a photon striking the detector at point \mathbf{m}' is detected and assigned to bin \mathbf{m} . This probability is assumed here to be independent of which projection is being measured—hence the block-diagonal form—but there could also be a dependence on j if different detectors were used for different projections.

Similarly, we can define an $M^2J \times N^3$ matrix $\mathbf{H}^{(un,prop)}$ representing propagation without scatter from the source location to the detector input; its elements are given by

$$H_{\mathbf{m}'\mathbf{n}}^{(un,prop)} = \frac{\tau \epsilon_d^2}{4\pi} \int_{2\pi} d\Omega T_j(\mathbf{r}_{\mathbf{m}'}, \hat{\mathbf{s}}) \int_0^\infty d\ell \phi_{\mathbf{n}}(\mathbf{r}_{\mathbf{m}'} - \hat{\mathbf{s}}\ell) \exp \left[- \int_0^\ell d\ell' \mu_{tot}(\mathbf{r}_{\mathbf{m}'} - \hat{\mathbf{s}}\ell', \mathcal{E}_0) \right]. \quad (17.207)$$

With these definitions, we see that

$$\mathbf{H}^{(un)} = \mathbf{H}^{(det)} \mathbf{H}^{(un,prop)}. \quad (17.208)$$

A further factorization is achieved if we assume that the attenuation coefficient $\mu_{tot}(\cdot)$ is slowly varying over a distance scale defined by the size of the voxel. If the voxel is small enough, then the function $\phi_{\mathbf{n}}(\mathbf{r}_{\mathbf{m}'} - \hat{\mathbf{s}}\ell)$ is zero unless $\mathbf{r}_{\mathbf{m}'} - \hat{\mathbf{s}}\ell \approx \mathbf{r}_{\mathbf{n}}$, so we can write

$$\exp\left[-\int_0^\ell d\ell' \mu_{tot}(\mathbf{r}_{\mathbf{m}'} - \hat{\mathbf{s}}\ell', \mathcal{E}_0)\right] \approx \exp\left[-\int_0^{|\mathbf{r}_{\mathbf{m}'} - \mathbf{r}_{\mathbf{n}}|} d\ell'' \mu_{tot}\left(\mathbf{r}_{\mathbf{n}} + \frac{\mathbf{r}_{\mathbf{m}'} - \mathbf{r}_{\mathbf{n}}}{|\mathbf{r}_{\mathbf{m}'} - \mathbf{r}_{\mathbf{n}}|} \ell'', \mathcal{E}_0\right)\right], \quad (17.209)$$

where $\ell'' \equiv \ell - \ell'$, and we note that $\ell \approx |\mathbf{r}_{\mathbf{m}'} - \mathbf{r}_{\mathbf{n}}|$ within the current approximation. Since the right-hand side of (17.209) is independent of $\hat{\mathbf{s}}$ and ℓ , we can remove it from the integrals in (17.207) and write

$$H_{\mathbf{m}'\mathbf{n}}^{(un,prop)} = H_{\mathbf{m}'\mathbf{n}}^{(geom)} A_{\mathbf{m}'\mathbf{n}}, \quad (17.210)$$

where

$$H_{\mathbf{m}'\mathbf{n}}^{(geom)} = \frac{\tau \epsilon_d^2}{4\pi} \int_{2\pi} d\Omega T_j(\mathbf{r}_{\mathbf{m}'}, \hat{\mathbf{s}}) \int_0^\infty d\ell \phi_{\mathbf{n}}(\mathbf{r}_{\mathbf{m}'} - \hat{\mathbf{s}}\ell) \quad (17.211)$$

and

$$A_{\mathbf{m}'\mathbf{n}} = \exp\left[-\int_0^{|\mathbf{r}_{\mathbf{m}'} - \mathbf{r}_{\mathbf{n}}|} d\ell'' \mu_{tot}\left(\mathbf{r}_{\mathbf{n}} + \frac{\mathbf{r}_{\mathbf{m}'} - \mathbf{r}_{\mathbf{n}}}{|\mathbf{r}_{\mathbf{m}'} - \mathbf{r}_{\mathbf{n}}|} \ell'', \mathcal{E}_0\right)\right]. \quad (17.212)$$

The first factor in (17.210) represents geometric or straight-line propagation from the voxel location to the detector element without attenuation or scatter, and the second factor is the attenuation along this path in the small-voxel approximation. The element-by-element product in (17.210) is called a *Hadamard product* and denoted \odot (see Sec. A.2.8), and we can write

$$\mathbf{H}^{(un,prop)} = \mathbf{H}^{(geom)} \odot \mathbf{A}, \quad \mathbf{H}^{(un)} = \mathbf{H}^{(det)} \left[\mathbf{H}^{(geom)} \odot \mathbf{A} \right]. \quad (17.213)$$

We might also be able to assume that the attenuation factor is slowly varying over a scale defined by the spatial resolution of the detector or, in other words, that the attenuation of a photon from any point in the object to the point where the photon strikes the detector face is approximately the same as the attenuation to the point where the detector *thinks* the photon strikes it. If that is the case, we can replace $\mathbf{r}_{\mathbf{m}'}$ with $\mathbf{r}_{\mathbf{m}}$ in $A_{\mathbf{m}'\mathbf{n}}$, and we have

$$\mathbf{H}^{(un)} \approx \left[\mathbf{H}^{(det)} \mathbf{H}^{(geom)} \right] \odot \mathbf{A}. \quad (17.214)$$

The advantage of this form is that the product $\mathbf{H}^{(det)} \mathbf{H}^{(geom)}$ depends on the system, while \mathbf{A} depends only on the particular patient being imaged. Thus, if we can characterize the system response in air, then a simple element-by-element correction yields a patient-specific \mathbf{H} matrix, at least when scatter is neglected.

With scatter, the full \mathbf{H} matrix is given by

$$\mathbf{H} = \mathbf{H}^{(sc)} + \left[\mathbf{H}^{(det)} \mathbf{H}^{(geom)} \right] \odot \mathbf{A}. \quad (17.215)$$

Now we have an additive patient-specific correction as well as a multiplicative one. The scatter matrix $\mathbf{H}^{(sc)}$ cannot, however, be decomposed as neatly as $\mathbf{H}^{(un)}$. The Hadamard factorization with an attenuation factor does not work since the scatter arriving at a point on the detector face may come from many different points in the object, each with its own attenuation factor. Moreover, the attenuation coefficient depends on photon energy \mathcal{E} , so different attenuation factors would have to be applied for different scattered photons to be rigorous.

To understand the roles of detector and propagation with scatter, we can define an energy-dependent scatter propagation matrix $\mathbf{H}^{(sc,prop)}(\mathcal{E})$ in such a way that $H_{\mathbf{m}'\mathbf{n}}^{(sc,prop)}(\mathcal{E})\Delta\mathcal{E}$ is the probability that a photon emitted from voxel \mathbf{n} will undergo one or more scattering events and arrive at point \mathbf{m}' on the discretized detector face with energy in the small interval $(\mathcal{E} - \frac{1}{2}\Delta\mathcal{E}, \mathcal{E} + \frac{1}{2}\Delta\mathcal{E})$. With this definition, the overall scatter matrix has elements given by

$$H_{\mathbf{m}'\mathbf{n}}^{(sc)} = \sum_{\mathbf{m}'} \int_0^{\mathcal{E}_0^-} d\mathcal{E} \eta(\mathcal{E}) P_{acc}(\mathcal{E}) \int_{\mathbf{m}} d^2\hat{r} \text{pr}(\hat{\mathbf{r}}|\mathbf{r}_{\mathbf{m}'}, \mathcal{E}) H_{\mathbf{m}'\mathbf{n}}^{(sc,prop)}(\mathcal{E}). \quad (17.216)$$

Because of the integral over energy, factorization into purely detector-dependent and detector-independent factors is not possible. We may, however, be able to assume that $\text{pr}(\hat{\mathbf{r}}|\mathbf{r}_{\mathbf{m}'}, \mathcal{E})$ is approximately independent of \mathcal{E} , at least for energies such that $P_{acc}(\mathcal{E}) \neq 0$. In that case, we can write

$$\mathbf{H}^{(sc)} = \mathbf{H}^{(est)} \mathbf{H}^{(sc,prop)}, \quad (17.217)$$

where $\mathbf{H}^{(est)}$ is a matrix expressing the position-estimation process, with elements given by

$$H_{\mathbf{m}'\mathbf{m}'}^{(est)} = \delta_{jj'} \int_{\mathbf{m}} d^2\hat{r} \text{pr}(\hat{\mathbf{r}}|\mathbf{r}_{\mathbf{m}'}), \quad (17.218)$$

and $\mathbf{H}^{(sc,prop)}$ (without the energy argument) is defined by

$$H_{\mathbf{m}'\mathbf{n}}^{(sc,prop)} = \int_0^{\mathcal{E}_0^-} d\mathcal{E} \eta(\mathcal{E}) P_{acc}(\mathcal{E}) H_{\mathbf{m}'\mathbf{n}}^{(sc,prop)}(\mathcal{E}). \quad (17.219)$$

Both of the factors in (17.217) involve characteristics of the detector, but the factorization is still useful since $\mathbf{H}^{(est)}$ expresses the spatial blur of the detector and $\mathbf{H}^{(sc,prop)}$ expresses its energy dependence. Moreover, $\mathbf{H}^{(est)}$ is independent of the patient being imaged, while $\mathbf{H}^{(sc,prop)}$ does depend on the patient.

Measurement of \mathbf{H} As suggested in Sec. 7.4.1, it is possible to measure an \mathbf{H} matrix by using a radioactive source with spatial distribution $\phi(\mathbf{r})$ and then systematically stepping it through the various positions $\{\mathbf{r}_{\mathbf{n}}\}$, creating the functions $\phi_{\mathbf{n}}(\mathbf{r}) = \phi(\mathbf{r} - \mathbf{r}_{\mathbf{n}})$. In principle, one could immerse this source in a medium with attenuating and scattering properties similar to those of the patient, thereby directly measuring $H_{\mathbf{m}'\mathbf{n}}$, but the practical difficulties in doing so hardly require enumeration.

A somewhat more practical method is to image the voxel source at various positions in air, which estimates $\mathbf{H}^{(det)}\mathbf{H}^{(geom)}$. The Hadamard product with a patient-specific attenuation matrix as in (17.214) then gives an estimate of $\mathbf{H}^{(un)}$ completely empirically.

This method is used routinely at the University of Arizona, but it produces startlingly large matrices. For example, when the FASTSPECT system (Rowe *et al.*, 1993) is configured for imaging human brains, a volume of at least 3000 cm^3 must be mapped, requiring 375,000 values of \mathbf{n} if 2 mm voxels are used. Since FASTSPECT uses 24 small, modular scintillation cameras, with the output of each discretized into a 64×64 array, each source location gives $24 \times 64 \times 64 \approx 100,000$ measurements, and the dimensions of $\mathbf{H}^{(un)}$ are thus around $100,000 \times 375,000$.

Sparseness Most iterative algorithms can be written to take advantage of sparse matrices. In SPECT, $\mathbf{H}^{(un)}$ is sparse since photons detected in bin \mathbf{m} must have originated somewhere near the line of sight from that detector location back through the collimator or pinhole into the object space; most object voxels are far from this line of sight and cannot contribute to $g_{\mathbf{m}}$. Thus most of the elements of $\mathbf{H}^{(un)}$ are near zero and do not have to be stored. In FASTSPECT, for example, only about 2% of the elements are stored.

Scattered photons, on the other hand, can in principle make it from any object voxel to any data bin, so the sparseness is lost. Since iterative algorithms with sparse matrices execute faster than ones with filled matrices, there is a practical incentive to ignore scattering or to try to compensate for it somehow.

Approximate shift-invariance and interpolation of \mathbf{H} In Sec. 16.2.2, we argued that the point response of a collimator was approximately shift-invariant for lateral translations of the point source [see (16.88)]. To be sure, this response depends on distance from the collimator face, but only by means of a slowly varying scale factor. Similarly, the point response of a pinhole aperture is also approximately shift-invariant laterally and slowly varying longitudinally. Moreover, the detector response is also approximately shift-invariant for most detectors. We can take advantage of these features to reduce the number of components of $\mathbf{H}^{(un)}$ that must be measured.

The trick is to decompose each column of $\mathbf{H}^{(un)}$ into its centroid on the detector and a spread about the centroid by writing

$$H_{\mathbf{m}\mathbf{n}}^{(un)} = h_{j\mathbf{n}}[\mathbf{m} - \mathbf{m}_c(\mathbf{n}, j)], \quad (17.220)$$

where the 2D index vector $\mathbf{m}_c(\mathbf{n}, j)$ denotes the centroid of the image of $\phi_{\mathbf{n}}(\mathbf{r})$ on the detector output for the j^{th} projection angle. Because of the sparseness as discussed above, $h_{j\mathbf{n}}[\mathbf{m} - \mathbf{m}_c(\mathbf{n}, j)]$ is nonzero for only a small set of \mathbf{m} near $\mathbf{m}_c(\mathbf{n}, j)$.

If $h_{j\mathbf{n}}(\mathbf{m})$ and $\mathbf{m}_c(\mathbf{n}, j)$ are slowly varying functions of source location \mathbf{n} , then we may not need to measure $\mathbf{H}_{\mathbf{m}\mathbf{n}}^{(un)}$ for all \mathbf{n} ; it might suffice to measure every other point or every third point in each of the three directions. The matrix elements for the unmeasured points can be recovered by interpolation of the centroids and averaging the blur functions $h_{j\mathbf{n}}(\mathbf{m})$ for the neighboring measured points. This interpolation can be done on the fly during iterative reconstruction, so it is not necessary to store the matrix elements for unmeasured points. If every other point is measured, there is a savings of a factor of 8 in measurement time and storage required, and if every third point is measured the savings is a factor of 27.

Monte-Carlo estimation of \mathbf{H} The probabilistic interpretation of \mathbf{H} suggests that it can be usefully estimated by Monte Carlo methods. As we saw in Sec. 10.4.5, the essence of a Monte Carlo calculation is simply to trace photons from a source

to a detector in a computer. For Monte Carlo calculation of the \mathbf{n}^{th} column of \mathbf{H} with a voxel representation, the source in question is the \mathbf{n}^{th} voxel, and tracing photons from this source is a computer simulation of the measurement process described above. One difference between the computer simulation and an actual measurement, however, is that we can choose to omit the effects of the detector in the former. That is, we can choose to estimate $\mathbf{H}^{(un,prop)}$ and $\mathbf{H}^{(sc,prop)}$ by Monte Carlo methods and then obtain the final \mathbf{H} matrix by multiplying them by a sparse matrix characteristic of the detector.

The interpolation methods described above for measured \mathbf{H} matrices apply also to Monte Carlo calculation, but now the savings are in computation time, not measurement time.

17.3 NOISE AND IMAGE QUALITY

In order to discuss image quality in SPECT, we need an understanding of the noise properties of the images, which means we must both characterize the noise in the raw data and analyze how that noise propagates through the data processing, including any preprocessing steps and the reconstruction algorithm itself. Basic tools for this analysis were developed in Chaps. 8, 11, 12 and 15, and here we shall apply them to SPECT.

In Sec. 17.3.1 we discuss the noise properties of the measured data and how it is modified before being used in image reconstruction. In Sec. 17.3.2, we discuss the effects of noise on reconstructed images, and in Sec. 17.3.3, we address the thorny topic of reconstruction artifacts. Finally, in Sec. 17.3.4 we apply what we have learned to objective assessment of image quality in SPECT.

17.3.1 Noise in the data

We know from the discussions in Chaps. 11 and 12 that the raw data in SPECT are strictly Poisson, in spite of such complicated phenomena as attenuation, scatter, depth-dependent blur and position estimation. That is, conditional on a particular object, the measurements $\{g_{\mathbf{m}}\}$ are independent of each other, and each is a Poisson random variable (see also Sec. 16.2.4).

The mean of $g_{\mathbf{m}}$, however, is $[\mathcal{H}\mathbf{f}]_{\mathbf{m}}$, not $[\mathbf{H}\boldsymbol{\theta}]_{\mathbf{m}}$. As in (15.10), we can write

$$\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}, \quad (17.221)$$

but in terms of the approximate representation (15.6) or (17.198), we can also write [*cf.* (15.11)]

$$\mathbf{g} = \mathcal{H}\mathbf{f}_a + \mathcal{H}\mathbf{f} - \mathcal{H}\mathbf{f}_a + \mathbf{n} \equiv \mathbf{H}\boldsymbol{\theta} + \boldsymbol{\epsilon}, \quad (17.222)$$

where the overall error $\boldsymbol{\epsilon}$ (modeling error plus noise) is given by

$$\boldsymbol{\epsilon} = \mathcal{H}\mathbf{f} - \mathcal{H}\mathbf{f}_a + \mathbf{n}. \quad (17.223)$$

There is no reason to believe that the modeling error is small compared to the Poisson noise. Indeed, the Poisson contribution to $\boldsymbol{\epsilon}$ can be made arbitrarily small by increasing the exposure time and hence the mean number of photons collected. (The modeling error can also be made arbitrarily small by increasing the number of expansion functions in (17.198), but this is seldom practical.)

Nevertheless, the covariance matrix of \mathbf{g} is essentially unchanged by the modeling error, at least so long as object randomness is not considered. Without approximation, we have that

$$[\mathbf{K}_{\mathbf{g}|\mathbf{f}}]_{\mathbf{m}\mathbf{m}'} = [\mathcal{H}\mathbf{f}]_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'}, \quad (17.224)$$

where $\delta_{\mathbf{m}\mathbf{m}'}$ is really the product of three Kronecker deltas, one for each of the two components of the detector index and one for the projection angles. Since $\mathbf{H}\boldsymbol{\theta}$ is usually a good approximation to $\mathcal{H}\mathbf{f}$, there is probably no great error in writing

$$[\mathbf{K}_{\mathbf{g}|\mathbf{f}}]_{\mathbf{m}\mathbf{m}'} \approx [\mathbf{H}\boldsymbol{\theta}]_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'}. \quad (17.225)$$

In particular, the modeling error does not introduce any correlations since $\mathcal{H}\mathbf{f} - \mathcal{H}\mathbf{f}_a$ is a nonrandom vector. We emphasize, however, that this is true only conditional on a particular object; when object randomness is considered, the covariance of the modeling error will not be diagonal.

Correction for detector imperfections Real detectors suffer from nonuniform response and possibly geometric distortion, and it is common practice to correct the raw projection data before applying a reconstruction algorithm. For example, nonuniformity in the flood response of the detector can be corrected by dividing by a stored flood image (see Sec. 7.2.1), and various interpolation algorithms can be used to correct distortion. These corrections make most reconstruction algorithms more accurate since the data after correction come closer to what was assumed in the derivation of the algorithm, but they also alter the noise properties of the data.

Simple flood division can have a surprisingly complicated effect on the covariance matrix of SPECT data. Since an experimental flood image itself suffers from Poisson noise, the corrected measurements are ratios of two Poisson random variables, which are not themselves a Poisson random variable. The covariance matrix for the corrected data in a single projection is still diagonal, but the diagonal elements are not equal to the mean. If, however, the same detector is used to record all of the projections by rotating it to different angles, then the fluctuations introduced by dividing by a common noisy flood are correlated from angle to angle, and the covariance matrix is no longer diagonal in the angular variables j and j' . Fortunately, this complication can be avoided by using a very large number of counts in the reference flood image.

Distortion in scintillation cameras of the Anger type arises from bias in the position estimation (see Sec. 12.3.6). With bias, detected events are not assigned to their correct locations on the camera face, even on average. If we apply a discretized analytic reconstruction to such distorted projection data, severe artifacts can result from the mismatch between the actual data characteristics and those assumed in derivation of the algorithm. Similarly, if we use an iterative algorithm with an analytic \mathbf{H} matrix that takes no account of the distortion, then again artifacts ensue.

There are essentially three ways to avoid problems with camera distortion: (1) characterize it and incorporate it in the reconstruction algorithm; (2) avoid it in the first place by using unbiased position estimators; or (3) correct the data after measurement but before starting reconstruction. Options 1 and 2 require calibration steps that would be onerous in routine clinical applications. We can characterize the distortion by using a measured \mathbf{H} matrix, but we saw in Sec. 17.2.6 that the resulting matrix is huge, and it can be used only in time-consuming iterative algorithms. Similarly, we know from Sec. 12.3.6 how to construct a maximum-likelihood

position estimator, which is unbiased in the limit of a large number of optical photons per scintillation event, but it also requires an additional calibration step to determine the response functions of the individual photomultipliers.

Thus routine clinical practice currently uses some sort of distortion correction. The usual procedure is to record a high-count image of a radioactive grid and then interpolate the data so that the resulting image after interpolation is undistorted. When this same interpolation is applied to actual, noisy projection data, distortion is removed on average, but short-range correlations can be introduced. To the authors' knowledge, the effect of these correlations on the reconstructed images has not been studied.

Scatter correction Since real gamma-ray detectors do not have perfect energy discrimination, measured projection data will inevitably have contributions from both unscattered and scattered photons. Almost all reconstruction algorithms are derived on the assumption of no scatter, and severe quantitative errors can result when such algorithms are applied to real data. Much effort has been expended on ways of preprocessing the data to remove the effects of scatter on average, but much less attention has been paid to the effect of these corrections on statistical properties of the data.

One common way of removing scatter is to use two energy windows, one centered on the photopeak and one centered at a substantially lower energy, separated from the photopeak by more than the energy resolution of the detector. With isotopes that emit only a single gamma-ray energy, there is very little probability that an unscattered photon will contribute to the lower window, so the number of counts in that window can be used to form an estimate of the mean number of scattered photons contributing to a particular detector bin in a particular projection direction. This estimate can then be used along with some assumed scatter spectrum and knowledge of $P_{acc}(\mathcal{E})$ to compute an estimate of the scatter contribution in the photopeak window and subtract it off.

Since the number of counts in the lower window is a Poisson random variable, the corrected photopeak measurement is a weighted difference between Poisson random variables. This difference is not itself Poisson, but it is statistically independent from detector bin to detector bin and also from projection angle to projection angle. Thus the covariance matrix of the corrected data remains diagonal, but the diagonal elements are not equal to the mean.

Noise in the \mathbf{H} matrix Up to here in this book, we have regarded the system matrix \mathbf{H} as a deterministic quantity; we may not know it very well, but it isn't random. When we either measure it directly or compute it by Monte Carlo simulation, however, \mathbf{H} becomes random in a sense: if we were to repeat the measurement or simulation, we would get a different matrix. On the other hand, if we use this random matrix in any reconstruction algorithm, it becomes a fixed characteristic of the algorithm. Errors of \mathbf{H} arising from Poisson statistics in a measurement are, in principle, no different from modeling errors. They do not contribute to the covariance of reconstructed images if we think of that covariance in terms of repeated images, all reconstructed with the same \mathbf{H} , but they do, of course, affect objective measures of image quality.

17.3.2 Noise in reconstructed images

As we know from Secs. 15.2.6, 15.3.6 and 15.4.7, Poisson noise in the raw data can propagate in complicated ways through linear or nonlinear reconstruction algorithms. In this section we point out some of the complications that are specific to emission tomographic reconstruction.

Noise in one-step linear reconstructions The variance and covariance after application of a linear reconstruction operator \mathbf{O} were derived in Sec. 15.2.6. Transcribing (15.120) and (15.121) into our multi-index notation and making the same approximation as in (17.225), we obtain

$$\left[\mathbf{K}_{\hat{\theta}|\mathbf{f}}\right]_{\mathbf{nn}'} = \sum_{\mathbf{m}} [\mathcal{H}\mathbf{f}]_{\mathbf{m}} O_{\mathbf{nm}} O_{\mathbf{n}'\mathbf{m}}^* \approx \sum_{\mathbf{m}} [\mathbf{H}\boldsymbol{\theta}]_{\mathbf{m}} O_{\mathbf{nm}} O_{\mathbf{n}'\mathbf{m}}^*, \quad (17.226)$$

$$\text{Var}\{\hat{\theta}_{\mathbf{n}}|\mathbf{f}\} = \sum_{\mathbf{m}} [\mathcal{H}\mathbf{f}]_{\mathbf{m}} |O_{\mathbf{nm}}|^2 \approx \sum_{\mathbf{m}} [\mathbf{H}\boldsymbol{\theta}]_{\mathbf{m}} |O_{\mathbf{nm}}|^2. \quad (17.227)$$

The variance expressions can also be written as [*cf.* (15.122) and (15.123)]

$$\text{Var}\{\hat{\theta}_{\mathbf{n}}|\mathbf{f}\} = \int_{\mathbf{S}_f} d^q r \aleph_{\mathbf{n}}(\mathbf{r}) f(\mathbf{r}) \approx \sum_{\mathbf{n}'} \aleph_{\mathbf{nn}'} \theta_{\mathbf{n}'}, \quad (17.228)$$

where $\aleph_{\mathbf{n}}(\mathbf{r})$ is the noise kernel, defined by

$$\aleph_{\mathbf{n}}(\mathbf{r}) \equiv \sum_{\mathbf{m}} |O_{\mathbf{nm}}|^2 h_{\mathbf{m}}(\mathbf{r}), \quad (17.229)$$

and \aleph is a matrix approximation to the noise kernel, with elements given by

$$\aleph_{\mathbf{nn}'} \equiv \sum_{\mathbf{m}} |O_{\mathbf{nm}}|^2 H_{\mathbf{mn}'}. \quad (17.230)$$

The noise kernel thus makes it possible to see how noise at different locations in the reconstruction arises from different points in the object.

In evaluating these variance and covariance expressions, relatively crude approximations to $[\mathcal{H}\mathbf{f}]_{\mathbf{m}}$ or $[\mathbf{H}\boldsymbol{\theta}]_{\mathbf{m}}$ can often be used. Blurring of the data by the collimator or detector is relatively unimportant in (17.227), for example, since $|O_{\mathbf{nm}}|^2$ is nonnegative and hence itself a blurring operator. In addition, small or low-contrast features in the object can be ignored if they do not affect the mean data very much. For example, suppose the object is a cylindrical phantom of diameter D with uniform activity f_0 except for a small, hot sphere simulating a tumor. If the diameter of the tumor is D_t and its activity is f_t , then the tumor can be ignored for purposes of computing the noise (though not for purposes of computing the mean image) if $D_t f_t \ll D f_0$. In this case, most of the counts come from the large cylindrical region, so most of the noise comes from there as well.

Filtered backprojection To understand the implications of (17.226)–(17.230) for SPECT reconstructions, let us consider filtered backprojection with the sampled filter function of (17.192). That filter was derived for 2D reconstruction, but it is

applicable to 3D rotating-camera SPECT with a parallel-hole collimator since the 3D volume can be reconstructed one 2D slice at a time (see Sec. 17.1.4).

The matrix elements of (17.192) are given by¹²

$$O_{\mathbf{n}jk} = \int_{-\infty}^{\infty} |\nu| d\nu A(\nu) \exp(2\pi i \mathbf{r}_{\mathbf{n}} \cdot \hat{\mathbf{n}}_j \nu) \exp(-2\pi i \nu p_k) = h_A(\mathbf{r}_{\mathbf{n}} \cdot \hat{\mathbf{n}}_j - p_k), \quad (17.231)$$

where $h_A(p) = \mathcal{F}_1^{-1}\{|\nu|A(\nu)\}$. This function (or actually, its negative) is plotted in Fig. 2.6b for one particular choice of $A(\nu)$, but other choices will give similar behavior: the filter function $h(p)$ will always have a central positive core and negative wings that fall off as $-1/p^2$.

With (17.229) and (17.231), the noise kernel for filtered backprojection is given by

$$\aleph_{\mathbf{n}}(\mathbf{r}) = \sum_j \sum_k h_A^2(\mathbf{r}_{\mathbf{n}} \cdot \hat{\mathbf{n}}_j - p_k) h_{jk}(\mathbf{r}). \quad (17.232)$$

Similarly, the covariance matrix can be written as

$$\left[\mathbf{K}_{\hat{\theta}|\mathbf{f}} \right]_{\mathbf{nn}'} = \sum_j \sum_k h_A(\mathbf{r}_{\mathbf{n}} \cdot \hat{\mathbf{n}}_j - p_k) h_A(\mathbf{r}_{\mathbf{n}'} \cdot \hat{\mathbf{n}}_j - p_k) [\mathcal{H}\mathbf{f}]_{jk}. \quad (17.233)$$

As noted above, we do not need to be very precise in specifying the mean data $[\mathcal{H}\mathbf{f}]_{jk}$ when computing the noise properties, so rough approximations to $h_{jk}(\mathbf{r})$ can be used. In particular, if we ignore attenuation and all blurring processes, we can write

$$h_{jk}(\mathbf{r}) \approx C \delta(p_k - \mathbf{r} \cdot \hat{\mathbf{n}}_j), \quad (17.234)$$

where [*cf.* (16.98) and (16.104)]

$$C = \tau \eta(\mathcal{E}_0) P_{acc}(\mathcal{E}_0) \epsilon^2 \frac{\alpha_{pf} D_b^2}{16L_b^2}, \quad (17.235)$$

with τ being the exposure time for a single projection and ϵ^2 the area of a bin in the camera output.

Continuous data Though the discrete expressions (17.232) and (17.233) should be used when accurate results are desired, considerable insight into the noise properties of filtered backprojection can be obtained by regarding the data as continuous and replacing the sums by integrals. First, we assume that very fine angular sampling is used so that the sum over j can be replaced by an integral over projection angle ϕ . With rotating-camera SPECT, this approximation can be realized in practice to an arbitrary accuracy since the camera can be stepped in fine angular increments with no difficulty. Second, we assume that the grid used to record the irradiance on the detector is fine compared to the large-scale structure of the mean data; as noted above, we do not need to worry much about small-scale structure in the mean data

¹²We are now using a mixed index notation, where the multi-index \mathbf{n} specifies the voxel in the reconstruction and the scalar indices j and k specify rotation angle and 1D position on the detector, respectively. The reader should not confuse \mathbf{n} with the unit vector $\hat{\mathbf{n}}_j$.

when calculating the noise. Taking the sampling intervals in p and ϕ as Δp and $\Delta\phi$, respectively, and assuming 360° rotation of the camera, we can rewrite (17.233) as

$$\left[\mathbf{K}_{\hat{\theta}|\mathbf{f}}\right]_{\mathbf{nn}'} = \frac{1}{\Delta\phi\Delta p} \int_0^{2\pi} d\phi \int_{-\infty}^{\infty} dp h_A(\mathbf{r}_n \cdot \hat{\mathbf{n}} - p) h_A(\mathbf{r}_{n'} \cdot \hat{\mathbf{n}} - p) [\mathcal{H}\mathbf{f}](p, \phi). \quad (17.236)$$

With approximation (17.234), the covariance matrix becomes

$$\left[\mathbf{K}_{\hat{\theta}|\mathbf{f}}\right]_{\mathbf{nn}'} = \frac{C}{\Delta\phi\Delta p} \int_{-\infty}^{\infty} d^2r_o f(\mathbf{r}_o) \int_0^{2\pi} d\phi h_A[(\mathbf{r}_n - \mathbf{r}_o) \cdot \hat{\mathbf{n}}] h_A[(\mathbf{r}_{n'} - \mathbf{r}_o) \cdot \hat{\mathbf{n}}]. \quad (17.237)$$

The variance is obtained by setting $\mathbf{n} = \mathbf{n}'$, or

$$\text{Var}\{\hat{\theta}_n|\mathbf{f}\} = \frac{C}{\Delta\phi\Delta p} \int_{-\infty}^{\infty} d^2r_o f(\mathbf{r}_o) \int_0^{2\pi} d\phi h_A^2[(\mathbf{r}_n - \mathbf{r}_o) \cdot \hat{\mathbf{n}}], \quad (17.238)$$

so the noise kernel is given by

$$\aleph_n(\mathbf{r}_o) = \frac{C}{\Delta\phi\Delta p} \int_0^{2\pi} d\phi h_A^2[(\mathbf{r}_n - \mathbf{r}_o) \cdot \hat{\mathbf{n}}]. \quad (17.239)$$

An immediate conclusion from (17.238) is that the mapping from the object to the variance distribution is shift-invariant under our assumptions of continuous data and simple Radon system kernel (17.234). It does not follow, however, that the noise is stationary; for a stationary random process, the variance must be independent of position, while here it is given as a convolution of the noise kernel with the object.

Another useful form for the noise kernel can be obtained by the change of variable $u = |\mathbf{r}_n - \mathbf{r}_o| \cos \phi'$, where ϕ' is the angle between $\mathbf{r}_n - \mathbf{r}_o$ and $\hat{\mathbf{n}}$. Then we have

$$\aleph_n(\mathbf{r}_o) = \frac{2C}{\Delta\phi\Delta p} \int_{-|\mathbf{r}_n - \mathbf{r}_o|}^{|\mathbf{r}_n - \mathbf{r}_o|} du \frac{h_A^2(u)}{\sqrt{|\mathbf{r}_n - \mathbf{r}_o|^2 - u^2}}. \quad (17.240)$$

To interpret this result, we recognize that $h_A^2(u)$ is nonnegative and falls off asymptotically as $1/u^4$, so it is highly concentrated near $u = 0$. The width of this function is of order $1/\nu_A$, where ν_A is the width of $A(\nu)$. When $|\mathbf{r}_n - \mathbf{r}_o| \gg 1/\nu_A$, we see that

$$\aleph_n(\mathbf{r}_o) \approx \frac{2C}{\Delta\phi\Delta p} \frac{1}{|\mathbf{r}_n - \mathbf{r}_o|} \int_{-\infty}^{\infty} du h_A^2(u) = \frac{2C}{\Delta\phi\Delta p} \frac{1}{|\mathbf{r}_n - \mathbf{r}_o|} \int_{-\infty}^{\infty} d\nu \nu^2 A^2(\nu), \quad (17.241)$$

where the last step follows from Parseval's theorem, (3.80). To be explicit, if we choose

$$A(\nu) = \exp\left(-\frac{\nu^2}{2\nu_0^2}\right), \quad (17.242)$$

then

$$\int_{-\infty}^{\infty} d\nu \nu^2 A^2(\nu) = \frac{\sqrt{\pi}}{2} \nu_0^3. \quad (17.243)$$

This result shows that the variance at a point in the reconstruction varies as the cube of the rolloff frequency of the filter function. Since the spatial resolution varies only linearly with ν_0 , a two-fold increase in resolution is accompanied by an eight-fold increase in variance (or $2\sqrt{2}$ -fold in standard deviation).

Disk object Additional features of the noise in filtered backprojection can be discerned by considering a uniform disk object. For simplicity, we continue to assume continuous data and the Radon kernel of (17.234).

For a disk object of radius R_d and activity f_0 , (17.237) becomes

$$\left[\mathbf{K}_{\hat{\theta}|\mathbf{f}} \right]_{\mathbf{nn}'} = \frac{Cf_0}{\Delta\phi\Delta p} \int_0^{R_d} r_o dr_o \int_0^{2\pi} d\theta_o \int_0^{2\pi} d\phi h_A[(\mathbf{r}_n - \mathbf{r}_o) \cdot \hat{\mathbf{n}}] h_A[(\mathbf{r}_{n'} - \mathbf{r}_o) \cdot \hat{\mathbf{n}}]. \quad (17.244)$$

Representing the filter functions by their Fourier transforms and swapping integrals, we obtain

$$\left[\mathbf{K}_{\hat{\theta}|\mathbf{f}} \right]_{\mathbf{nn}'} = \frac{Cf_0}{\Delta\phi\Delta p} \int_{-\infty}^{\infty} d\nu |\nu| A(\nu) \int_{-\infty}^{\infty} d\nu' |\nu'| A(\nu') \int_0^{R_d} r_o dr_o \int_0^{2\pi} d\theta_o \int_0^{2\pi} d\phi \\ \times \exp\{2\pi i[(\mathbf{r}_n - \mathbf{r}_o) \cdot \hat{\mathbf{n}}\nu]\} \exp\{-2\pi i[(\mathbf{r}_{n'} - \mathbf{r}_o) \cdot \hat{\mathbf{n}}\nu']\}, \quad (17.245)$$

where the minus sign in the last exponential is allowed since $h_A(p)$ is real. The integrals over r_o and θ_o comprise the Fourier transform of the disk evaluated at $\hat{\mathbf{n}}(\nu - \nu')$, and the transform can be performed by (3.258). The integral over ϕ can be performed by (3.247), so we find

$$\left[\mathbf{K}_{\hat{\theta}|\mathbf{f}} \right]_{\mathbf{nn}'} = \frac{2\pi R_d C f_0}{\Delta\phi\Delta p} \int_{-\infty}^{\infty} d\nu |\nu| A(\nu) \int_{-\infty}^{\infty} d\nu' |\nu'| A(\nu') \\ \times \frac{J_1[2\pi R_d(\nu - \nu')]}{\nu - \nu'} J_0(2\pi|\mathbf{r}_n\nu - \mathbf{r}_{n'}\nu'|). \quad (17.246)$$

As the disk radius goes to infinity, the besinc approaches a 1D delta function:

$$\lim_{R_d \rightarrow \infty} \frac{J_1[2\pi R_d(\nu - \nu')]}{\nu - \nu'} = 2\delta(\nu - \nu'). \quad (17.247)$$

Thus

$$\left[\mathbf{K}_{\hat{\theta}|\mathbf{f}} \right]_{\mathbf{nn}'} \rightarrow \frac{4\pi R_d C f_0}{\Delta\phi\Delta p} \int_{-\infty}^{\infty} d\nu |\nu|^2 A^2(\nu) J_0(2\pi|\mathbf{r}_n - \mathbf{r}_{n'}|\nu). \quad (17.248)$$

Thus the covariance *matrix* has the form of a continuous stationary autocovariance *function* sampled at $\mathbf{r}_n - \mathbf{r}_{n'}$. Since this function is rotationally symmetric, and since the 2D Fourier transform of a rotationally symmetric function is the Hankel transform [see (3.248)], we can also write

$$\left[\mathbf{K}_{\hat{\theta}|\mathbf{f}} \right]_{\mathbf{nn}'} \rightarrow \frac{2R_d C f_0}{\Delta\phi\Delta p} \mathcal{F}_2^{-1} \{ |\nu| A^2(\nu) \} \Big|_{r=|\mathbf{r}_n - \mathbf{r}_{n'}|}. \quad (17.249)$$

By the Wiener-Khinchin theorem (8.133), it follows that the noise power spectrum (before sampling on the reconstruction grid) is proportional to $|\nu| A^2(\nu)$. We must remember, however, that the noise is stationary in this sense only in the limit $R_d \rightarrow \infty$; for a finite disk the noise is not stationary and the noise power spectrum is not defined.

To see the lack of stationarity, we can rewrite (17.246) as

$$\begin{aligned} [\mathbf{K}_{\hat{\theta}|\mathbf{f}}]_{\mathbf{nn}'} &= \frac{2\pi R_d C f_0}{\Delta\phi \Delta p} \int_{-\infty}^{\infty} d\nu |\nu| A(\nu) \int_{-\infty}^{\infty} d\nu' |\nu'| A(\nu') \\ &\times \frac{J_1[2\pi R_d \Delta\nu]}{\Delta\nu} J_0(2\pi|\bar{\mathbf{r}}\Delta\nu - \Delta\mathbf{r}\bar{\nu}|), \end{aligned} \quad (17.250)$$

where $\bar{\mathbf{r}} \equiv \frac{1}{2}(\mathbf{r}_{\mathbf{n}} + \mathbf{r}_{\mathbf{n}'})$, $\Delta\mathbf{r} \equiv \mathbf{r}_{\mathbf{n}} - \mathbf{r}_{\mathbf{n}'}$ and similarly for the frequency variables. Because of the presence of $\bar{\mathbf{r}}$, this covariance matrix is no longer obtained by sampling a stationary autocovariance function.

One qualitative observation from (17.250) is that the correlations tend to be directed radially away from the center of the disk since the second Bessel function has its maximum value when $\Delta\mathbf{r} = \bar{\mathbf{r}}\Delta\nu/\bar{\nu}$ or, in other words, when the vector $\Delta\mathbf{r}$ is parallel to $\bar{\mathbf{r}}$. This argument is confirmed by the reconstruction shown in Fig. 17.8 with its strong radial correlations.

Fig. 17.8 Reconstruction of a brain phantom by filtered backprojection. (a) Simulated object. (b) Noisy sinogram. (c) Reconstruction. (Courtesy of Craig Abbey).

Another qualitative observation is that the variance is quite spread out, extending well beyond the edges of the object in Fig. 17.8. In essence, this comes about since the variance pattern is the object convolved with a noise kernel that varies approximately as $1/r_o$ as seen in (17.241). Moreover, because of this slow decay, the variance at the center of the disk is proportional to the radius of the disk, even when that radius is much greater than the spatial resolution of the system. In short, noise in filtered backprojection is very nonlocal.

The reader who wishes to study this problem further — and perhaps remove some of the approximations we made — is encouraged to use the stochastic Wigner distribution function. Numerical evaluation of the integrals will be required, but the results will explain the correlations seen in Fig. 17.8. Another very useful exercise is to apply the methods developed here to the case where attenuation in the object is modeled by the exponential Radon transform (see Sec. 17.1.6) and reconstruction is performed by the Tretiak-Metz algorithm.

Noise in nonlinear reconstructions As we saw in Chap. 15, there are two general approaches to nonlinear image reconstruction. One approach, called implicit estimation, is to specify a functional, often called an objective functional, that should be minimized by proper choice of the reconstruction vector $\hat{\theta}$. The objective functional is frequently chosen so that the minimum is unique, and in that case it really

doesn't matter, except in terms of computational effort, what specific algorithm is used to find the minimum. The other approach is to state a specific iterative algorithm, such as the MLEM (maximum-likelihood expectation maximization) algorithm of (15.305), and run it for some number of iterations. The algorithm need not be one for which convergence is guaranteed, and it need not be related to a specific objective functional.

Noise in implicit estimates was discussed in Sec. 15.3.6 under the assumption that the objective functional is differentiable (with respect to both the data and the reconstruction) at its minimum. This condition may not be satisfied if the functional includes a positivity constraint, but if it is, then the final reconstruction is approximately related to the data by a linear mapping as in (15.221). At this point the methods derived above for analyzing noise in one-step linear reconstruction can be applied, but the linear mapping depends on the object.

Noise in iterative algorithms can be analyzed by recursive methods described in Sec. 15.4.7. Again a differentiability condition is required, but now it is only the update rule that needs to be differentiable, not the functional at the final estimate. Many popular iterative algorithms, including the MLEM algorithm, satisfy this condition, and the recursive methods give highly accurate predictions of the mean and covariance as a function of iteration number (Wilson *et al.*, 1994; Wang and Gindi, 1997; Soares *et al.*, 1998).

Example: MLEM The MLEM algorithm, if ever run to completion, would maximize the likelihood $\text{pr}(\mathbf{g}|\boldsymbol{\theta})$. As we discussed in Sec. 15.4.6, however, maximum likelihood is seldom a desirable end point in image reconstruction. Running the MLEM algorithm for a large number of iterations usually results in a virtually useless image, often one consisting of a few bright pixels like the night-sky reconstructions discussed in Sec. 15.3.5.

Fig. 17.9 Sequence of reconstructions of a brain phantom by the MLEM algorithm after 10, 20, 50, 100, 200, and 400 iterations (left to right, top to bottom). (Courtesy of D. W. Wilson.)

This behavior is seen in the sequence of reconstructions shown in Fig. 17.9. As the iteration proceeds, the image becomes sharper and noisier. When compared to the reconstruction obtained by filtered backprojection in Fig. 17.8, the MLEM images have a much more localized variance pattern, with no significant noise outside the boundaries of the disk. This point is reinforced by Fig. 17.10, where the mean image of a brain phantom is shown along with a spatial map of the variance. The variance pattern looks strikingly like the mean image, an effect that is predicted by the recursive approach to noise propagation discussed in Sec. 15.4.7. An intuitive

way to understand the variance structure in MLEM, or any other reconstruction algorithm that enforces positivity, is to note that the constrained reconstruction cannot go negative. Thus when the mean is small, the variance must be small also.

Fig. 17.10 Images illustrating the statistics of the MLEM algorithm. (a) Estimate of the mean image. (b) Estimate of the variance map. The object was a Hoffman brain phantom, and noise-free data were simulated for a SPECT system with 64 projection angles and 64 pixels per projection. Then 2,000 independent random data sets were generated by adding Poisson noise corresponding to an average of 100,000 counts. Reconstructions were performed for 100 iterations, and the 2,000 images were used to compute the sample mean and variance at each pixel, as shown. (Courtesy of D. W. Wilson.)

17.3.3 Artifacts

In addition to noise, there are also defects commonly referred to as *artifacts*¹³ in reconstructed images. In general terms, artifacts are deviations between an object and its image, but we know from Sec. 7.1.4 that some deviations are inevitable; no digital image can ever exactly match a continuous object. Not all of these deviations, however, are called artifacts. We accept the fact that a digital image is blurred, perhaps noisy, and displayed on a discrete pixel grid, but if the image exhibits streaks or large areas of erroneous information, we refer to the defects as artifacts.

We can distinguish two general classes of artifact, depending on whether they are evident in the image of a point or require an object of large area. We shall call these two classes *point artifacts* and *areal artifacts*, respectively.

Qualitatively, a point artifact is any nonlocal or long-range structure in the overall system point response function (PRF), including the reconstruction algorithm. Thus blur and pixellization, being short range, are not artifacts, but streaks arising from inadequate angular sampling in tomography are. The scale that distinguishes local from nonlocal effects can be expressed in terms of the maximum spatial frequency passed by the system, including any reconstruction algorithm or post-processing filter used. If we denote this maximum frequency by ρ_{max} , then structures in the PRF extending beyond about $1/\rho_{max}$ will be termed nonlocal and hence artifactual.

¹³Etymologically, artifact (or artefact) derives from the Latin *arte factum*, something made with skill. However, it is *lack* of skill in designing or modeling the system that leads to artifacts. Even if we take the modern meaning of artifact as anything manmade, there is a logical problem since the reconstruction is made by a computer, not a human.

Areal artifacts can also be defined in terms of the system PRF, but they relate to spatial variations in the strength of the PRF. If we denote the PRF for the overall CD mapping from object function to discrete reconstructed image as $p_{\mathbf{n}}(\mathbf{r})$, then there are two distinct measures of the strength: the system sensitivity and the flood response. These terms are discussed in Secs. 7.2.1 and 7.3.1, but in brief system sensitivity is the sum of $p_{\mathbf{n}}(\mathbf{r})$ over \mathbf{n} and flood uniformity is its integral over \mathbf{r} . Nonuniformities in either of these measures will be called areal artifacts.

Of course, nonconstant sensitivity or flood response can be problematical in direct imaging systems, but they can usually be corrected in those cases. For example, a measured flood response can be used to renormalize the image as in (7.109). With indirect imaging, on the other hand, we may not always know the cause of the areal artifact, or we may not have enough information to correct it. As an example, attenuation of the radiation in the patient's body in SPECT can lead to an areal artifact, and we cannot correct for it fully if we do not know the distribution of attenuation coefficient.

In reconstructed images, both kinds of artifact are joint characteristics of the imaging system and the reconstruction algorithm. They arise from null functions of the system and/or errors in system modeling, but their nature and their effect on objective measures of image quality depend on algorithmic issues such as nature and degree of regularization, number of iterations, and whether the algorithm enforces positivity.

Both kinds of artifact are deterministic rather than stochastic properties of an image. The term *noise artifacts* also appears in the literature, referring to long-range noise correlations, but we have already discussed that effect in Sec. 17.3.2.

Null functions To isolate the effect of null functions on artifacts, we ignore noise in the data, so that

$$\mathbf{g} = \mathcal{H}\mathbf{f}, \quad (17.251)$$

and we assume for now that we know \mathcal{H} perfectly. If we use this \mathcal{H} to compute a pseudoinverse estimate without adopting a discrete representation, say by the Backus-Gilbert method described in Sec. 15.2.2, then

$$\hat{\mathbf{f}} = \mathcal{H}^+\mathbf{g} = \mathcal{H}^+\mathcal{H}\mathbf{f} = \mathbf{f}_{meas} = \mathbf{f} - \mathbf{f}_{null}. \quad (17.252)$$

In many situations, including limited-angle tomography and aliasing, the term \mathbf{f}_{null} is not spatially localized, so it produces an artifact. Note, however, that it is really the *lack* of null functions in the image that constitutes the artifact; the actual object contains null functions, and eliminating them from the image is what gives nonlocal structures.

Sampling and aliasing Sampling and aliasing were analyzed in Sec. 3.5, but from the viewpoint of bandlimited functions. The main result from that section is that a bandlimited function can be recovered exactly from its samples if the Nyquist condition is satisfied. The interpolating function turned out to be a sinc function of appropriate width. Given our definition of artifact, however, we should consider the point response function of the overall process (sampling and interpolation), and points are not bandlimited.

Suppose, for example, that we sample a 2D function $f(\mathbf{r})$ with a regular array of small detectors at locations $\mathbf{r} = \mathbf{m}\epsilon$, producing a data set $\{g_{\mathbf{m}}\}$. If $f(\mathbf{r}) = \delta(\mathbf{r} - \mathbf{r}')$,

where \mathbf{r}' is the point location, then at most one of the data values is nonzero. Calling that value $g_{\mathbf{m}'}$, we can write the result of sinc interpolation as [cf. (3.298)]

$$\hat{f}(\mathbf{r}) = \sum_{\mathbf{m}} g_{\mathbf{m}} \operatorname{sinc}\left(\frac{\mathbf{r} - \mathbf{m}\epsilon}{\epsilon}\right) = g_{\mathbf{m}'} \operatorname{sinc}\left(\frac{\mathbf{r} - \mathbf{m}'\epsilon}{\epsilon}\right). \quad (17.253)$$

The long tails of the sinc function are the artifacts. Similar long tails occur in tomographic reconstruction when the filter function has a sharp cutoff frequency.

Note that it was necessary to consider the interpolation or reconstruction step before the artifacts became evident. The CD PRF of the sampling step alone is compact since only a single detector element, $\mathbf{m} = \mathbf{m}'$, is activated by the point object. Other interpolation functions, such as triangle functions or Gaussians, would have produced more compact overall PRFs and weaker artifacts in the sense we have defined them.

Another way to look at aliasing is in terms of null functions. Any CD system has a null space, and any two objects that differ by a null function produce the same data and cannot be distinguished by the system, so we say they are aliased. Figure 3.8 gives an example of two cosine functions that differ in frequency by the reciprocal of the sampling interval, so they agree exactly at the sample points. Neither of these functions is a null function of the sampling operator, but the difference between them is.

In tomography, aliasing occurs because there are a finite number of projections and a finite number of measurements per projection, but again two objects are aliased if they differ by a null function. This difference function is almost always spatially extended, so aliasing produces artifacts.

Aliasing and Fourier crosstalk A convenient way of quantifying the degree of aliasing is by the Fourier crosstalk matrix, introduced in Sec. 7.3.3 and applied to tomography in Sec. 17.1.3. Unlike other Fourier methods, the Fourier crosstalk matrix does not assume any form of shift-invariance, and it is motivated by CD system models rather than CC ones. The Fourier crosstalk matrix is an exact description of any CD system, fully equivalent to the integral operator $\mathcal{H}^\dagger \mathcal{H}$. Though it is an infinite matrix, its elements have simple physical interpretations. The diagonal elements tell us how well a particular Fourier-series coefficient is measured by the system. More importantly for the present discussion, however, the off-diagonal elements specify the degree of aliasing between two different Fourier components.

The idea of degree of aliasing is seldom discussed in treatments of direct imaging systems since it is not an issue for the idealized detector models usually used. If we consider an infinite detector array with uniformly spaced elements on a regular grid, then the null functions of the detector are easy to characterize. Two Fourier-transform kernels whose spatial frequencies differ by a multiple of the (vector) spatial frequency of the sampling grid produce the same data vectors (within a constant related to the size of the detector elements), so the null functions are differences between Fourier kernels. Loosely speaking, we say that the null functions are differences in plane waves, though of course we are discussing irradiance patterns and not waves at all.

In tomography, however, the null functions are not just differences between plane waves, and in fact they are usually quite difficult to determine. In the Fourier-series approach with the crosstalk matrix, we consider the action of the CD system on plane-wave components, but we use plane waves with finite support, and we do

not pretend that these functions are either null functions or singular functions of the system. The degree of aliasing between two such components is measured by the cosine of the angle between the resulting vectors in the Hilbert data space [see (7.266)]. When these vectors are nearly parallel, then it is very difficult to distinguish the two Fourier-series components, and we say they are nearly aliased.

Examples of crosstalk matrices for cone-beam SPECT are given by Barrett and Gifford (1994). We shall have more to say about aliasing in SPECT and its relation to image quality in the next section.

Discretization errors Image reconstruction usually requires a discrete model of the object. As we know from Chap. 7, any such discretization must produce errors, but it is not so obvious that these errors should be classified as artifacts. Discretization of an object function produces short-range errors and thus is not artifactual by itself, but when a discretized object is imaged (in the computer), then a kind of aliasing or moiré pattern can result, and that is artifactual.

This kind of aliasing is not described by the Fourier crosstalk matrix, which assumes that the object is a function of a continuous variable rather than a discrete array. Instead it is the result of applying a DD reconstruction operator to the data produced by a CD system.

For example, if the CD operator is the unregularized pseudoinverse of some matrix representation of the system operator, we know from Sec. 15.2.1 that the discrete reconstructed image in the absence of noise is given by [cf. (15.53)]

$$\hat{\theta} = \mathbf{H}^+ \mathbf{g} = \left[\mathcal{H} \mathcal{D}_\phi^\dagger \right]^+ \mathcal{H} \mathbf{f}. \quad (17.254)$$

By our definition, this image contains artifacts to the extent that the CD kernel of $\left[\mathcal{H} \mathcal{D}_\phi^\dagger \right]^+ \mathcal{H}$ has long tails or areal defects.

For comparison, we also know from Sec. 15.2.2 that it is possible to perform a reconstruction without adopting a discrete object representation or a system matrix. In that case, with no noise we get the reconstructed function,

$$\hat{\mathbf{f}} = \mathcal{H}^+ \mathcal{H} \mathbf{f}. \quad (17.255)$$

We can sample this function for display purposes and smooth it in the process. If we use the same smoothing functions here as in the object discretization leading up to (17.254), the result is

$$\hat{\theta} = \mathcal{D}_\phi \mathcal{H}^+ \mathcal{H} \mathbf{f}. \quad (17.256)$$

This time the reconstruction contains artifacts if the CC kernel of $\mathcal{D}_\phi \mathcal{H}^+ \mathcal{H}$ has long tails or areal defects. Since the operator \mathcal{D}_ϕ is local and independent of location in the reconstructed image, it does not by itself introduce artifacts; any artifacts in (17.256) come from tails or areal defects of the CC operator $\mathcal{H}^+ \mathcal{H}$. Recall from Sec. 15.2.1 that $\left[\mathcal{H} \mathcal{D}_\phi^\dagger \right]^+ \mathcal{H} \neq \mathcal{D}_\phi \mathcal{H}^+ \mathcal{H}$ except in special cases, so (17.254) can exhibit artifacts even if (17.256) does not. In physical terms, some of the artifacts from $\left[\mathcal{H} \mathcal{D}_\phi^\dagger \right]^+ \mathcal{H}$ are the result of a moiré effect between the discretization grid and the detector grid, but that effect is absent in $\mathcal{D}_\phi \mathcal{H}^+ \mathcal{H}$. On the other hand, this latter operator can also exhibit artifacts since \mathcal{H} is sampled in angle and in the detector plane.

Errors in system modeling Another broad class of artifacts arises from inaccurate modeling of the system. In general terms, we might collect data through an actual system described by a CD operator \mathcal{H} , but assume erroneously that the system was described by some other operator \mathcal{H}_a , where the subscript stands for *approximate* or *assumed*. If we form a matrix representation of the system, it will be given by $\mathbf{H} = \mathcal{H}_a \mathcal{D}_\phi^\dagger$ rather than $\mathcal{H} \mathcal{D}_\phi^\dagger$. Depending on the nature of the error in \mathcal{H} , a wide variety of artifacts can be produced.

Examples of physical system errors that might be ignored in the formation of the system matrix include alignment errors, such as tilt of the camera head or errors in locating the center of rotation, or detector distortion or nonuniformity. Any of these errors can produce long-range artifacts; for example, if the center of rotation is not specified correctly, it produces a characteristic streak artifact resembling a tuning fork around a point object.

Uncorrected detector nonuniformity can produce either streak or areal artifacts, depending on the nature of the nonuniformity. In general, if we define s_m as the sensitivity of the detector used in the m^{th} measurement, we can write

$$g_m = s_m[\mathcal{H}\mathbf{f}]_m + n_m = \bar{s}[\mathcal{H}\mathbf{f}]_m + (s_m - \bar{s})[\mathcal{H}\mathbf{f}]_m + n_m, \quad (17.257)$$

where \bar{s} is the average sensitivity of all detectors. This equation shows that the variations in sensitivity act, in a sense, as an object-dependent noise term. If the detector sensitivities are constant, this term is not stochastic, so this term does not enter into the data covariance matrix for a fixed object. It does, however, constitute a modeling error if we use an assumed \mathbf{H} matrix that does not account for the detector sensitivity in the reconstruction.

To see how detector nonuniformity can lead to streak artifacts, suppose that a different array is used for each projection angle (as in some multi-camera systems developed at the University of Arizona) and that one of the arrays has a single bad element, say the one indexed by $\mathbf{m} = \mathbf{m}_0$. Then the image reconstructed by a matrix with elements $O_{\mathbf{nm}}$ might look relatively artifact-free except that it would contain the erroneous superimposed image $O_{\mathbf{nm}_0}$, which is just the DD PRF of the reconstruction operator. Since this PRF is highly nonlocal, the detector defect produces a streak artifact. If the same detector is used in all projections, as in any single-head rotating-camera system, then a bad element will show up in all projections and appear as a vertical line in the sinogram display of the data (see Sec. 4.4.1). Because of the sharp discontinuity in the data, a streak artifact will again result. On the other hand, slow variations in detector sensitivity will produce areal artifacts.

Motion artifacts Often an object moves or changes in some way during data acquisition, making it a spatio-temporal function, yet the reconstruction algorithm attempts to recover a purely spatial function. For example, during a SPECT scan, there is internal motion due to respiration, heart beats and peristalsis, and there may be an overall motion simply because the patient fidgets. Moreover, the radio-tracer can redistribute during acquisition, but the reconstruction algorithm usually treats the object as static.

In some circumstances, temporal changes in the object do not cause artifacts. For example, if we collect all of the data with a static imaging system, so that each detector element is just a time integral of the radiation incident on it, then the data come from a time integral of the spatio-temporal object, and the algorithm seeks to

recover this integrated object in some sense. In other words, there is motion blur, but no long-range structures that we would classify as artifacts.

If the detector system is also changing in time, however, complicated motion artifacts can arise. In rotating-camera SPECT, for example, a single camera is scanned to different projection angles. A fan-beam or cone-beam projection is acquired at each detector location, but if the object changes during the scan, then projections of *different* objects are acquired. Since the reconstruction algorithm is based on the assumption that the projections come from the same object, there are inconsistencies in the data that, in practice, lead to severe artifacts.

One might attempt to avoid this problem by doing a full spatio-temporal reconstruction, but the risk is that the motion artifacts would simply be replaced by sampling artifacts; if only M measurements can be made during the exposure time, then attempting to reconstruct the object at K time points means that only M/K of the measurements correspond to each temporal frame. The strategy may nevertheless succeed if there are strong temporal correlations.

Nonlinearities Many indirect imaging systems are really nonlinear but are modeled as linear to facilitate image reconstruction. In Sec. 16.1, for example, we discussed at length the nonlinear relationship between x-ray projection data and the object, specified as a distribution of the x-ray attenuation coefficient. In Sec. 16.1.7 we showed how the simple expedient of taking the logarithm of the data yields an approximate linearization, but we also discussed the residual errors. These errors can lead to areal artifacts in computed tomography if they are slowly varying, but also to streaks if a strongly absorbing point-like object is present.

In SPECT we do not have to deal with an inherently nonlinear relation between an object and its projections, but the detectors may exhibit nonlinearities at high count rates. As noted in Sec. 11.3.1, these nonlinearities result since the occurrence of one gamma-ray interaction can paralyze the detector and prevent the detection of another occurring soon after. This effect spoils the independence of the detected events and invalidates our Poisson data models, but even in the mean it constitutes a modeling error that can produce artifacts.

The general mathematical description for data produced by a nonlinear detector is

$$\mathbf{g} = \mathcal{N}\{\mathcal{H}\mathbf{f}\} = \mathcal{H}\mathbf{f} + [\mathcal{N} - \mathbf{I}]\{\mathcal{H}\mathbf{f}\}, \quad (17.258)$$

where \mathcal{N} is a nonlinear operator. If \mathcal{N} is a monotonic point operator, as defined in Sec. 7.5.1, and if it is well characterized, then the effects can be corrected by applying \mathcal{N}^{-1} to the data before reconstruction. With Anger cameras, however, the nonlinearity may be neither local nor monotonic. A high count rate anywhere on the camera face can affect the entire detector, and the electronics might be paralyzable so that the observed count rate will first increase and then decrease with increasing photon flux. Such effects cannot be corrected by any data processing before reconstruction, so they are almost always ignored, with potential artifactual consequences.

Attenuation and scatter As we have discussed earlier in this chapter, attenuation and scattering of gamma rays in the patient's body are strong effects in SPECT, and they are a prime source of artifacts. Many methods for correcting the effects of attenuation and scatter have been described in the literature, but in every case they involve many assumptions and approximations. Nevertheless, they can be useful in

reducing if not eliminating the artifacts. For a comprehensive review, see King *et al.* (2003).

Regularization and artifacts Regularization can cover up artifacts in some cases. If the null functions are predominantly high-frequency, then any regularization or post-reconstruction smoothing that eliminates high frequencies from the image also eliminates artifacts arising from null functions. Of course, the smoothing also blurs the image, but this blur can be local and hence not classified as an artifact. Similarly, artifacts related to the sidelobes of the sinc function with sharp-cutoff reconstruction filters are artifacts, but we know from Sec. 15.2.6 that they can be minimized or eliminated by apodization or regularization. Sometimes, however, the artifacts have significant low-frequency components, so regularization or smoothing does not help; an example would be the streak artifacts resulting from limited-angle tomography (Barrett *et al.*, 1991).

On the other hand, regularization can interact with other sources of artifacts and accentuate them. To see how, consider an iterative reconstruction with the least-squares data-agreement functional and Tikhonov regularization, as discussed in Sec. 15.3.3. If we neglect noise and discretization issues and presume perfect knowledge of \mathcal{H} , we know that the regularized least-squares solution is [*cf.* (15.156)]

$$\hat{\mathbf{f}}_\eta = [\mathcal{H}^\dagger \mathcal{H} + \eta \mathbf{I}]^{-1} \mathcal{H}^\dagger \mathbf{g} = [\mathcal{H}^\dagger \mathcal{H} + \eta \mathbf{I}]^{-1} \mathcal{H}^\dagger \mathcal{H} \mathbf{f}. \quad (17.259)$$

Now suppose that there are variations in detector sensitivity, so that

$$\mathcal{H} = \mathbf{s} \odot \mathcal{H}_0, \quad (17.260)$$

where \mathbf{s} is a vector of sensitivity factors as in (17.257), \odot denotes the Hadamard product, and \mathcal{H}_0 is an operator without sensitivity variations but otherwise identical to \mathcal{H} . With some abuse of notation, we can write

$$\hat{\mathbf{f}}_\eta = [\mathcal{H}_0^\dagger \mathbf{s}^2 \mathcal{H}_0 + \eta \mathbf{I}]^{-1} \mathcal{H}_0^\dagger \mathbf{s}^2 \mathcal{H}_0 \mathbf{f}, \quad (17.261)$$

where $\mathcal{H}_0^\dagger \mathbf{s}^2 \mathcal{H}_0 \mathbf{f}$ is to be interpreted as $\mathcal{H}_0^\dagger [\mathbf{s} \odot \mathbf{s} \odot (\mathcal{H}_0 \mathbf{f})]$.

Each sensitivity factor gets squared in forming $\mathcal{H}_0^\dagger \mathbf{s}^2 \mathcal{H}_0$, but that would not have much effect on the image in the absence of regularization since

$$\lim_{\eta \rightarrow 0} \hat{\mathbf{f}}_\eta = [\mathcal{H}_0^\dagger \mathbf{s}^2 \mathcal{H}_0]^+ \mathcal{H}_0^\dagger \mathbf{s}^2 \mathcal{H}_0 \mathbf{f}. \quad (17.262)$$

In this limit, the pseudoinverse enforces strict agreement with the (noise-free) data, in the sense that $\|\mathcal{H}_0(\hat{\mathbf{f}} - \mathbf{f})\| = 0$. Since the Hadamard product with a nonzero sensitivity factor introduces no new null functions, this implies $\|\mathcal{H}(\hat{\mathbf{f}} - \mathbf{f})\| = 0$. Thus, in the limits of no noise and no regularization, the pseudoinverse reconstruction from \mathcal{H}_0 is artifact-free if the one from \mathcal{H} is. In essence, the \mathbf{s}^2 factor in the forward operator is cancelled by the same factor in the pseudoinverse.

The situation is different, however, if the regularizing parameter does not approach zero. The effect of regularization is specifically to prevent complete agreement with the data, since agreement with noisy data produces noisy images. We

are not considering noise here, but in the mean regularization prevents exact cancellation of the s^2 factors and therefore makes the sensitivity variations visible in the reconstructed image, even if they are properly modeled.

One way to avoid this pitfall is not to regularize, instead using a very small value of η , but then to control noise by post-reconstruction smoothing of the image. Another possibility is to use a regularizer such as the gradient or Laplacian of \mathbf{f} that is insensitive to the low spatial frequencies in the image. If the sensitivity is slowly varying, the effect cancels out even though high-frequency noise is well controlled.

Positivity and support constraints As we discussed in some detail in Chap. 15, prior information can often be put to very good use in indirect imaging. Though we may make assertions about smoothness and norms, what we really know about an object in most cases is just that it is nonnegative and has bounded support. In Sec. 15.4 we learned a number of methods for imposing positivity and support constraints.

As a general rule, constraints are useful to the degree that an unconstrained reconstruction would violate them. A well sampled tomographic system with a well characterized system operator and high-count data will produce a good image, with few negative values and little activity outside the true boundary of the object, even with algorithms that do not explicitly enforce positivity and support constraints. With poor sampling or an imperfectly characterized system operator, however, the images will contain artifacts. Streak artifacts often extend beyond the boundaries, and artifacts associated with null functions almost always contain negative values. In these cases, therefore, positivity and support constraints can be quite valuable.

We saw in Sec. 15.1.4 that positivity can place quantitative bounds on the magnitude of null functions, and that in turn places bounds on the level of artifacts in images obtained with algorithms that produce agreement with the data and also enforce positivity. Similar quantitative bounds can be ascribed to support constraints, but the details have not been worked out in the literature.

17.3.4 Image quality

In Sec. 16.2, we noted that a major limitation of planar nuclear medicine was the basic fact that it mapped a 3D object to a 2D image. For estimation tasks, attempts to quantify activity in a region of interest were thwarted by overlapping activity contributing to the projection of the ROI, and for detection tasks this same overlapping activity reduced the contrast and hence the lesion detectability. The clinical goals of ECT are therefore to obtain more accurate quantitation, improved contrast and hence improved lesion detectability.

The objective-assessment paradigm has been embraced enthusiastically by the SPECT community, and there is now a large literature on objective comparisons of different data-acquisition systems and algorithms. Ideal, Hotelling, channelized Hotelling and human observers have been used for detection and classification tasks, and variances, mean-square errors and Cramér-Rao bounds have been used for estimation tasks.

Our goal in this section is to give a broad overview of objective assessment of image quality as it has been applied to SPECT and to discuss some of the considerations in choosing tasks and observers.

SKE detectability in the raw data As in Sec. 16.2.5, we begin by considering the SKE/BKE detection task. This task can be performed by an observer given access to the raw, uncorrected data, to unreconstructed data after correction for distortion and/or scatter, or to reconstructed images. The observer can be the ideal observer, the Hotelling observer or even a human; for SKE/BKE tasks, humans can be trained to read sinogram displays of projection data.

The simplest of these combinations is the ideal observer acting on the raw, uncorrected data. The data are rigorously Poisson in that case, and the log-likelihood ratio was given in (13.131) or (16.117). To apply that formula to SPECT, we need only change the data index from \mathbf{m} to $\mathbf{m} = (\mathbf{m}, j)$, with j being the angular index as before; thus

$$\text{SNR}_\lambda^2 = \frac{[\sum_{\mathbf{m}}(\bar{g}_{2\mathbf{m}} - \bar{g}_{1\mathbf{m}}) \ln(\bar{g}_{2\mathbf{m}}/\bar{g}_{1\mathbf{m}})]^2}{\frac{1}{2} \sum_{\mathbf{m}}(\bar{g}_{2\mathbf{m}} + \bar{g}_{1\mathbf{m}}) \ln^2(\bar{g}_{2\mathbf{m}}/\bar{g}_{1\mathbf{m}})}. \quad (17.263)$$

In SPECT the signal to be detected usually makes a small contribution to the mean data, in which case [cf. (13.135) or (16.119)]

$$\text{SNR}_\lambda^2 \approx \sum_{\mathbf{m}} \frac{s_{\mathbf{m}}^2}{\bar{g}_{\mathbf{m}}}. \quad (17.264)$$

At this point in Sec. 16.2.5, we considered a spatially compact signal and a slowly varying object, such that $\bar{g}_{\mathbf{m}}$ was approximately the same for all pixels where the signal $s_{\mathbf{m}}$ is nonzero. This approximation is less plausible in SPECT because of the angular variation; even if $\bar{g}_{\mathbf{m}}$ is approximately the same for all detector elements in the vicinity of the signal in a single projection, it usually varies significantly from projection to projection.

One immediate conclusion from (17.263) or (17.264) is that it is desirable to have high uptake of the radiotracer in the lesion and low uptake (per unit volume) in the background; this is a consideration for the biochemist designing the tracers but not for the image scientist designing the system.

We can also use these formulas, as we did in Sec. 16.2.5 for the planar case, to study how the spatial resolution of the detector and collimator affect SNR^2 . The conclusions will be the same: it is advantageous to improve the detector resolution, but a collimator with better resolution is detrimental to performance of this task since it comes at the expense of photon collection. In both planar nuclear medicine and SPECT, the optimum collimator for SKE/BKE lesion detection is no collimator at all. This conclusion should have no effect at all on the choice of collimators; it should affect our choice of task if the collimator is the element being evaluated.

SKE/BKE detectability in the reconstruction Though SKE/BKE tasks are not useful for collimator optimization, they can be used to study the effects of algorithmic parameters. In SPECT, the algorithm serves not only to provide a reconstructed image but also to control the noise (through choice of apodization or regularization) and to control artifacts by pre- or post-reconstruction data corrections and imposition of constraints. All of these measures influence SKE/BKE detectability by a human observer. They do not, however, influence the ideal observer, at least if we posit that the ideal observer is given access to the same input information that goes into the algorithm. To the extent that any of the data corrections or constraints are useful, the ideal observer—being ideal—will use them.

The Hotelling observer, on the other hand, does not have access to all possible information about the data; it knows only the mean vectors and the covariance matrices under the two hypotheses. We showed in Sec. 13.2.12 that the Hotelling observer was invariant to any linear, invertible transformation of the data, but it is not so obvious that Hotelling performance could not be improved by nonlinear algorithms.

MLEM algorithm and local NEQ To investigate the usefulness of the Hotelling observer in evaluating nonlinear algorithms, Donald Wilson (1994) used the MLEM algorithm on an SKE/BKE task and determined the Hotelling SNR as a function of the number of iterations. The MLEM algorithm was described in Sec. 15.4.6, and Wilson's methodology for computing the statistics of the images was described in Sec. 15.4.7.

The Hotelling SNR was computed by a discrete version of (13.266), which expresses the SNR for detection of a signal at location \mathbf{r}_0 in terms of the stochastic Wigner distribution function (WDF). For evaluating an iterative reconstruction algorithm, this formula can be written as

$$\left[\text{SNR}_{\text{Hot}}^{(k)}(\mathbf{r}_0) \right]^2 = \int d^2\boldsymbol{\rho} \frac{|S^{(k)}(\boldsymbol{\rho})|^2}{W^{(k)}(\mathbf{r}_0, \boldsymbol{\rho})}, \quad (17.265)$$

where $S^{(k)}(\boldsymbol{\rho})$ is the Fourier transform of the mean signal in the reconstructed image at the k^{th} iteration, and $W^{(k)}(\mathbf{r}_0, \boldsymbol{\rho})$ is the corresponding stochastic WDF. We use continuous notations for these quantities here, but in practice both \mathbf{r} and $\boldsymbol{\rho}$ are measured on discrete grids and integrals are replaced by sums.

We know from Sec. 8.2.5 that the stochastic WDF can be interpreted as a local noise power spectrum (LNPS), describing the frequency content of the background texture in the vicinity of the signal location in the image. It would facilitate the analysis if we could also define a local modulation transfer function (LMTF), but it is not obvious how this can be done since the overall system — data acquisition plus reconstruction algorithm — is neither linear nor shift-invariant. Two assumptions are required. First, it is assumed, as above, that the signal in the raw data is weak compared to the background, so that the response to the signal can be represented as the linear term in a Taylor series. Then it is assumed that the signal is spatially compact and that the blurring by system and algorithm is slowly varying over the support of the signal.

With the weak-signal assumption, we can write the signal in the reconstruction at the k^{th} iteration as

$$s^{(k)}(\mathbf{r}) \approx \int d^2r' p^{(k)}(\mathbf{r} - \mathbf{r}'; \mathbf{r}' | \mathbf{f}_b) f_s(\mathbf{r}'), \quad (17.266)$$

where \mathbf{f}_s and \mathbf{f}_b are the signal and background, respectively, in the object space, and $p^{(k)}(\mathbf{r} - \mathbf{r}'; \mathbf{r}' | \mathbf{f}_b)$ is the space-variant, object-dependent PSF for the overall system after k iterations. Analytic expressions for such a PSF can be devised (see Secs. 15.3.6 and 15.4.7), but it can also be determined experimentally in simulation studies by forming two noise-free data sets, one where the object is \mathbf{f}_b and one where it is \mathbf{f}_b plus a weak point source; after iterating for k steps, the difference between the two images is proportional to $p^{(k)}(\mathbf{r} - \mathbf{r}'; \mathbf{r}' | \mathbf{f}_b)$.

The second assumption takes advantage of the small spatial extent of the signal to write

$$s^{(k)}(\mathbf{r}) \approx \int d^2r' p^{(k)}(\mathbf{r} - \mathbf{r}'; \mathbf{r}_0 | \mathbf{f}_b) f_s(\mathbf{r}'), \quad (17.267)$$

where the signal part of the object function, $f_s(\mathbf{r}')$, is centered at $\mathbf{r}' = \mathbf{r}_0$. A Fourier transform yields

$$S^{(k)}(\boldsymbol{\rho}) = P^{(k)}(\boldsymbol{\rho}; \mathbf{r}_0 | \mathbf{f}_b) F_s(\boldsymbol{\rho}), \quad (17.268)$$

where $P^{(k)}(\boldsymbol{\rho}; \mathbf{r}_0 | \mathbf{f}_b)$ is a local transfer function, dependent on the known signal location and the known background object as well as the iteration number.

We can now rewrite (17.265) as

$$\left[\text{SNR}_{\text{Hot}}^{(k)}(\mathbf{r}_0) \right]^2 = |P^{(k)}(0; \mathbf{r}_0 | \mathbf{f}_b)|^2 \int d^2\rho |S^{(k)}(\boldsymbol{\rho})|^2 \text{LNEQ}(\boldsymbol{\rho}), \quad (17.269)$$

where the *local noise-equivalent quanta* is defined by

$$\text{LNEQ}(\boldsymbol{\rho}) \equiv \frac{[\text{LMTF}(\boldsymbol{\rho})]^2}{\text{LNPS}(\boldsymbol{\rho})} = \left| \frac{P^{(k)}(\boldsymbol{\rho}; \mathbf{r}_0 | \mathbf{f}_b)}{P^{(k)}(0; \mathbf{r}_0 | \mathbf{f}_b)} \right|^2 \frac{1}{W^{(k)}(\mathbf{r}_0, \boldsymbol{\rho})}. \quad (17.270)$$

Thus we have manipulated the Hotelling SNR into a form that looks just like the one for linear, shift-invariant systems and stationary noise, yet we have not really made any of these assumptions. Because of the MLEM algorithm, the overall system is nonlinear, but it behaves linearly for weak signals; the nonlinear dependence on the background component remains. Similarly, the system is not shift-invariant and the noise is not stationary, but the signal is confined to a small spatial region and we neglect the variations of system response and noise properties over this region.

Wilson computed the LMTF, LNPS and LNEQ as a function of k for several objects and MLEM reconstructions. His results are shown in Fig. 17.11. As the iterations proceed, the algorithm recovers finer details and the LMTF gets broader. At the same time, however, the LNPS increases at all frequencies because of noise amplification; Eventually the LNPS approaches the characteristic ramp-like power spectrum that would be seen with filtered backprojection. If one looked only at LMTF and LNPS, it would not be obvious what effect the iterations were having on detectability, since both the signal and the noise are increasing at higher frequencies as k increases.

The LNEQ, however, tells an interesting story. Though both $[\text{LMTF}]^2$ and LNEQ are increasing at all frequencies as k increases, their ratio is relatively unchanged, especially at higher spatial frequencies. Thus, for any signal that satisfies our assumptions, the Hotelling SNR is nearly invariant to iteration number. We could not reach this conclusion analytically since we know only that Hotelling performance is invariant to invertible, linear algorithms, and MLEM is nonlinear.

The conclusion to this point is that it doesn't matter very much how many iterations of MLEM are used, so long as the task is detection of a known, weak, compact signal in a known background and the observer is either ideal or Hotelling. To choose a stopping point for the MLEM algorithm, we must use a different task, a different observer, or both.

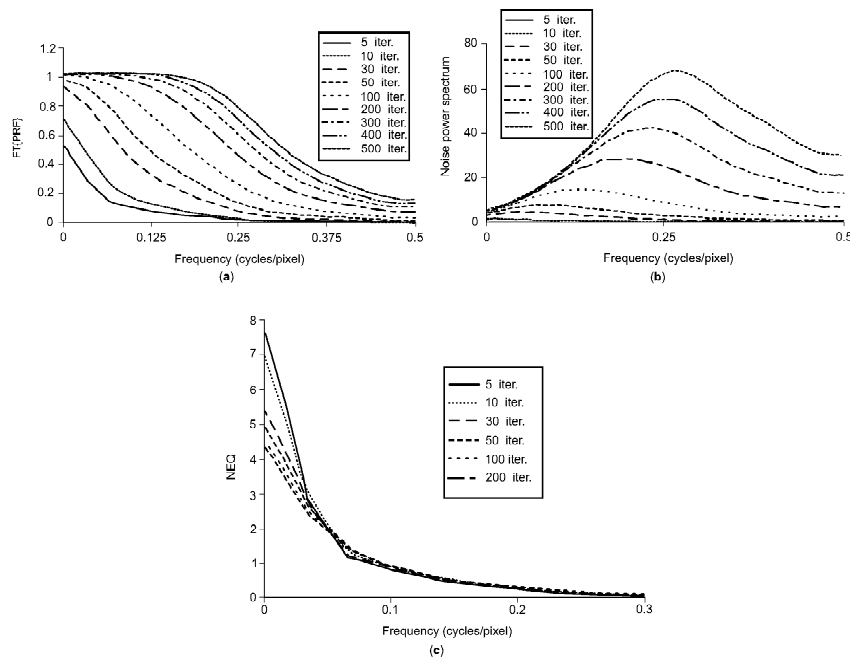

Fig. 17.11 Variation of local MTF, local noise power spectrum and local noise-equivalent quanta with iteration number in the MLEM algorithm. (Courtesy of D. W. Wilson.)

Effect of attenuation correction Another application of the Hotelling observer and SKE/BKE tasks was to the comparison of various linear reconstruction algorithms based on the exponential Radon transform (ERT). As we noted in Sec. 17.2.4, there are many different versions of the inverse ERT, all of which give the same mean image but which differ greatly in their noise characteristics.

The performance of the Hotelling observer on an SKE/BKE task was computed for several different inverse-ERT algorithms by Soares (1994, 1995). The task was detection of a small uniform signal disk superimposed on a larger background disk. The Hotelling SNR was computed on both the raw data and on the output of each of the algorithms. The key result was that all except one of the algorithms gave an SNR identical to that in the raw data. The exception was the Tretiak-Metz algorithm, described in Sec. 17.2.4, which showed much poorer performance. Since the Hotelling observer is invariant to linear, invertible algorithms, we must conclude that the Tretiak-Metz algorithm, though it is exact for continuous, noise-free data, is not invertible in the sense that discrete, noisy data could be recovered from the output of the algorithm. This conclusion is perhaps not surprising when one recalls that the filter function for this algorithm, shown in Fig. 17.7, sets a range of frequency components to zero.

This example illustrates one advantage of SKE/BKE tasks and the Hotelling observer: they can be used to identify algorithms that remove information relevant to a detection task from the data. However, the Hotelling observer provides no way of choosing among algorithms that do not remove information.

Random backgrounds We have seen that nonrandom, uniform backgrounds can give very misleading results in planar nuclear medicine and SPECT. We can introduce randomness in several ways, depending on whether the studies use physical phantoms, simulated images or real clinical images.

Physical phantoms are usually plastic containers filled with radioactive water and possibly various other plastic objects representing organs or lesions. The organs and lesions can be more or less radioactive than the water depending on what clinical application is under consideration. The background can be made random by using random levels of radioactivity in the water or organ phantoms or by moving the organs around in the water. Randomness on a smaller spatial scale can be incorporated by using many small vials with random activities or small nonradioactive objects immersed in the radioactive bath; see for example, Sain and Barrett (2003).

In simulation studies we have greater freedom in representing random backgrounds than is possible with physical phantoms. Just as in planar nuclear medicine (see Sec. 16.2.5), we can use the lumpy or clustered lumpy backgrounds described in Sec. 8.4.4, but these models have free parameters that must be chosen, and there can be concern that the conclusions of the image-quality studies might be affected by the choices. Kupinski *et al.* (2003) have outlined a method of estimating the parameters by using a relatively small number of actual images, provided they are taken through a well characterized imaging system.

Another possibility in simulation studies is to use high-resolution digitized anatomical images to define organ boundaries (see, *e.g.*, Gilland *et al.*, 1992) and then to randomly assign activity levels to each organ. To make the simulation more realistic, the statistics of these organ-to-organ activity variations can be determined from pharmacokinetic studies in animals or humans, and the internal variations within an organ can be simulated as above with a lumpy background.

Finally, for the ultimate in realism, clinical images can be used. For comparing reconstruction algorithms, the same raw projection data can be processed in several different ways, perhaps with or without attenuation correction or compensation for other system properties. If different collimators or other hardware variations are to be compared, the same patient must be imaged multiple times. Clinical images are out of the question for systematic optimization of the data-acquisition hardware, but they can be used to verify the results of a simulation-based optimization study.

Another practical issue with clinical images is obtaining an adequate number of cases with verified pathology. For this reason some investigators have used images of normal volunteers or verified normal patients and then added the lesions artificially. For example, Llacer (1993) used real PET projection data from normal subjects and added simulated projections of a lesion to generate data for abnormal cases. Chan *et al.* (1997) took this idea a step further by acquiring separate physical images of a small object representing a lesion and adding them to the normal patient data.

Random signals The signals in a SPECT detectability study can vary in location, size, shape and uptake of the tracer. In simulation studies, it is straightforward to generate any of these variations, but the main question is how to model the signal statistics.

Usually the main consideration in choosing the size and contrast of the lesion is statistical power rather than clinical realism. In comparing collimators, for ex-

ample, it does little good to include large, high-contrast lesions that would be easily detected with any of the collimators under consideration, or small, low-contrast ones that are never visible. The lesion size and contrast should be chosen to challenge the systems and provide adequate statistical power in choosing one collimator over another. A good rule of thumb is that the lesion size and contrast should be chosen to yield an area under the ROC curve, for whatever observer is used, of about 0.85. Since this criterion cannot be met for all collimators simultaneously, it is advisable to use lesions of different sizes and contrasts, but there is little value in lumping them into a single binary decision task. Rather than asking whether a lesion of random size is present or absent, it is useful to conduct separate ROC studies with each lesion size. If it should turn out that collimator A is better for small lesions and collimator B is better for larger ones, that is valuable additional information that would be lost if different lesion sizes were randomly chosen in a single study. The only drawback is that more observer time is required for multiple ROC studies, but that is not much of an issue with model observers.

Similar considerations apply to signal location. In SPECT, detectability of a lesion is affected by its proximity to normal organ structures and by how deep it is within the patient's body, so it is useful to vary the signal location. It does not follow, however, that the signal location must be unknown to the observer. As discussed in Sec. 14.3.2, we can consider a sequence of SKE tasks and determine the variations of detectability with signal location. With numerical observers, we can even display these results as continuous maps of detectability as a function of position.

It is true, however, that signal size and location are random and unknown in clinical practice, and the practitioner cannot choose one collimator for superficial lesions and another for deep lesions; some kind of average figure of merit must be used. One approach that gives an overall figure of merit without sacrificing statistical power is to average the SKE detectability (SNR^2) over a clinically relevant range of lesion sizes and locations. An important question that has not been adequately studied is whether this average can give a different rank ordering of systems than would be obtained from a single ROC study with random locations.

Somewhat different considerations come into play when the reconstruction algorithm is being studied. For one thing, algorithmic variations tend to have less effect on detectability than do variations in the collimator, so there is less need to vary the signal contrast. The contrast can be chosen, say by means of a pilot study, and left at that value throughout a range of algorithmic variations.

Signal size is still important since almost any algorithm includes a regularization or smoothing parameter that varies the tradeoff between spatial resolution and noise, but again it is not necessary to vary the size randomly within a single ROC study. Should it turn out that one regularizing parameter is better for large lesions and another is better for small lesions, it would be possible in principle to allow the clinician to vary the regularization during the reading session.¹⁴

Randomness in signal location could be more important for algorithmic comparisons than for hardware optimization. In Chap. 14, we emphasized that the main function of an algorithm is to match the information in the raw data to the capabilities and limitations of a human observer. One limitation of humans is that

¹⁴Analysis of the socio-economic issues involving increased reading time vs. improved diagnosis is far too complicated for this book.

they are inefficient in searching an image for a lesion in a random, unknown location. Of course, ROC performance always degrades with location uncertainty, but the amount of degradation can depend on the reconstruction algorithm or display system. One algorithm could produce a lesion image of low contrast but also low noise, such that a human observer concentrating on a known location would have a good detectability. The same observer might have poor performance in a search task with that algorithm but could conceivably do better with a different algorithm that improved the contrast even at the expense of noise or resolution. The general question, which needs much further study, is whether the rank ordering of algorithms and displays is likely to be the same for SKE or SKEV (signal known exactly but variable) tasks as it is for search tasks.

Representative studies with human observers Psychophysical studies have become quite routine in nuclear medicine, and especially in SPECT. We cannot attempt a comprehensive review of this rapidly changing literature here, but we mention a few representative studies to indicate the general directions of the field. The studies listed under this heading involve just human observers without attempting to correlate the results to model observers; comparisons of humans and models as well as a few studies with model observers alone are discussed under the next heading.

Gilland *et al.* (1992) compared the filtered-backprojection (FBP) algorithm to MLEM using simulated SPECT images, and Llacer (1993) compared the same two algorithms for PET FDG (fluorinated deoxyglucose) imaging. In both cases MLEM was somewhat better, probably because it incorporates a positivity constraint and an accurate system model.

Gooley and Barrett (1992) compared a wide range of algorithms in a situation where even stronger prior information was available. They considered cardiac imaging with a blood-pool tracer that filled the left ventricle, and the task was to detect a wall-motion abnormality where a small region of the ventricle did not contract and hence showed up as a protrusion on an image obtained when the heart was maximally contracted (end systole). The strong prior information was that the activity within the ventricle was essentially uniform, so a slice through the object would show only two values, depending on whether the point was in the blood pool or not. Many different algorithms were evaluated; some of them assumed that the object was binary-valued and some did not. Algorithms that enforced this strong constraint led to much better human performance than those that did not, but there was little difference among algorithms that produced a continuous range of gray values. Amusingly, maximum entropy was minimum image quality for this task.

Numerous other human studies of cardiac imaging have been performed. LaCroix *et al.* (2000) evaluated iterative algorithms with attenuation correction for myocardial perfusion studies, where the tracer used went preferentially to perfused regions and hence the signal to be detected was a cold region called a perfusion defect. This study compared differences in defect detection between myocardial SPECT images reconstructed using conventional FBP without attenuation correction and those reconstructed using MLEM with nonuniform attenuation correction. It was found that MLEM with attenuation correction was superior, particularly for patients with large breasts or with a diaphragm raised to the level of the heart. If uncorrected, attenuation from these structures can produce cold regions similar to perfusion defects, hence false positives.

A similar study of the effects of attenuation correction in SPECT myocardial imaging was performed by Jang *et al.* (1998), and Sankaran *et al.* (2002) studied optimization of the regularization parameter and the detector-response compensation for the same application. Detector-response effects were studied with LROC analysis by Gifford *et al.* (2000b).

Representative studies with human and model observers There has been considerable research, summarized in Sec. 14.2.2, on validating anthropomorphic observers in general, but now there is also a substantial literature on this subject specific to nuclear medicine. When both human and model observers are used in the same paper and a high correlation between the results is found, it adds to our confidence in the predictive power of the models. The most investigated and most successful anthropomorphic models have been variants on the channelized Hotelling observer (CHO). Much of the rationale for the use of this observer in SPECT comes from work done at the University of Massachusetts, and we begin with a summary of that effort.

King *et al.* (1997) studied different data-acquisition and processing strategies for liver imaging. Both square, nonoverlapping (SQR) channels and difference-of-Gaussian (DOG) channels were used for the CHO. Since the goal was to see if the model observers predicted the human's rank ordering of the different acquisition strategies, the results were evaluated by Spearman's rank correlation coefficient. This coefficient turned out to be 0.94 for the SQR channels and 0.96 for the DOG channels if no scatter correction was used; poorer correlation was found with scatter correction. Using the same data, however, Gifford *et al.* (2000a) found much better correlation in the latter case by slightly modifying the parameters of the CHOs and by ensuring that the humans and CHOs operated on exactly the same images.

Gifford *et al.* (1999) compared the performance of human observers in an LROC (localization-ROC) experiment to the CHO on a simple ROC experiment. Of course the absolute performance of the humans, who had to contend with location uncertainty, was much worse than that of the CHO on the SKE task, but surprisingly the rank ordering was excellent.

Other work by Gifford *et al.* (2002) studied the effects of subset size and number of iterations in block-iterative methods for tumor detection in thoracic SPECT. Again excellent agreement between human and CHO was found, with a Spearman rank correlation coefficient of 0.976.

Other groups have also successfully compared humans and CHOs. Wollenweber *et al.* (1999) studied defect detection in myocardial SPECT. Chen *et al.* (2002a) compared triple-head 360° vs. dual-head 180° acquisition, with and without attenuation correction. The CHO and human results both showed better detection performance in the 360° scan. The same group (Chen *et al.*, 2002b) also extended the CHO concept to 3D, giving the observers access to multiple tomographic slices in three different orientations. Both multi-slice and single-slice CHOs showed good correlation with humans.

A few papers have appeared (*e.g.*, Chan *et al.*, 1997, and Qi and Huesman, 2001) that use only model observers without checking the results against human studies. As the literature validating the models grows and a consensus on which model to use becomes firmly established, more such papers can be expected and the full value of model observers will be seen.

Computational issues with model observers The great advantage of model observers, of course, is that they permit a much wider exploration of system parameters than would be possible with psychophysical studies, but eventually computational limitations will become apparent. A notable step towards more efficient computation of CHO performance was taken by Bonetto *et al.* (2000). They used the approach of Fessler (1996) described in Sec. 15.3.6 to approximate the mean vector and covariance matrix of a MAP (maximum *a posteriori*) reconstruction. The results include the random effects of Poisson noise and background variations, but only to the extent that the prior used in the reconstruction algorithm matches the actual background randomness.

Artifacts and detectability In Sec. 17.3.3 we defined artifacts as nonlocal defects in the deterministic point response function of the overall imaging system, including the data acquisition and the reconstruction algorithm. Many artifacts can be characterized loosely as long tails on the PRF, but it is not so obvious why long tails are bad, in an objective sense. In fact, if we were considering an SKE/BKE detection task and an ideal observer, the long tails on the PRF would not degrade performance. The observer would know the PRF exactly and would be able to compute the resultant signal in the image in spite of the tails.

Thus, as with collimator optimization, we must consider more realistic tasks in order to see why the wide PRF is detrimental. Qualitatively, long tails are bad if the background is random since they couple random variations in the background to a distant signal location. A linear observer, whether Hotelling, CHO or human, will center a template on a known signal location but have a variance from background fluctuations that is much greater than it would be without the tails.

This effect can be seen neatly in the extensive work of Kenneth Hanson on tomography with sparse angular sampling (Hanson, 1988, 1989, 1990a, 1990b). He used typically just eight projections and an object consisting of a random collection of high-contrast discs. The signal to be detected was also a disc but with just one-tenth the amplitude of the background discs. With linear reconstructions algorithms, streak artifacts from the high-contrast discs were very evident and significantly reduced the detectability of the low-contrast disc. With nonlinear iterative algorithms such as ART (algebraic reconstruction technique), the artifacts were suppressed and the detectability improved. Hanson then went on to optimize the ART algorithm for task performance.

Much further work along these lines is needed to fully understand the role of artifacts in lesion detectability.

Estimation tasks In one sense, estimation tasks are the very essence of tomography. As we saw in Chap. 15, image reconstruction can be formulated in terms of estimation of the expansion coefficients in an approximate representation of the object. Usually a voxel representation is adopted, and the reconstruction is an attempt to estimate the integrals of the object over voxels, or voxel values for short.

It is common in the SPECT literature to try to use the accuracy of these voxel estimates as a measure of image quality. In this view, the goal of the imaging is not to perform a particular task but to recreate the object as accurately as possible. Fidelity rather than task performance is the measure of image quality. As we saw in Sec. 13.3.2, however, there is considerable ambiguity in defining image quality in terms of fidelity. We identified three different ways of defining the error between

an object and an image and three different ways of averaging that error, so there are nine possible definitions of the mean-square error (MSE) between object and image.

Basically, this ambiguity arises because all real imaging systems have null functions. Infinitely many objects can give exactly the same mean data and hence the same values for any estimates derived from the data. If these objects have different values for their integrals over voxels, then there is no unambiguous way of defining the bias or MSE of the voxel estimates. As we phrased it in Sec. 15.1.3, voxel values are almost never estimable parameters.

From a task-based viewpoint, the inability to define the bias or MSE of voxel values is of no concern since the goal of imaging is never to determine even a single voxel value, much less a set of them. In clinical SPECT, we are often indeed interested in estimating quantitative parameters, but never just voxel values. Instead we might want to know the total uptake of a tracer in a region of interest in the brain or the change in volume of the left ventricle when the heart contracts. Unlike voxel values, these parameters are of direct medical interest, and mathematically they are much more likely to be estimable (see Sec. 15.1.3 for a definition). Thus estimation tasks, as we view them, are not about estimating a huge number of irrelevant and definitely unestimable parameters but rather a few highly relevant and approximately estimable ones.

Viewed this way, there is a large literature on estimation tasks in SPECT. The common term for an estimation task in that literature is *quantitation* or *quantification*.¹⁵ The typical SPECT quantitation study uses a real or simulated phantom with a uniform background and immerses into it a spherical or cylindrical container with an activity higher than that of the background. Projection data are acquired and an image is formed by the authors' favorite reconstruction algorithm. Usually a fuzzy bump where the reconstructed gray values exceed those of the uniform background is seen in the image, and from this bump it is desired to estimate the activity in the container. A common approach is to define a region of interest the same size as the container and sum up the gray values in the region to get the activity estimate. The process can be repeated with many realizations of the raw data for the same object, and a bias, variance and mean-square error of this scalar parameter can be computed.

To put this discussion into the language of statistical estimation theory, the region-of-interest procedure yields a linear estimate with a predefined template. Unlike maximum-likelihood estimates it takes no account of the data statistics or the characteristics of the imaging system, and unlike Bayesian estimates it makes no assumptions about the prior distribution of parameter values. It is, nevertheless, a valid and common estimate, and its mean and variance can be assessed as any other estimate would be. If the container is large compared to the system resolution, the parameter is at least approximately estimable and a mean-square error can be defined and estimated.

¹⁵To *quantitate* means to measure or determine the quantity of something, especially with precision. To *quantify* can mean the same thing, but it often means assigning a quantity to something that has only quality. The reader can decide, on a scale of 1 to 10, which term is preferable in nuclear medicine.

Recommendations Rather than evaluating a system on how well an estimation task *is* performed by a suboptimal, *ad hoc* procedure, we can also evaluate it on how well the task *can be* performed by an optimal procedure. Our recommendation is to use the bias and variance of a maximum-likelihood estimator as the basic error characterizations for an estimation task, combining them into an MSE when a scalar figure of merit is desired. When there is difficulty in computing the variance of the ML estimate, Cramér-Rao bounds can be used.

These estimates and error measures can be computed either from the raw projection data or from the reconstructed image. The former is recommended if the objective is to evaluate the data-acquisition hardware in terms of an estimation task, while the latter is required if the algorithm is to be evaluated.

What limits task performance? In most discussions of estimator performance, the emphasis is on characteristics of the estimator. Maximum-likelihood estimation is preferred, for example, because it is known to be asymptotically unbiased, asymptotically efficient, and efficient in any case if an efficient estimator exists. These issues tell only a part of the story, however, when ML estimation is used in SPECT. The actual performance of the estimator is more likely to be limited by errors in modeling the imaging system than by intrinsic properties of the estimator.

If the input to the ML estimator is the raw projection data, then the ML estimator requires detailed knowledge of the image-forming process, including the attenuation and scatter in the patient's body and the space-variant blur of the collimator. It also requires knowledge of the data statistics, but in this case the data are pure Poisson. If, on the other hand, the input to the ML estimator is the reconstructed image rather than the raw data, then the algorithm should take into account attenuation, scatter and space-variant blur. In that case the deterministic description of the overall system might be assumed to be a simple blur function, but the noise on the input to the estimator is no longer Poisson (see Secs. 15.2.6, 15.3.6 and 15.4.7). In either case, errors in describing any aspect of the system will introduce a systematic error or bias that cannot be erased by any of the nice asymptotic properties of ML methods.

Practical examples Most of the practical work on evaluation and optimization of nuclear imaging systems for estimation tasks comes from the group at Harvard, which was previously mentioned in the context of planar imaging in Sec. 16.2.6. Some of their recent work deals with joint estimation-classification tasks, and some of it is ancillary work aimed at developing simulation tools, but we shall briefly survey it all here.

One particularly complicated clinical situation this group has studied uses tracers labelled with ^{67}Ga . This isotope has a complicated emission spectrum, with principal energies around 93, 185 and 300 keV, but also some higher-energy lines that cause severe difficulties with septal penetration. Moore and El Fakhri (2001) developed highly accurate and realistic Monte Carlo simulation methods in which the patient's anatomy is represented by segmented CT images of a commercial anthropomorphic torso phantom. With this tool, El Fakhri *et al.* (2002) studied the effect of the energy window settings on the performance of estimation and detection tasks. In other work, unpublished at this writing, these same authors have optimized the design of collimators for this application.

A related study (Kijewski *et al.*, 2001) of considerable practical importance applied similar ideas to analyzing the effects of the collimator and SPECT system geometry on simulated but realistic tasks related to diagnosis and management of Parkinson's disease. Cramér-Rao bounds on estimates of activity concentration and striatal volume were computed and related to the likelihood ratio for several binary classification tasks. The authors compared three commercial SPECT systems, two of relatively high spatial resolution and one of lower resolution. In all cases the higher-resolution systems performed better.

18

Coherent Imaging and Speckle

Coherent imaging modalities include holography, laser illuminators, radar and ultrasound. Images taken with these systems exhibit a phenomenon called *speckle*, which is not seen in our everyday experience with incoherent light. Whenever a diffuse object is illuminated with radiation that is spatially and temporally coherent, its image will show high-contrast, fine-scale structures not related in any obvious way to the characteristics of the object. This effect can be observed by shining a laser pointer on a piece of paper and inspecting the spot visually.¹ Even though the irradiance profile of the laser beam is smooth and featureless, the image on your retina will be highly noisy or “speckled.”

Further experimentation with the laser pointer reveals other characteristics of speckle. It should be found that the size of the speckle blobs depends on the diameter of the pupil of the eye; if the experiment is performed in a darkened room where the pupil is dilated, the speckle blobs will be small, but if it is performed in bright sunlight or with a pinhole in front of the eye, the blobs will be larger. The contrast of the speckle patterns will, however, remain unchanged; unlike the kinds of noise considered in Chap. 12, speckle noise does not depend on the light level. If the laser beam is attenuated with a neutral-density filter or if a brighter laser is used, the contrast in the speckle pattern remains the same. Moreover, laser speckle is always in focus; the contrast does not depend on where you focus your eyes.

Our goals in this chapter are to understand these qualitative features of speckle noise and to give mathematical descriptions of them, and in the process to show how the mathematical methods of earlier chapters can be applied to coherent imaging. The treatment of diffraction theory and coherent imaging in Chap. 9 will be crucial, and some little-known aspects of random processes from Chap. 8 will find

¹The reader is cautioned to observe only the reflected light and to obey Gaskill’s rule of laser safety: “Never look down the laser beam with your remaining eye!”

application here. Of course, the principles and methodology of objective assessment of image quality, from Chaps. 13 and 14, will also be put to good use.

We begin in Sec. 18.1 by looking at the basic aspects of speckle with relatively little mathematics. We show why statistical models are applicable to speckle, and we state some well-known results for the univariate probability density function (PDF) and autocorrelation function of the irradiance in an observation plane with either imaging or nonimaging systems.

In Sec. 18.2 we analyze the statistical properties of speckle in detail. Our goal in this section is nothing less than a full infinite-dimensional description of the statistics of the irradiance in a simple nonimaging system. The main tool for this investigation will be the *characteristic functional*, introduced in Sec. 8.2.3.

In Sec. 18.3 we extend the analysis to imaging systems and relate it to the familiar continuous-to-discrete (CD) model for digital imaging systems that we have used often in this book. In this section our goal is characterize the multivariate (but finite-dimensional) statistics of the digital image as fully as possible.

In Sec. 18.4 we acknowledge that speckle is not the only source of randomness in coherent imaging systems. We consider also measurement noise and the stochastic nature of the objects being imaged, and we relate these effects to objective metrics of image quality.

In Secs. 18.2–18.4 we place considerable emphasis on object models that lead to Gaussian statistics on the fields in an image or observation plane, but in Sec. 18.5 we look at models that lead to decidedly non-Gaussian fields. In particular we consider objects that consist of randomly placed points, and we find a close connection with Poisson point processes as analyzed in Chap. 11.

In Sec. 18.6 we look specifically at 3D imaging system such as medical ultrasound and radar where time of flight is used to encode the third dimension. The systems discussed there use amplitude-sensitive detectors to detect the scattered field, and the analysis is easier than for systems with irradiance sensitive detectors because the step of conversion of amplitude to irradiance is nonlinear. Both Gaussian and non-Gaussian speckle are treated.

18.1 BASIC CONCEPTS

Coherent light has a definite phase at each point on a surface, and in many situations that phase admits of simple mathematical descriptions. For example, a monochromatic plane wave has a phase that is constant on a plane, and a spherical wave has a phase that is constant on a sphere. If a coherent wave is reflected from a rough opaque surface or transmitted through a rough transparent surface such as a ground glass, it remains coherent but the phase is no longer simple, and in almost all situations it is unknown. The best we can say in general is that it varies rapidly and unpredictably from point to point. Speckle is the diffraction pattern from such an irregular, rapidly varying optical field. The fine structure results from interference of the light coming from different points on the rough object. The object roughness makes the phase complicated but does not make it vary randomly with time, so the light is still coherent and interference still occurs.

In this section we look qualitatively at some basic aspects of this phenomenon. In Sec. 18.1.1 we first discuss the role of statistics in describing what is essentially a deterministic problem. Then we review some basic results on the point statistics

and correlation properties of speckle in a nonimaging context. In Sec. 18.1.2 we bring in a lens and a discrete detector array and begin to come to grips with just what it means to analyze speckle in an imaging system.

18.1.1 Elementary statistical considerations

If we knew the complex amplitude transmittance of a ground glass or the complex amplitude reflectance of a rough surface, we could compute the diffraction pattern by the methods developed in Chap. 9. Since we virtually never have that detailed information, we must resort to statistical methods. For example, we can consider a particular ground glass to be one realization of a spatial random process, and we can then investigate statistical properties of the diffraction pattern such as its mean, autocovariance function and various probability density functions. It is important to emphasize, however, that all statistical properties must be interpreted in terms of averages over ensembles of ground glasses, not as spatial or temporal averages. The statistical averages may turn out to be *functions* of space or time, but they are not *averages* over space or time. It can be quite misleading to invoke ergodicity in speckle problems.

Light emerging from rough surfaces One simplifying assumption that we can make regarding the statistical properties of the field emerging from a ground glass (or other rough object) is that the phase is completely random. If the thickness of a slab of glass changes by an amount Δh , then the phase of the light, relative to what it would be without the change in thickness, is $\Delta\phi = k(n-1)\Delta h$, where n is the refractive index of the glass and $k = 2\pi/\lambda$, with λ being the wavelength in free space. Thus if the height variations are random with a standard deviation of several wavelengths, the phases are approximately uniformly distributed over $(-\pi, \pi)$. Under this assumption a field of the form $A(\mathbf{r})\exp[i\phi(\mathbf{r})]$ is a zero-mean random process.

We can also say something about the autocorrelation function of this random process. Diffuse objects are rough on the scale of the wavelength of light—or else they wouldn't be diffuse. We know from Sec. 10.2.7 that the spatial autocorrelation function of an optical field is closely related to the angular distribution of the light. For example, a Lambertian surface has a radiance that is independent of angle and a radiant intensity proportional to the cosine of the angle of light propagation measured from the surface normal. We saw in (10.110) *et seq.* that this angular dependence is associated with a particular autocorrelation function, a sinc function with width approximately equal to the wavelength. We also mentioned—and left it to the reader to show—that any process that completely randomized the direction of light led to precisely this autocorrelation function and hence a Lambertian angular distribution.

Thus a natural statistical model of the light from a coherently illuminated diffuse object is that it is a 2D spatial random process with completely random phase and an autocorrelation function that is sharply peaked on the scale of a wavelength. This simple statement will take us quite far in the analysis of speckle.

Light on an observation plane Suppose the light from a coherently illuminated rough surface propagates through free space to an observation plane. We know from diffraction theory that all points on the surface contribute to the field at each point

on the observation plane, and this observation allows us to draw further conclusions about the nature of speckle.

The elementary argument, to be made more precise in Sec. 18.2.4, is that many statistically independent points on the rough surface contribute to the field at each point on an observation plane. It then follows from the central-limit theorem that the complex field at each observation point is Gaussian. If the ground glass is rough enough that the phases of the light are uniformly distributed on $(-\pi, \pi)$, then the field at an observation point is a circular Gaussian, where the real and imaginary parts are i.i.d. Gaussians (see Sec. 8.3.6). In this case, we know that the modulus of the complex field (square root of the irradiance) follows a Rayleigh law [see (C.140) and (8.231)], while the irradiance or squared modulus follows an exponential law [see (8.232)]. If the phase is not uniformly distributed on $(-\pi, \pi)$, there will be an undiffracted plane-wave component to the light, and the modulus will follow a Rician law [see (C.141)].

Speckle contrast When the irradiance obeys an exponential law, we can make a simple statement about the speckle contrast. We stated in Sec. C.5.3 (and the reader may verify) that the variance of an exponential law is equal to the square of the mean. Thus the standard deviation is equal to the mean, and the ratio of mean to standard deviation, often called a *signal-to-noise ratio*, is unity. This explains the observation, noted in the introduction of this chapter, that speckle contrast is independent of light level.

Blob size The probability laws discussed above give only the univariate statistics of the field or its modulus at a single point. A more complete statistical description requires accounting for the correlations in the field and irradiance. We shall now present a simple argument based on local spatial frequencies that will enable us to estimate the range of these correlations, roughly corresponding to the size of a speckle blob.

Consider a stationary ground glass in the plane $z = 0$ illuminated with a monochromatic plane wave. For now, no imaging system is used, and the diffraction pattern is observed in a parallel plane $z = z_0$. By Huygens' principle, each point on the ground glass emits a spherical wave, and since the light is coherent, each spherical wave interferes with every other spherical wave. The spherical wave coming from point \mathbf{r}_1 on the ground glass produces a wave at point \mathbf{r} in the observation plane, a distance z from the ground glass, which is given in the Fresnel approximation by [cf. (9.94)]

$$u_z(\mathbf{r}) \propto \exp \left[i\pi \frac{|\mathbf{r} - \mathbf{r}_1|^2}{\lambda z} + i\phi(\mathbf{r}_1) \right], \quad (18.1)$$

where $\phi(\mathbf{r}_1)$ is the phase of the light at point \mathbf{r}_1 . By (5.35), the 2D local spatial frequency of this wave at point \mathbf{r} is given by

$$\boldsymbol{\rho}_1(\mathbf{r}) = \frac{1}{2\pi} \nabla \left[\frac{\pi}{\lambda z} |\mathbf{r} - \mathbf{r}_1|^2 + i\phi(\mathbf{r}_1) \right] = \frac{1}{\lambda z} (\mathbf{r} - \mathbf{r}_1), \quad (18.2)$$

where the subscript on $\boldsymbol{\rho}_1(\mathbf{r})$ indicates that it is associated with the wave emanating from \mathbf{r}_1 . If we consider also a second point \mathbf{r}_2 , then it generates a wave of local spatial frequency $\boldsymbol{\rho}_2(\mathbf{r})$, and the irradiance in the interference pattern between the

two waves contains the difference frequencies² given by

$$\pm[\boldsymbol{\rho}_1(\mathbf{r}) - \boldsymbol{\rho}_2(\mathbf{r})] = \pm \frac{1}{\lambda z}(\mathbf{r}_2 - \mathbf{r}_1). \quad (18.3)$$

Thus the largest spatial frequency in the interference pattern is determined by the largest separation of the two points on the ground glass, $|\mathbf{r}_2 - \mathbf{r}_1|_{max}$. As a rule of thumb, then, the correlation length or *blob size* of the speckle, denoted by ℓ_b , is the reciprocal of the maximum spatial frequency, or

$$\ell_b = \frac{\lambda z}{|\mathbf{r}_2 - \mathbf{r}_1|_{max}} = \frac{\lambda}{\Delta\theta}, \quad (18.4)$$

where $\Delta\theta$ is the angular subtense of the object from a point in the observation plane.

By considering the diffraction patterns of all pairs of points on the ground glass and averaging over the random phases, we can derive an expression for the autocorrelation function of the irradiance on the observation plane. This autocorrelation will be approximately zero when the distance between two observation points exceeds the blob size ℓ_b .

Multivariate statistics of the irradiance The simple arguments above yield the mean and autocorrelation function of the irradiance on the observation plane. If that irradiance were Gaussian, we would have a full statistical description since all properties of a Gaussian random process are determined by its mean and autocorrelation. Since an irradiance cannot be negative, however, it cannot be Gaussian, and we have just argued that its single-point PDF is exponential. To get a full description, therefore, we need all possible multi-point PDFs (see Sec. 8.2.2) or, equivalently, the characteristic functional of the process (see Sec. 8.2.3). Deriving this description is the major goal of Sec. 18.2.

18.1.2 Speckle in imaging

Consider a simple unit-magnification imaging system in which a lens of focal length f is placed a distance $2f$ from a coherently illuminated diffuse object and the image is observed a distance $2f$ behind the lens. To be definite, we can think of the object as a ground glass with a photographic transparency laid over it.

With the lens between the rough object and the observation plane, we can no longer say that all points on the object contribute to the field at each observation point; instead, only points within an area defined by the coherent point spread function (PSF) contribute. If the lens is diffraction-limited, then a large lens aperture means that a smaller area on the object contributes to each image point. If, on the other hand, the lens is aberrated, then a larger aperture may mean a *larger* PSF and *more* contributing area.

²One might wonder why there are no sum frequencies. The reason is that each wave has an unstated temporal factor with temporal frequency ν . The sum of the two spatial frequencies comes with a sum of the two temporal frequencies, and the difference of the spatial frequencies comes with the difference in the temporal frequencies. The factor $\exp[-2\pi i(\nu + \nu)t]$ averages to zero over any measurement time but $\exp[-2\pi i(\nu - \nu)t]$ does not.

If the contributing area contains many statistically independent regions on the ground glass, we can again invoke the central-limit theorem and claim that the field in the observation plane is Gaussian. If we also assume that the phase variations of the ground glass are approximately uniformly distributed on $(-\pi, \pi)$, the field is circular Gaussian.

The correlation length of this circular Gaussian is, however, no longer determined by the overall size of the ground glass; now the lens aperture controls the correlations. One way to see this point is to consider a very large ground glass with no photographic transparency. The field emerging from the ground glass is a circular Gaussian with a very short correlation length, and when it has propagated to the lens plane, it is still a circular Gaussian with a very short correlation length. According to (9.163), the lens multiplies the field by a quadratic phase, but adding a deterministic phase to one that is completely random leaves it completely random. Thus the field emerging from the lens is a circular Gaussian with a very short correlation length, but now it is nonzero only over the lens aperture. When it propagates to the image plane, it is yet another circular Gaussian, this time with a correlation length given approximately by (18.4), with $\Delta\theta$ now being the solid angle subtended by the lens aperture from a point in the image plane. Thus a smaller lens aperture means larger speckle blobs.

This argument depends critically on the field emerging from the ground glass having very short correlation length. At the opposite extreme, suppose the “ground” glass is smooth and slowly undulating. It may still have a total phase variation that is uniformly distributed over $(-\pi, \pi)$, but now its amplitude transmittance contains only relatively low spatial frequencies. We know from Sec. 9.2.1 that low spatial frequencies in the transmittance imply low deflection angles for the light. We can decompose the field into its plane-wave components, and most of those components will be within the pass-band of the lens if the lens aperture is large and the phase variations of the ground glass are slow. In that case, no speckle at all is observed; instead, the lens gives a faithful image of the phase object, reproducing its phase variations in the image plane. Speckle results when some of the light is deflected to larger angles and misses the lens.

The image detector Optical detectors respond to irradiance, so it is important to know the statistics of the irradiance. As we argued above, the irradiance at a point follows an exponential law if the field is circular Gaussian. This observation does not, however, take us very far towards the understanding of image statistics, for several reasons.

First, an optical detector integrates the irradiance over its area, and there is no guarantee that a single-point exponential law on the irradiance will lead to an exponential law on the detector output. To the contrary, if the detector area is large compared to the correlation length of the irradiance incident on the detector, we can again invoke the central-limit theorem and argue that the detector output is Gaussian, not exponential.

It is only when the detector is very small compared to this correlation length that an exponentially distributed output would be seen; observation of point statistics of the irradiance requires a point-like detector. Since, as noted above, the correlation length is controlled by the lens aperture, the point-detector approximation could be invalidated in any optical imaging system simply by stopping down the lens.

The second reason why the exponential law on the irradiance is inadequate for the analysis of imaging systems is that it is a univariate law, giving very little information about the multivariate statistics on the output of a detector array. It is tempting to assume that the outputs of different detector elements in an array are statistically independent. In that case the multivariate PDF would be a product of exponentials if each univariate PDF were exponential; this assumption is virtually never valid in practical systems. As we just saw, getting the exponential univariate PDF requires a detector small compared to the correlation length, but statistical independence requires that these point-like detectors be far apart compared to the correlation length. Practical detector arrays have contiguous detector elements with very little gap between them, so both conditions cannot be satisfied simultaneously.

Other noise sources The final reason for the inadequacy of the exponential law is that it describes only a single source of statistical variation. As we know from Chaps. 11 and 12, real optical detectors are also afflicted by Poisson noise from the discrete nature of photoelectric interactions and by Gaussian noise arising from electronic sources.

Moreover, the randomness of the objects being imaged must be considered in a full statistical description of the imaging process. In previous chapters we have often encountered doubly stochastic processes where the Poisson law was correct for a single object realization, but different objects gave different Poisson means. With coherent illumination and a photon-counting detector, we have a triply stochastic Poisson process. For a given object and speckle realization, the multivariate output of a discrete detector array is a Poisson random vector, but our statistical view of speckle considers an ensemble of ground glasses (or other fine-scale phase variations), and each of these realizations leads to a different mean vector for the Poisson distribution. If there is also an ensemble of objects (say photographic transparencies), each object produces its own PDF for the speckle distribution. The overall PDF is an average over Poissons given the irradiance distribution, an average over all irradiances given an object (but different ground glasses), and an average over objects. Moreover, if the output of the detector is processed by noisy electronics, both Gaussian and Poisson are present, and in that case we have a quadruply stochastic process.

Characteristic functions and functionals A full statistical description of a discrete image requires a huge multivariate PDF, or equivalently a huge multivariate characteristic function. In Chap. 8 we learned a lot about calculating characteristic functions for imaging systems, and we shall put that knowledge to good use in this chapter.

As we saw in Sec. 8.2.3, the continuous irradiance distribution incident on a detector array can be described by a characteristic *functional* (really an infinite-dimensional characteristic function), and we also saw that characteristic functionals can be propagated rather simply through linear imaging systems. The difficulty in the present context is that speckle is essentially a coherent phenomenon, so we must consider the imaging system as being linear in the field, but the detector responds to irradiance, so we need the characteristic functional not only for the field but also for its squared modulus. We shall see in Secs. 18.2 and 18.3 how to do this conversion.

Field-sensitive detection Analysis of speckle would be much easier if detectors responded to field rather than irradiance, and indeed some detectors do just that. For radio waves and microwaves we can build systems that respond directly to the field—otherwise your television set wouldn't work! As the temporal frequency of the wave increases, however, it becomes increasingly difficult to build electronics that will follow the rapid field variations, so field-sensitive detectors become less feasible, and they are essentially nonexistent in the optical frequency range.

An exception to this statement is *heterodyne* detectors. Since the 1920s all radio receivers have been built on the heterodyne principle in which the incoming modulated radio signal is mixed with a local oscillator signal in a nonlinear (ideally, square-law) detector. The nonlinearity produces sum and difference frequencies, and typically the difference-frequency signal is amplified further before final detection to extract the desired modulation signal.

Homodyne detection is the special case of heterodyne detection where the frequency of the local oscillator is the same as the center frequency of the incoming radio signal. If there were no modulation on that signal, the homodyne detector output would consist of two components, one at zero frequency and one at twice the original frequency. Both heterodyne and homodyne techniques can be applied to optical signals since the post-detection electronics needs only to be fast enough to respond to the difference signal, not the original optical signal.

The archetype optical homodyne system is holography. Consider an optical system with coherent illumination, and denote the field at the image plane by $u_{im}(\mathbf{r})$, and suppose we superimpose on it a local-oscillator wave (or *reference wave* in holographic jargon) $u_{ref}(\mathbf{r})$. If the two waves are completely coherent, then the total irradiance in the detector plane is given by

$$I(\mathbf{r}) = |u_{im}(\mathbf{r}) + u_{ref}(\mathbf{r})|^2 = |u_{im}(\mathbf{r})|^2 + |u_{ref}(\mathbf{r})|^2 + u_{im}^*(\mathbf{r}) u_{ref}(\mathbf{r}) + u_{ref}^*(\mathbf{r}) u_{im}(\mathbf{r}). \quad (18.5)$$

For homodyne detection, all four of these terms have the same temporal frequency, but they may have different spatial frequencies. For example, if the reference wave is a tilted plane wave with 2D spatial frequency $\boldsymbol{\rho}_{ref}$ in the detector plane, then the first two terms in (18.5) are independent of $\boldsymbol{\rho}_{ref}$, the third is centered at $\boldsymbol{\rho}_{ref}$ and the fourth is centered at $-\boldsymbol{\rho}_{ref}$. Because of this difference in the spatial-frequency spectra, the four terms can be separated in subsequent processing; holographic image reconstruction boils down to isolating the fourth term and extracting or recreating the field $u_{im}(\mathbf{r})$.

Heterodyne detection works essentially the same way, except now the four terms in (18.5) differ in their temporal frequencies. Post-detection bandpass filtering can isolate the fourth term, provided that the detector is fast enough to respond to the difference frequency.

With both homodyne or heterodyne detection, therefore, the combination of a square-law (irradiance-sensitive) detector and suitable post-detection processing results in a measured signal linear in the image field $u_{im}(\mathbf{r})$. Because the illumination is coherent in both cases, this field is speckled if it was the result of diffraction from a rough object. One useful approximation in analyzing the speckle statistics of homodyne and heterodyne systems, therefore, is to lump the square-law detector and post-detection processing into a single box in the system block diagram and assume that the output of the box is a linear functional of the input field, $u_{im}(\mathbf{r})$.

That this linearity is only an approximation can be seen by examining the contents of the box in more detail. If the box contains a discrete detector array,

each element integrates the irradiance over its face, and the output of the array is a set of samples of the form $\int_m d^2r |u_{im}(\mathbf{r}) + u_{ref}(\mathbf{r})|^2$, where subscript m indicate integration over the face of the m^{th} detector element. This integral is nonlinear in $u_{im}(\mathbf{r})$, and no amount of post-processing can fully undo the nonlinearity since the continuous field $u_{im}(\mathbf{r})$ cannot be reconstructed exactly from a finite set of samples. We might consider passing to the limit of an essentially infinite number of samples by using film as detector (which we almost always do in holography), but even then we have to assume that the film responds linearly to the irradiance.

Microwave and ultrasonic imaging The complications of heterodyne and homodyne detection are needed only because we cannot build detectors that are fast enough to respond to optical frequencies. This problem does not arise with radio waves and microwaves, where we can indeed build systems that are linear throughout. A microwave dish, for examples, integrates the field over its face and produces an output voltage that is a linear functional of the field. An array of microwave dishes is the analog of an optical detector array except that each element responds linearly to field rather than irradiance.

Most ultrasonic transducers also respond linearly to field, though in this case an acoustic or pressure field rather than an electromagnetic one. An ultrasonic transducer is made of a *piezoelectric* material in which a strain produces a voltage. To a good approximation, the total voltage from a transducer of finite area is proportional to the integral of the strain amplitude across that area. This strain distribution can be produced by an acoustic wave that has been reflected from a rough surface or a random volumetric distribution of scatterers, and in that case it suffers from speckle just as an optical wave does. An important difference, however, is that linear-systems theory can be used without approximation to analyze the speckle statistics in ultrasound. If the speckle at any stage can be assumed on the basis of central-limit arguments to be Gaussian, it remains Gaussian because any linear transformation of a Gaussian is a Gaussian (see Sec. 8.3.3).

Nevertheless, most papers on speckle in ultrasonic and microwave imaging do not use linear models, and most of them invoke Rayleigh or Rician rather than Gaussian statistics. The reason for this is that, even though the detectors respond linearly to the fields, the displayed image usually involves an envelope detection or demodulation step. To the extent that the detector array samples $u_{im}(\mathbf{r})$ finely, this post-detection processing is an attempt to compute $|u_{im}(\mathbf{r})|$ or $|u_{im}(\mathbf{r})|^2$. In the former case, Rayleigh statistics are relevant, and in the latter case, exponential statistics are applicable. In neither case, however, would the Rayleigh or exponential law provide the requisite information on the multivariate image statistics.

An additional complication in ultrasonic imaging, as usually practiced in medical sonography, is that pulsed signals are used to obtain spatial resolution along the direction perpendicular to the transducer face. In this case the system model must include both temporal and spatial aspects. Suitable models will be derived in Sec. 18.6.

18.2 SPECKLE IN A NONIMAGING SYSTEM

This section is devoted to the analysis of the simple system depicted in Fig. 18.1, where a ground glass is illuminated with a monochromatic plane wave and the

diffraction pattern is observed on a plane parallel to the ground glass. Both the field and the irradiance in this diffraction pattern will be studied.

As noted in Sec. 18.1.1, we assume that the detailed properties of individual ground glasses are not known and not even of interest; our results are couched in terms of an ensemble of ground glasses. An individual ground glass is a sample function of a random process corresponding to this ensemble, and both the field and the irradiance in the observation plane are sample functions obtained by mathematical transformation of the ground-glass function.

Fig. 18.1 Geometry for analyzing the speckle pattern in a nonimaging system.

Our objective is to learn as much as possible about the statistics of the field and irradiance random processes, while making as few assumptions as possible about the ground-glass random process. Since sample functions of a random process are vectors in an infinite-dimensional Hilbert space, we require an infinite-dimensional statistical description. We shall use the characteristic functional for this purpose; for important background information, see Secs. 8.2.3 and 8.3.5. Previous discussions of the statistical properties of speckle in finite-dimensional terms have been given by Dainty (1975, 1976, 1984), Goodman (1975, 1985) and Osche (2002). A previous treatment based on the infinite-dimensional characteristic functional is Zardecki and Delisle (1977).

18.2.1 Description of the ground glass

Descriptions of a ground glass (or other rough object) can be divided into three categories: physical, operational and mechanistic. A physical description focuses on how the ground glass is produced and what it looks like on a microscopic scale. An operational description asks only how the ground glass modifies a light field. A mechanistic description probes the interaction between the first two descriptions and asks how the physical characteristics relate to the operational ones. Any of these descriptions can be either deterministic or stochastic. A deterministic description gives a precise description of one particular piece of ground glass, and a stochastic description makes statements about ensemble averages.

We shall briefly survey all of these approaches but conclude at the end that we can be satisfied with a stochastic operational description, namely the random

amplitude transmittance. The reader who agrees with this conclusion *a priori* can skip to Sec. 18.2.2.

What is a ground glass? Literally, a ground glass is a piece of glass that has been roughened by grinding it with an abrasive such as emery or corundum. Physically, its surface consists of irregular peaks and valleys. Operationally, it scatters light and appears diffuse to the eye. Much the same effect can be produced by etching the glass with hydrofluoric acid, so we may as well be discussing etched glass rather than ground glass. Operationally, we could also use a translucent material such as teflon or opal glass, which also scatter light and appear diffuse.

Surface-height profile If the light scattering takes place at a surface, as with a literally ground or etched glass, the physical quantity of interest is the profile of the rough surface. If the glass is in the x - y plane, its surface is described by $z = h(x, y)$, where $h(x, y)$ is usually referred to as the *surface-height profile* of the individual ground glass.

This profile can be measured by various devices called *profilometers*; for example, a fine stylus can be dragged over the surface and its deflection observed electrically or optically. Thus the surface-height profile $h(x, y)$, or $h(\mathbf{r})$ in our usual 2D vector notation, is an observable property of an individual ground glass. A common summary description of an individual profile is its standard deviation, often called the *RMS roughness*. Other measures obtainable by profilometry include the mean peak-to-valley distance and the histogram of observed heights.

If we consider an ensemble of ground glasses that have all been roughened in the same way, we can consider $h(\mathbf{r})$ to be a sample function of a random process. For a ground glass of finite size, this sample function is square-integrable and hence a vector in an \mathbb{L}_2 Hilbert space.

It is neither uncommon nor unreasonable to assume that the individual $h(\mathbf{r})$ is a sample function of a stationary random process, truncated by a rect function describing the overall support. We need not quibble over whether this statement should be interpreted as wide-sense or narrow-sense stationarity (see Sec. 8.2.4) since the same physical considerations justify both assumptions; we must assume only that the grinding process does the same things to the glass at all points. If one wanted to look in detail at this assumption, it would have to be admitted that the physical grinding process behaves differently at the edges of a specimen than at the center, so stationarity in either sense would be more applicable to etched glass than to ground glass, but this level of detail is far beyond our needs.

If we do make the assumption that an individual ground glass is a truncated sample from a stationary random process, the histogram of measured heights can be regarded as a histogram estimate of the true single-point PDF on the height, and the observed RMS roughness can be squared to get an estimate of the variance; both single-point PDF and variance of the random process are independent of position \mathbf{r} under the assumption of stationarity. We can also use the profilometer data to get an estimate of the autocorrelation function of the process, and we might even take a discrete Fourier transform to estimate the power-spectral density. (See, however, the caveats in Sec. 8.2.7, and especially Fig. 8.1.)

Operational descriptions based on radiometry We have already met one operational description of a rough surface, the bidirectional transmittance distribution function

(BTDF) defined in Sec. 10.2.4. This description is appropriate to a ground glass since it is essentially a thin optical element with all of the scattering occurring at the surface. It is not a stochastic description since it involves only the average radiances of the incident and scattered light, and it is a very incomplete description since it says nothing about fluctuations around these averages.

Operational descriptions based on the field When the complex field is of interest, thin optical elements can be described deterministically by an *amplitude transmittance* $t(\mathbf{r})$, defined as in (9.153) by

$$u_+(\mathbf{r}) = u_-(\mathbf{r})t(\mathbf{r}), \quad (18.6)$$

where $u_+(\mathbf{r})$ is the field just after the optical element, and $u_-(\mathbf{r})$ is the field incident on it. We can apply this idea to a ground glass simply by defining the transmittance $t_{GG}(\mathbf{r})$ as $u_+(\mathbf{r})/u_-(\mathbf{r})$. We don't really need to know how the ground glass does what it does, just how it modifies the field.

In this view, $t_{GG}(\mathbf{r})$ is one sample function drawn from the ensemble of ground glasses. The statistics of $t_{GG}(\mathbf{r})$ can be described just as with any other random process. Ideally we would like to know the characteristic functional, but as we shall see below we can quite often get by with much simpler statistical statements.

Mechanistic models A simple mechanistic model is the one used in Sec. 9.6.1 to describe the amplitude transmittance of a thin lens. As discussed in more detail in that section, a thin optical element modifies the phase of the light by an amount,

$$\phi(\mathbf{r}) = \frac{2\pi}{\lambda}(n_g - 1)h(\mathbf{r}), \quad (18.7)$$

where λ is the free-space wavelength of the light and n_g is the refractive index of the glass. In this model, all of the light is presumed to pass through the element, and the amplitude transmittance is

$$t(\mathbf{r}) = \exp[i\phi(\mathbf{r})]. \quad (18.8)$$

Though a useful mental picture, (18.7) should not be taken seriously for rough surfaces. It ignores the fact that some light will be scattered or reflected in the backward direction, and the whole idea of phase modulation by optical elements stemmed from consideration of slabs of glass, not elements with structures comparable in size to a wavelength. Nevertheless, (18.7) does indicate that the phase variations result from surface-height variations, and it shows that very rough surfaces can produce very large phase changes.

Another mechanistic model, frequently used in SAR and reflection-mode ultrasound, assumes that the object consists of discrete point scatterers. Since each point is at a random location, it imparts a random phase to the wave. In its simplest form, this model takes the amplitude transmittance (or reflectance) to be a Poisson random process, but sometimes the scattering amplitude is also considered to be random. We shall have much more to say about point-scattering models in Sec. 18.5, but for now we shall think of the transmittance of the ground glass as a general random process, not necessarily a point process.

For further discussion of possible mechanistic models, see Zhao *et al.* (2001) and Osche (2002).

18.2.2 Some simplifying assumptions

We shall model the ground glass operationally as a pure phase object, with a random amplitude transmittance given by

$$t_{GG}(\mathbf{r}) = \exp[i\phi(\mathbf{r})] S(\mathbf{r}), \quad (18.9)$$

where $S(\mathbf{r})$ is a binary support function. The autocorrelation function of this complex random process is defined by

$$R_{GG}(\mathbf{r}, \mathbf{r}') = \langle t_{GG}(\mathbf{r}) t_{GG}^*(\mathbf{r}') \rangle = S(\mathbf{r}) S(\mathbf{r}') \langle \exp\{i[\phi(\mathbf{r}) - \phi(\mathbf{r}')]\} \rangle. \quad (18.10)$$

Two simplifying assumptions are commonly made with this model. One is that the ground glass is sufficiently rough that it completely randomizes the phases. In terms of the simple mechanistic model of (18.7), this amounts to assuming that $\sigma_h \gg \lambda$, where σ_h^2 is the variance of the surface-height profile. We can state this assumption in terms of the univariate or single-point PDF for the phase:

$$\text{pr}[\phi(\mathbf{r})] = \frac{1}{2\pi} \text{rect} \left[\frac{\phi(\mathbf{r})}{2\pi} \right] \quad (\text{for all } \mathbf{r}). \quad (18.11)$$

It follows that

$$\langle t_{GG}(\mathbf{r}) \rangle = 0, \quad (18.12)$$

where the average is over an ensemble of ground glasses. With this assumption, autocorrelation and autocovariance are the same thing since the mean is zero, and we denote the latter as $K_{GG}(\mathbf{r}, \mathbf{r}')$.

The second useful assumption is that the autocovariance function is sharply peaked compared to other functions of interest, such as the point spread function of an imaging system. Thus, noting that $K_{GG}(\mathbf{r}, \mathbf{r}) = 1$ within the support, we write

$$K_{GG}(\mathbf{r}, \mathbf{r}') \approx S(\mathbf{r}) \ell_c^2 \delta(\mathbf{r} - \mathbf{r}'), \quad (18.13)$$

where ℓ_c is the *correlation length*,³ defined by

$$\ell_c^2 \equiv \int_{\infty} d^2 r' K_{GG}(\mathbf{r}, \mathbf{r}'). \quad (18.14)$$

This integral is independent of \mathbf{r} if ℓ_c is small compared to the support and \mathbf{r} is not within ℓ_c of the border. In practice, we know from Sec. 10.2.7 that $\ell_c \approx \lambda$, where λ is the wavelength.

With this zero-mean complex Gaussian random process, it is tempting to assume further that circular Gaussian statistics apply (see Sec. 8.3.6), but that would be an oversimplification; for a pure phase function, $|t_{GG}(\mathbf{r})| = 1$, so Gaussian statistics are definitely not applicable. Nevertheless, we shall show via the central-limit theorem that the speckle field at an observation plane is very closely Gaussian.

³The reader should not confuse correlation length with coherence length. The latter term is often used to describe polychromatic radiation (see Sec. 9.7.4), but here we are considering monochromatic radiation where the coherence length is infinite.

Field emerging from the ground glass We assume for simplicity that the ground glass is illuminated with a unit-amplitude plane wave propagating in the z direction. The complex amplitude of this plane wave is $\exp(ikz)$, where $k = 2\pi/\lambda$. If we assume that the ground glass lies in the plane $z = 0$, then $u_-(\mathbf{r})$ in (18.6) is unity, and the field emerging from the ground glass is

$$u_0(\mathbf{r}) = t_{GG}(\mathbf{r}). \quad (18.15)$$

Thus the field has exactly the same statistical properties as the ground glass itself with this illumination.

Propagation to the observation plane Our interest will be in the field in an observation plane parallel to the ground glass and a distance z away. We denote this field as $u_z(\mathbf{r})$ and the corresponding irradiance as $I_z(\mathbf{r}) \equiv |u_z(\mathbf{r})|^2$. We know from Sec. 9.4 how to compute $u_z(\mathbf{r})$ if we know $u_0(\mathbf{r})$. We can denote this relation abstractly as

$$\mathbf{u}_z = \mathcal{P}_z \mathbf{u}_0, \quad (18.16)$$

where \mathcal{P}_z is a propagation operator (not to be confused with a projection operator). Specifically, in the Fresnel approximation (see Sec. 9.4.6),

$$u_z(\mathbf{r}) = \frac{\exp(ikz)}{i\lambda z} \int_{\infty} d^2 r_0 u_0(\mathbf{r}_0) \exp\left(i\pi \frac{|\mathbf{r} - \mathbf{r}_0|^2}{\lambda z}\right). \quad (18.17)$$

If $t_{GG}(\mathbf{r})$ is a zero-mean random process, then so are $u_0(\mathbf{r})$ and $u_z(\mathbf{r})$. If, on the other hand, $\langle t_{GG}(\mathbf{r}) \rangle \neq 0$, then there is a nonrandom component to $u_z(\mathbf{r})$. If the support of the ground glass is large, this component is essentially an undiffracted plane wave. It is common terminology to say that the speckle is *fully developed* if $\langle u_0(\mathbf{r}) \rangle = 0$. If $\langle u_0(\mathbf{r}) \rangle \neq 0$ and there is an undiffracted plane-wave component, the speckle is said to be *partially developed*.

18.2.3 Propagation of characteristic functionals

In a statistical context, (18.16) and (18.17) apply to sample functions of random processes, and the theory of speckle boils down to analysis of the effects of various transformations on random processes. The transformation in (18.17) is a linear integral operator, but computation of the irradiance is a nonlinear point operation, and detection of the irradiance with a discrete detector array is a linear CD mapping. A useful tool for analyzing all of these transformations is the characteristic functional (see Secs. 8.2.3 and 8.3.5).

The characteristic functional for the transmittance of the ground glass is defined as

$$\Psi_{\mathbf{t}_{GG}}(\boldsymbol{\xi}) = \left\langle \exp \left[-i\pi \left(\boldsymbol{\xi}^\dagger \mathbf{t}_{GG} + \mathbf{t}_{GG}^\dagger \boldsymbol{\xi} \right) \right] \right\rangle, \quad (18.18)$$

where $\boldsymbol{\xi}$ is a vector in $\mathbb{L}_2(\mathbb{R}^2)$ corresponding to the complex-valued, square-integrable function $\xi(\mathbf{r})$, and \mathbf{t}_{GG} corresponds to $t_{GG}(\mathbf{r})$. Similarly, the field emerging from the ground glass in the plane $z = 0$ has a characteristic functional given by

$$\Psi_{\mathbf{u}_0}(\boldsymbol{\xi}) = \left\langle \exp \left[-i\pi \left(\boldsymbol{\xi}^\dagger \mathbf{u}_0 + \mathbf{u}_0^\dagger \boldsymbol{\xi} \right) \right] \right\rangle. \quad (18.19)$$

The characteristic functional for the propagated field is given by

$$\begin{aligned}\Psi_{\mathbf{u}_z}(\boldsymbol{\xi}) &= \left\langle \exp \left[-i\pi \left(\boldsymbol{\xi}^\dagger \mathbf{u}_z + \mathbf{u}_z^\dagger \boldsymbol{\xi} \right) \right] \right\rangle \\ &= \left\langle \exp \left\{ -i\pi \left[\boldsymbol{\xi}^\dagger (\mathcal{P}_z \mathbf{u}_0) + (\mathcal{P}_z \mathbf{u}_0)^\dagger \boldsymbol{\xi} \right] \right\} \right\rangle = \Psi_{\mathbf{u}_0} \left(\mathcal{P}_z^\dagger \boldsymbol{\xi} \right).\end{aligned}\quad (18.20)$$

In Sec. 18.2.4, we shall use the central-limit theorem to argue that $u_z(\mathbf{r})$ is a circular Gaussian random process under broad assumptions. When that conclusion holds, we can give an explicit form for $\Psi_{\mathbf{u}_z}(\boldsymbol{\xi})$; we know from (8.251) that it is given by

$$\Psi_{\mathbf{u}_z}(\boldsymbol{\xi}) = \exp \left(-\pi^2 \boldsymbol{\xi}^\dagger \mathcal{K}_{\mathbf{u}_z} \boldsymbol{\xi} \right), \quad (18.21)$$

where $\mathcal{K}_{\mathbf{u}_z}$ is the autocovariance operator, an integral transform with the autocovariance function as its kernel. To be explicit, the quadratic form in (18.21) is a scalar given by

$$\boldsymbol{\xi}^\dagger \mathcal{K}_{\mathbf{u}_z} \boldsymbol{\xi} = \int_{-\infty}^{\infty} d^2 r \int_{-\infty}^{\infty} d^2 r' \xi^*(\mathbf{r}) K_{\mathbf{u}_z}(\mathbf{r}, \mathbf{r}') \xi(\mathbf{r}'). \quad (18.22)$$

Since $\mathcal{K}_{\mathbf{u}_z}$ is positive-definite, $\boldsymbol{\xi}^\dagger \mathcal{K}_{\mathbf{u}_z} \boldsymbol{\xi}$ is real even though all factors in (18.22) may be complex.

We learned in Sec. 8.2.6 how to propagate autocovariance operators; with (8.147) and (18.13) we see that

$$\mathcal{K}_{\mathbf{u}_z} = \mathcal{P}_z \mathcal{K}_{\mathbf{u}_0} \mathcal{P}_z^\dagger \approx \ell_c^2 \mathcal{P}_z \mathcal{P}_z^\dagger. \quad (18.23)$$

In the Fresnel approximation, the kernel of the operator $\mathcal{K}_{\mathbf{u}_z}$ is⁴

$$\begin{aligned}K_{\mathbf{u}_z}(\mathbf{r}, \mathbf{r}') &= \frac{\ell_c^2}{\lambda^2 z^2} \int_A d^2 r'' \exp \left(i \frac{\pi}{\lambda z} |\mathbf{r} - \mathbf{r}''|^2 \right) \exp \left(-i \frac{\pi}{\lambda z} |\mathbf{r}' - \mathbf{r}''|^2 \right) \\ &= \frac{\ell_c^2}{\lambda^2 z^2} L^2 \operatorname{sinc} \left(\frac{L}{\lambda z} |\mathbf{r} - \mathbf{r}'| \right),\end{aligned}\quad (18.24)$$

where A denotes the area of the ground glass, of dimensions $L \times L$. The sinc function has a width of $\lambda z/L$, confirming the qualitative argument from Sec. 18.1.1 that the correlation length in the diffraction pattern is inversely proportional to the size of the ground glass.

18.2.4 Central-limit theorem

What follows is a fairly tedious derivation showing how the central-limit theorem applies to the present problem. The reader who is content with handwaving can skip this discussion and jump to Sec. 18.2.5.

The derivation here generally follows the development in Sec. 8.3.4, modified for random processes rather than random variables. A key difference, however, is

⁴A quadratic phase factor $\exp \left[i \frac{\pi}{\lambda z} (r^2 - r'^2) \right]$ has been dropped in (18.24) since it is near unity whenever the sinc function is appreciable.

that we do not add multiple random processes, but instead consider a single random process divided spatially into successively smaller component processes.

For generality we forego the zero-mean assumption and write

$$t_{GG}(\mathbf{r}) = \bar{t}_{GG} + \Delta t_{GG}(\mathbf{r}), \tag{18.25}$$

and similarly for the fields. We assume that $\Delta t_{GG}(\mathbf{r})$ is rapidly varying so that the ground glass can be written as a sum of nonoverlapping regions with negligible statistical dependence. If the dimensions of the ground glass are $L \times L$ and those of the regions in question are $\epsilon \times \epsilon$, we write the random part of the field emerging from the ground glass as

$$\Delta u_0(\mathbf{r}) = \sum_{\mathbf{k}} \Delta u_0^{(\mathbf{k})}(\mathbf{r}), \tag{18.26}$$

where \mathbf{k} is a 2D multi-index of integer components. Explicitly,

$$\Delta u_0^{(\mathbf{k})}(\mathbf{r}) = \Delta u_0(\mathbf{r}) \operatorname{rect} \left(\frac{\mathbf{r} - \mathbf{k}\epsilon}{\epsilon} \right) \equiv w^{(\mathbf{k})}(\mathbf{r}) \Delta u_0(\mathbf{r}), \tag{18.27}$$

where the components of \mathbf{k} run from $-K$ to K , with $K = (L - \epsilon)/(2\epsilon)$ and K odd. Note that the sum of rect functions is unity within the $L \times L$ support of the ground glass. We assume that we can choose $\ell_c \ll \epsilon \ll L$, and assume further that ℓ_c is the characteristic length beyond which the random process is not just uncorrelated but statistically independent; thus (18.26) represents a decomposition of the field into statistically independent components.

Propagating to the plane z , we have

$$\Delta \mathbf{u}_z^{(\mathbf{k})} = \mathcal{P}_z \Delta \mathbf{u}_0^{(\mathbf{k})}. \tag{18.28}$$

The characteristic functional of $\Delta \mathbf{u}_z$ is

$$\begin{aligned} \Psi_{\Delta \mathbf{u}_z}(\boldsymbol{\xi}) &= \left\langle \exp \left[-i\pi \left(\boldsymbol{\xi}^\dagger \Delta \mathbf{u}_z + \Delta \mathbf{u}_z^\dagger \boldsymbol{\xi} \right) \right] \right\rangle \\ &= \left\langle \exp \left\{ -i\pi \sum_{\mathbf{k}} \left[\boldsymbol{\xi}^\dagger \left(\mathcal{P}_z \Delta \mathbf{u}_0^{(\mathbf{k})} \right) + \left(\mathcal{P}_z \Delta \mathbf{u}_0^{(\mathbf{k})} \right)^\dagger \boldsymbol{\xi} \right] \right\} \right\rangle \\ &= \prod_{\mathbf{k}} \left\langle \exp \left\{ -i\pi \left[\boldsymbol{\xi}^\dagger \left(\mathcal{P}_z \Delta \mathbf{u}_0^{(\mathbf{k})} \right) + \left(\mathcal{P}_z \Delta \mathbf{u}_0^{(\mathbf{k})} \right)^\dagger \boldsymbol{\xi} \right] \right\} \right\rangle = \prod_{\mathbf{k}} \Psi_{\Delta \mathbf{u}_0^{(\mathbf{k})}} \left(\mathcal{P}_z^\dagger \boldsymbol{\xi} \right). \end{aligned} \tag{18.29}$$

If we were following the flow of Sec. 8.3.4 exactly, we would at this point assume that the the random processes $\Delta \mathbf{u}_0^{(\mathbf{k})}$ were independent and identically distributed, but in fact they are not identically distributed because of the spatial offsets. We can, however, expand $\Psi_{\Delta \mathbf{u}_0^{(\mathbf{k})}}(\boldsymbol{\xi})$ analogously to (8.205), yielding

$$\Psi_{\Delta \mathbf{u}_0^{(\mathbf{k})}}(\boldsymbol{\xi}) = 1 - \pi^2 \boldsymbol{\xi}^\dagger \left\langle \Delta \mathbf{u}_0^{(\mathbf{k})} \Delta \mathbf{u}_0^{(\mathbf{k})\dagger} \right\rangle \boldsymbol{\xi} + \dots, \tag{18.30}$$

where we have made use of the facts that $\Delta \mathbf{u}_0^{(\mathbf{k})}$ has zero mean and $\boldsymbol{\xi}^\dagger \langle \Delta \mathbf{u}_0^{(\mathbf{k})} \Delta \mathbf{u}_0^{(\mathbf{k})\dagger} \rangle \boldsymbol{\xi}$ is real. We have also assumed that $\langle [\boldsymbol{\xi}^\dagger \mathcal{P}_z \Delta \mathbf{u}_0^{(\mathbf{k})}]^2 \rangle$ and its complex conjugate are

negligible. We return to this assumption below; making it uncritically for now, we see that

$$\Psi_{\Delta u_z}(\boldsymbol{\xi}) = \prod_{\mathbf{k}} \left[1 - \pi^2 \left(\mathcal{P}_z^\dagger \boldsymbol{\xi} \right)^\dagger \left\langle \Delta \mathbf{u}_0^{(\mathbf{k})} \Delta \mathbf{u}_0^{(\mathbf{k})\dagger} \right\rangle \mathcal{P}_z^\dagger \boldsymbol{\xi} + \dots \right]. \quad (18.31)$$

At this point we invoke the fact that the field on the ground glass has a very short correlation length, much shorter than the region size ϵ and even shorter than a wavelength. The propagator \mathcal{P}_z , on the other hand, has a kernel that is slowly varying compared to a wavelength in the Fresnel approximation. Thus, for present purposes we can write

$$\left\langle \left[\Delta u_0^{(\mathbf{k})}(\mathbf{r}) \right] \left[\Delta u_0^{(\mathbf{k})}(\mathbf{r}') \right]^* \right\rangle \approx \ell_c^2 w^{(\mathbf{k})}(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') \quad (18.32)$$

or, in operator form,

$$\left\langle \left[\Delta \mathbf{u}_0^{(\mathbf{k})} \right] \left[\Delta \mathbf{u}_0^{(\mathbf{k})} \right]^\dagger \right\rangle = \ell_c^2 \mathcal{W}^{(\mathbf{k})}, \quad (18.33)$$

with $\mathcal{W}^{(\mathbf{k})}$ being a multiplicative operator with kernel $w^{(\mathbf{k})}(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}')$. Therefore,

$$\begin{aligned} \Psi_{\Delta u_z}(\boldsymbol{\xi}) &= \prod_{\mathbf{k}} \left[1 - \pi^2 \ell_c^2 \left(\mathcal{P}_z^\dagger \boldsymbol{\xi} \right)^\dagger \mathcal{W}^{(\mathbf{k})} \left(\mathcal{P}_z^\dagger \boldsymbol{\xi} \right) + \dots \right] \\ &= \prod_{\mathbf{k}} \left\{ 1 - \pi^2 \ell_c^2 \left(\boldsymbol{\xi}^\dagger \left[\mathcal{P}_z \mathcal{W}^{(\mathbf{k})} \mathcal{P}_z^\dagger \right] \boldsymbol{\xi} \right) + \dots \right\}. \end{aligned} \quad (18.34)$$

Taking a logarithm yields

$$\ln \{ \Psi_{\Delta u_z}(\boldsymbol{\xi}) \} = \sum_{\mathbf{k}} \ln \left\{ 1 - \pi^2 \ell_c^2 \left(\boldsymbol{\xi}^\dagger \left[\mathcal{P}_z \mathcal{W}^{(\mathbf{k})} \mathcal{P}_z^\dagger \right] \boldsymbol{\xi} \right) + \dots \right\}. \quad (18.35)$$

The operator in square brackets here, $[\mathcal{P}_z \mathcal{W}^{(\mathbf{k})} \mathcal{P}_z^\dagger]$, has a kernel

$$\begin{aligned} \left[\mathcal{P}_z \mathcal{W}^{(\mathbf{k})} \mathcal{P}_z^\dagger \right](\mathbf{r}, \mathbf{r}') &= \int_A d^2 r_1 \int_A d^2 r_2 p_z(\mathbf{r}, \mathbf{r}_1) w^{(\mathbf{k})}(\mathbf{r}_1) \delta(\mathbf{r}_1 - \mathbf{r}_2) p_z^*(\mathbf{r}_2, \mathbf{r}') \\ &= \int_A d^2 r_1 p_z(\mathbf{r}, \mathbf{r}_1) w^{(\mathbf{k})}(\mathbf{r}_1) p_z^*(\mathbf{r}_1, \mathbf{r}'). \end{aligned} \quad (18.36)$$

This integral varies as ϵ^2 and higher-order terms vary as higher powers. Thus, by the same arguments as in Sec. 8.3.4, we can drop the higher terms and expand the logarithm to obtain

$$\ln \{ \Psi_{\Delta u_z}(\boldsymbol{\xi}) \} \sim - \sum_{\mathbf{k}} \pi^2 \ell_c^2 \boldsymbol{\xi}^\dagger \mathcal{P}_z \mathcal{W}^{(\mathbf{k})} \mathcal{P}_z^\dagger \boldsymbol{\xi}. \quad (18.37)$$

Finally, since $\sum_{\mathbf{k}} \mathcal{W}^{(\mathbf{k})}$ is just the unit operator, we get

$$\ln \{ \Psi_{\Delta u_z}(\boldsymbol{\xi}) \} \sim - \pi^2 \ell_c^2 \boldsymbol{\xi}^\dagger \mathcal{P}_z \mathcal{P}_z^\dagger \boldsymbol{\xi} \quad (18.38)$$

or

$$\Psi_{\Delta u_z}(\boldsymbol{\xi}) \sim \exp \left(- \pi^2 \ell_c^2 \boldsymbol{\xi}^\dagger \mathcal{P}_z \mathcal{P}_z^\dagger \boldsymbol{\xi} \right). \quad (18.39)$$

The conclusion is that $\Delta u_z(\mathbf{r})$ is a circular Gaussian random process. If the mean transmittance of the ground glass is zero, then $u_z(\mathbf{r})$ is also circular Gaussian. If the mean transmittance is not zero, we get

$$\Psi_{\mathbf{u}_z}(\boldsymbol{\xi}) \sim \exp \left[- i \pi \left(\boldsymbol{\xi}^\dagger \mathcal{P}_z \bar{\mathbf{u}}_0 + \bar{\mathbf{u}}_0^\dagger \mathcal{P}_z^\dagger \boldsymbol{\xi} \right) \right] \exp \left(- \pi^2 \ell_c^2 \boldsymbol{\xi}^\dagger \mathcal{P}_z \mathcal{P}_z^\dagger \boldsymbol{\xi} \right). \quad (18.40)$$

A lapse of propriety Now let us return to (18.30), where we dropped $\langle [\xi^\dagger \mathcal{P}_z \Delta \mathbf{u}_0^{(k)}]^2 \rangle$ and its complex conjugate. This term can be written as

$$\left\langle \left[\xi^\dagger \mathcal{P}_z \Delta \mathbf{u}_0^{(k)} \right]^2 \right\rangle = \xi^\dagger \mathcal{P}_z \left\langle \left[\Delta \mathbf{u}_0^{(k)} \right] \left[\Delta \mathbf{u}_0^{(k)} \right]^t \right\rangle \mathcal{P}_z^t \xi^{\dagger t}. \quad (18.41)$$

We could drop this term immediately if we could argue that $\Delta \mathbf{u}_0^{(k)}$ was a *proper* random process. Recall from Sec. 8.3.6 that a complex random vector or process \mathbf{z} is proper if the mean $\langle \mathbf{z} \rangle$ and the *pseudocovariance* $\langle \mathbf{z} \mathbf{z}^t \rangle$ both vanish; in that case the second-order statistics are fully specified by the covariance defined as $\langle \mathbf{z} \mathbf{z}^\dagger \rangle$. A sufficient condition for \mathbf{z} to be proper is that it be zero mean and that the real and imaginary parts of any component be *i.i.d.* Consideration of Fig. 18.2 shows, however, that $\Delta \mathbf{u}_0^{(k)}$ does not satisfy these conditions; its mean is zero by construction, but its real and imaginary parts are neither independent nor identically distributed. We therefore have to look further for the rationale for neglecting this term.

Fig. 18.2 (a) Diagram illustrating the statistical properties of the field in the plane $z = 0$ when it cannot be assumed that the phase of this field is uniformly distributed on $(0, 2\pi)$. It is assumed here that $\langle u_0(\mathbf{r}) \rangle \neq 0$ and that $|u_0(\mathbf{r})| = 1$. Thus the allowed values of $\Delta u_0(\mathbf{r})$ lie on the arc shown, and by inspection the real and imaginary parts of $\Delta u_0(\mathbf{r})$ are neither independent nor identically distributed. (b) Similar diagram for the case where the phase is uniformly distributed. Now the mean is zero, $\Delta u_0(\mathbf{r}) = u_0(\mathbf{r})$, and the real and imaginary parts of $\Delta u_0(\mathbf{r})$ are *i.i.d.*

Since we have already assumed that the fields at two points on the ground glass are statistically independent unless the points are within ℓ_c , and that this distance is very small compared to the width of the kernel of \mathcal{P}_z , we can write the pseudocovariance function as [cf. (18.32)]

$$\left\langle \left[\Delta u_0^{(k)}(\mathbf{r}) \right] \left[\Delta u_0^{(k)}(\mathbf{r}') \right] \right\rangle \approx a_c w^{(k)}(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'), \quad (18.42)$$

where $a_c \leq \ell_c^2$ because of partial phase cancellation. Writing out (18.41) in integral form and using (18.42) yields [cf. (18.36)]

$$\left\langle \left[\xi^\dagger \mathcal{P}_z \Delta \mathbf{u}_0^{(k)} \right]^2 \right\rangle = a_c \int_{\infty} d^2 r \xi^*(\mathbf{r}) \int_{\infty} d^2 r' \xi^*(\mathbf{r}') \int_A d^2 r_1 p_z(\mathbf{r}, \mathbf{r}_1) w^{(k)}(\mathbf{r}_1) p_z(\mathbf{r}_1, \mathbf{r}'). \quad (18.43)$$

The important point to note here is the absence of a complex conjugate on either p_z factor, so there is no cancellation of quadratic phase factors. After performing

steps analogous to (18.36)–(18.38) and inserting the Fresnel propagation kernel, we find that the \mathbf{r}_1 integral takes the form

$$\frac{1}{\lambda^2 z^2} \int_A d^2 r_1 \exp \left[i \frac{\pi}{\lambda z} (|\mathbf{r}_1 - \mathbf{r}|^2 + |\mathbf{r}_1 - \mathbf{r}'|^2) \right]. \quad (18.44)$$

Because of the oscillating factor of $\exp(2i\pi r_1^2/\lambda z)$, this integral will be very small (compared to A) if the overall area of the ground glass covers many Fresnel zones, or $L^2/\lambda z \gg 1$. This is the opposite of the Fraunhofer condition (see Sec. 9.5.2), so the pseudocovariance term has a small effect in the near field of the ground glass, in essence because the propagation introduces large phase variations.

In summary, we can overlook the impropriety if either the ground glass or the propagation fully randomizes the phase of the field.

18.2.5 Statistics of the irradiance

We now know how to write the characteristic functional for the field $u_z(\mathbf{r})$ in the observation plane. The next step is to study the statistics of the irradiance, $I_z(\mathbf{r}) \equiv |u_z(\mathbf{r})|^2$. Because of the nonlinear nature of the transformation from field to irradiance, there is no general rule for transforming the characteristic functionals, but we shall see that a useful expression is possible when the field is a circular Gaussian.

Our approach will be to consider first a finely sampled but discrete field pattern and compute its characteristic *function*, then pass to the limit of an infinitesimal sampling interval and get the characteristic *functional* for the irradiance. Point sampling causes no difficulty because the propagator \mathcal{P}_z is a low-pass filter, blocking all 2D spatial frequencies of magnitude greater than the reciprocal of the wavelength (see Sec. 9.5.1).

We define an $N \times 1$ complex vector \mathbf{u}_z with components $u_z(\mathbf{r}_n)$ and an $N \times 1$ real vector \mathbf{I}_z with components given by $I_z(\mathbf{r}_n) = |u_z(\mathbf{r}_n)|^2$. The characteristic function (not functional, so we use ψ instead of Ψ) for \mathbf{I}_z is defined by

$$\psi_{\mathbf{I}_z}(\boldsymbol{\zeta}) = \langle \exp(-2\pi i \boldsymbol{\zeta}^t \mathbf{I}_z) \rangle, \quad (18.45)$$

where $\boldsymbol{\zeta}$ is an $N \times 1$ real vector, and the average is over real and imaginary components of \mathbf{u}_z .

If the field in plane z is circular Gaussian, then

$$\begin{aligned} \psi_{\mathbf{I}_z}(\boldsymbol{\zeta}) &= \frac{1}{\pi^N \det(\mathbf{K}_{\mathbf{u}_z})} \int_{\infty} d^{2N} u_z \exp(-\mathbf{u}_z^\dagger \mathbf{K}_{\mathbf{u}_z}^{-1} \mathbf{u}_z) \exp(-2\pi i \boldsymbol{\zeta}^t \mathbf{I}_z) \\ &= \frac{1}{\pi^N \det(\mathbf{K}_{\mathbf{u}_z})} \int_{\infty} d^{2N} u_z \exp[-\mathbf{u}_z^\dagger (\mathbf{K}_{\mathbf{u}_z}^{-1} + 2\pi i \mathbf{Z}) \mathbf{u}_z], \end{aligned} \quad (18.46)$$

where \mathbf{Z} is an $N \times N$ diagonal matrix with elements given by

$$Z_{mn} = \zeta_m \delta_{mn}. \quad (18.47)$$

Simultaneous diagonalization Key to evaluation of the integral in (18.46) is finding a representation where $\mathbf{K}_{\mathbf{u}_z}^{-1}$ and \mathbf{Z} are simultaneously diagonal. We shall use the diagonalization procedure from Sec. 1.4.6; this procedure diagonalizes two Hermitian

matrices \mathbf{A} and \mathbf{B} , even if they do not commute, by three steps. The first step is to diagonalize \mathbf{A} by a unitary transformation, then convert it to the unit matrix by a nonunitary *prewhitening* transform, finally diagonalize the transformed matrix \mathbf{B} by another unitary transformation. The prewhitening step requires that \mathbf{A} be nonsingular.

To apply this procedure to the problem at hand, we take $\mathbf{A} = \mathbf{K}_{\mathbf{u}_z}^{-1}$ and $\mathbf{B} = \mathbf{Z}$. Thus we first undiagonalize \mathbf{Z} , then rediagonalize it. We cannot, however, choose $\mathbf{A} = \mathbf{Z}$ since assuming that \mathbf{Z} is nonsingular is the same as requiring all $\zeta_n \neq 0$; in fact, most of the interest in the characteristic function is at $\boldsymbol{\zeta} = \mathbf{0}$.

Following Sec. 1.4.6, we first do a Karhunen-Loève transformation (see also Sec. 8.2.7) on $\mathbf{K}_{\mathbf{u}_z}$:

$$\mathbf{K}_{\mathbf{u}_z} \boldsymbol{\Upsilon} = \boldsymbol{\Upsilon} \mathbf{M}, \quad \boldsymbol{\Upsilon}^\dagger \mathbf{K}_{\mathbf{u}_z} \boldsymbol{\Upsilon} = \mathbf{M}, \quad \boldsymbol{\Upsilon}^\dagger \mathbf{K}_{\mathbf{u}_z}^{-1} \boldsymbol{\Upsilon} = \mathbf{M}^{-1}, \quad (18.48)$$

where $\boldsymbol{\Upsilon}$ is a unitary matrix and \mathbf{M} is a diagonal matrix with the eigenvalues of $\mathbf{K}_{\mathbf{u}_z}$ along the diagonal.

Next we prewhiten $\mathbf{K}_{\mathbf{u}_z}^{-1}$, obtaining

$$\mathbf{M}^{\frac{1}{2}} \boldsymbol{\Upsilon}^\dagger \mathbf{K}_{\mathbf{u}_z}^{-1} \boldsymbol{\Upsilon} \mathbf{M}^{\frac{1}{2}} = \mathbf{I}. \quad (18.49)$$

Finally, we rediagonalize \mathbf{Z} to get

$$\mathbf{W}^\dagger \mathbf{Z} \mathbf{W} = \mathbf{D}, \quad (18.50)$$

where \mathbf{D} is diagonal and

$$\mathbf{W} = \boldsymbol{\Upsilon} \mathbf{M}^{\frac{1}{2}} \boldsymbol{\Phi}. \quad (18.51)$$

Thus

$$\mathbf{W}^\dagger \mathbf{K}_{\mathbf{u}_z}^{-1} \mathbf{W} = \mathbf{I}, \quad \mathbf{W}^\dagger \mathbf{Z} \mathbf{W} = \mathbf{D}. \quad (18.52)$$

Note that $\mathbf{W}^\dagger \mathbf{K}_{\mathbf{u}_z}^{-1} \mathbf{W} = \mathbf{I}$ does not imply that $\mathbf{W}^\dagger \mathbf{K}_{\mathbf{u}_z} \mathbf{W} = \mathbf{I}$ since \mathbf{W} is not unitary.

Evaluation of the integral We can now perform the integral in (18.46) by introducing the change of variables:⁵

$$\mathbf{u}_z = \mathbf{W} \tilde{\mathbf{u}}_z. \quad (18.53)$$

The expression for the characteristic function now becomes⁶

$$\begin{aligned} \psi_{\mathbf{I}_z}(\boldsymbol{\zeta}) &= \frac{1}{\pi^N \det(\mathbf{K}_{\mathbf{u}_z})} \int_{\infty} d^{2N} u_z \exp[-\mathbf{u}_z^\dagger (\mathbf{K}_{\mathbf{u}_z}^{-1} + 2\pi i \mathbf{Z}) \mathbf{u}_z] \\ &= \frac{|\det(\mathbf{W})|^2}{\pi^N \det(\mathbf{K}_{\mathbf{u}_z})} \int_{\infty} d^{2N} \tilde{u}_z \exp[-\tilde{\mathbf{u}}_z^\dagger (\mathbf{I} + 2\pi i \mathbf{D}) \tilde{\mathbf{u}}_z], \end{aligned} \quad (18.54)$$

where $\boldsymbol{\zeta}$ is now hidden within \mathbf{D} (we'll retrieve it shortly), and $|\det(\mathbf{W})|^2$ is the Jacobian of the transformation. Since $\boldsymbol{\Phi}$ and $\boldsymbol{\Psi}$ are unitary, it follows from (A.78) and (A.83) that

$$|\det(\mathbf{W})|^2 = [\det(\mathbf{M}^{\frac{1}{2}})]^2 = \det(\mathbf{K}), \quad (18.55)$$

⁵Actually, this step is a bit tricky. With unitary transformations we would normally write $\tilde{\mathbf{u}} = \mathbf{W}^\dagger \mathbf{u}$, which is equivalent to (18.53) when $\mathbf{W}^\dagger = \mathbf{W}^{-1}$. To get the exponent into a form where our freshly diagonalized operators appear after a nonunitary transformation, however, we must define the transformation as in (18.53).

⁶The reader should not confuse the unit matrix \mathbf{I} in this expression with the irradiance $I_z(\mathbf{r})$, which we write as \mathbf{I}_z when we regard it as a vector in Hilbert space.

so the integral we need to evaluate is

$$\psi_{\mathbf{I}_z}(\zeta) = \frac{1}{\pi^N} \int_{-\infty}^{\infty} d^{2N} \tilde{\mathbf{u}}_z \exp[-\tilde{\mathbf{u}}_z^\dagger (\mathbf{I} + 2\pi i \mathbf{D}) \tilde{\mathbf{u}}_z]. \quad (18.56)$$

Since \mathbf{D} is diagonal, this integral factors into a product of N 2D integrals of the form

$$\begin{aligned} I_n &= \int_{-\infty}^{\infty} dx_n \int_{-\infty}^{\infty} dy_n \exp[-a_n(x_n^2 + y_n^2)] \\ &= \int_{-\infty}^{\infty} dx_n \exp(-a_n x_n^2) \int_{-\infty}^{\infty} dy_n \exp(-a_n y_n^2), \end{aligned} \quad (18.57)$$

where

$$a_n = 1 + 2\pi i D_{nn}. \quad (18.58)$$

Gaussians with complex coefficients have occurred several times previously in this book because of their role in Fresnel propagation problems (see Secs. 3.3.7, 4.3.2 and 9.4.6). By deforming the contour of integration as in (3.184), we find [cf. (3.185) with $\xi = 0$]

$$I_n = \frac{\pi}{a_n}, \quad (18.59)$$

and the original 2ND integral in (18.46) is

$$I = \prod_{n=1}^N I_n = \prod_{n=1}^N \frac{\pi}{a_n} = \frac{\pi^N}{\det(\mathbf{I} + 2\pi i \mathbf{D})}. \quad (18.60)$$

Thus

$$\psi_{\mathbf{I}_z}(\zeta) = \frac{1}{\det(\mathbf{I} + 2\pi i \mathbf{D})} = \frac{1}{\det(\mathbf{I} + 2\pi i \mathbf{W}^\dagger \mathbf{Z} \mathbf{W})}, \quad (18.61)$$

where, as a reminder,

$$\mathbf{W}^\dagger \mathbf{K}_{\mathbf{u}_z}^{-1} \mathbf{W} = \mathbf{I}, \quad Z_{mn} = \zeta_n \delta_{mn}, \quad [\mathbf{W}^\dagger \mathbf{Z} \mathbf{W}]_{mn} = D_n \delta_{mn}. \quad (18.62)$$

Equivalent forms By judiciously inserting a couple of unit matrices, written as $\mathbf{I} = \mathbf{\Psi}^\dagger \mathbf{\Psi}$, we get another expression for the characteristic function of the irradiance:

$$\psi_{\mathbf{I}_z}(\zeta) = \left[\det \left(\mathbf{I} + 2\pi i \mathbf{U}^\dagger \mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}} \mathbf{Z} \mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}} \mathbf{U} \right) \right]^{-1}, \quad (18.63)$$

where $\mathbf{U} \equiv \mathbf{\Psi} \mathbf{\Phi}$ is the unitary operator that diagonalizes the Hermitian matrix $\mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}} \mathbf{Z} \mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}}$. Since determinants are unchanged by unitary transformations, (18.63) is equivalent to

$$\psi_{\mathbf{I}_z}(\zeta) = \left[\det \left(\mathbf{I} + 2\pi i \mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}} \mathbf{Z} \mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}} \right) \right]^{-1}. \quad (18.64)$$

With some identities on determinants from App. A, we get

$$\det \left(\mathbf{I} + 2\pi i \mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}} \mathbf{Z} \mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}} \right) = \det \left[\mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}} \left(\mathbf{I} + 2\pi i \mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}} \mathbf{Z} \mathbf{K}_{\mathbf{u}_z}^{\frac{1}{2}} \right) \mathbf{K}_{\mathbf{u}_z}^{-\frac{1}{2}} \right] = \det(\mathbf{I} + 2\pi i \mathbf{K}_{\mathbf{u}_z} \mathbf{Z}), \quad (18.65)$$

so

$$\psi_{\mathbf{I}_z}(\zeta) = [\det(\mathbf{I} + 2\pi i \mathbf{K}_{\mathbf{u}_z} \mathbf{Z})]^{-1}. \quad (18.66)$$

This expression is consistent with the chi-squared characteristic function as given in (C.139). Specifically, if there are no correlations and $\mathbf{K}_{\mathbf{u}_z} = 2\sigma^2 \mathbf{I}$, then $\psi_{\mathbf{I}_z}(\zeta)$ is just a product of N factors like (C.139), each with 2 degrees of freedom.

Expansion in traces Determinants can be related to traces by (A.114), reproduced here for convenience:

$$-\ln[\det(\mathbf{I} - \mathbf{A})] = \text{tr } \mathbf{A} + \frac{1}{2} \text{tr } \mathbf{A}^2 + \frac{1}{3} \text{tr } \mathbf{A}^3 + \dots \quad (18.67)$$

Using this relation with $\mathbf{A} = -2\pi i \mathbf{K}_{\mathbf{u}_z} \mathbf{Z}$, we get

$$\psi_{\mathbf{I}_z}(\zeta) = \exp \left[-2\pi i \text{tr}(\mathbf{K}_{\mathbf{u}_z} \mathbf{Z}) - 2\pi^2 \text{tr}(\mathbf{K}_{\mathbf{u}_z} \mathbf{Z} \mathbf{K}_{\mathbf{u}_z} \mathbf{Z}) + \dots \right]. \quad (18.68)$$

As noted in App. A, this expansion converges if all eigenvalues of \mathbf{A} are < 1 in absolute value. Usually we want to use $\Psi_{\mathbf{I}_z}(\zeta)$ for calculating moments; convergence is guaranteed in that case since the moments all involve derivatives evaluated at the origin, and all eigenvalues of \mathbf{A} approach zero as $\zeta \rightarrow \mathbf{0}$.

Writing out the first term in the exponent of (18.68) in detail yields

$$\text{tr}(\mathbf{K}\mathbf{Z}) = \sum_{i,j} K_{ij} Z_{ji} = \sum_{i,j} K_{ij} \zeta_i \delta_{ji} = \sum_j K_{jj} \zeta_j. \quad (18.69)$$

Similarly, the second term is

$$\text{tr}(\mathbf{K}\mathbf{Z}\mathbf{K}\mathbf{Z}) = \sum_{i,j,k,\ell} K_{ij} Z_{jk} K_{k\ell} Z_{\ell i} = \sum_{j,k} \zeta_j K_{jk} K_{kj} \zeta_k = \sum_{j,k} \zeta_j |K_{jk}|^2 \zeta_k. \quad (18.70)$$

When these explicit expressions are used in (18.68), it is relatively straightforward to carry out the necessary derivatives and compute moments.

The continuous limit We can pass to the infinite-dimensional limit where vectors become functions by defining an integral operator \mathcal{Z} with kernel $\zeta(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}')$.⁷ Then the traces are interpreted as

$$\text{tr}(\mathcal{K}\mathcal{Z}) = \int_{\infty} d^2 r \zeta(\mathbf{r}) K(\mathbf{r}, \mathbf{r}), \quad \text{tr}(\mathcal{K}\mathcal{Z}\mathcal{K}\mathcal{Z}) = \int_{\infty} d^2 r \int_{\infty} d^2 r' \zeta(\mathbf{r}) |K(\mathbf{r}, \mathbf{r}')|^2 \zeta(\mathbf{r}'), \quad (18.71)$$

and similarly for higher-order terms.

At this stage we have an expression (albeit in terms of an infinite product of exponentials) for the characteristic functional of the irradiance for a nonimaging system. Specifically,

$$\Psi_{\mathbf{I}_z}(\zeta) = \exp[-2\pi i \text{tr}(\mathcal{K}_{\mathbf{u}_z} \mathcal{Z}) - 2\pi^2 \text{tr}(\mathcal{K}_{\mathbf{u}_z} \mathcal{Z} \mathcal{K}_{\mathbf{u}_z} \mathcal{Z}) + \dots]. \quad (18.72)$$

Equivalently, we can use the determinantal expression (18.66) and pass to the limit to obtain

$$\Psi_{\mathbf{I}_z}(\zeta) = \frac{1}{\det(\mathcal{I} + 2\pi i \mathcal{K}_{\mathbf{u}_z} \mathcal{Z})}, \quad (18.73)$$

provided we interpret the determinant of an integral operator as the infinite product of its eigenvalues. The factors in the product converge to unity as the eigenvalues of $\mathcal{K}_{\mathbf{u}_z}$ approach zero, so the fact that the product is infinite causes no grief.

⁷This operator is the Hadamard product of the Hilbert-space vector ζ and the unit operator \mathcal{I} (see Sec. A.2.8). We could have chosen to write it as $\mathcal{Z} = \zeta \odot \mathcal{I}$, but expressing it in terms of its kernel may be clearer.

Single-point statistics We can check our results by computing the univariate statistics for the irradiance at a single spatial location. The univariate characteristic function is given by

$$\psi_{I_z(\mathbf{r}_0)}(\nu) = \langle \exp[-2\pi i \nu I_z(\mathbf{r}_0)] \rangle = \left\langle \exp \left[-2\pi i \nu \int_{\infty} d^2 r I_z(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}_0) \right] \right\rangle. \quad (18.74)$$

Integration against a delta function is permissible since the propagator is a low-pass filter and hence $I_z(\mathbf{r})$ is a function in a reproducing-kernel Hilbert space, specifically Paley-Wiener space (see Secs. 1.8 and 3.5). Thus we can say that $I_z(\mathbf{r}_0)$ is the scalar product⁸ of $\delta(\mathbf{r} - \mathbf{r}_0)$ and the random process $I_z(\mathbf{r})$, and the univariate characteristic function is related to the characteristic functional of the process by

$$\psi_{I_z(\mathbf{r}_0)}(\nu) = \Psi_{\mathbf{I}_z}[\nu \delta(\mathbf{r} - \mathbf{r}_0)]. \quad (18.75)$$

Now $\zeta(\mathbf{r}) = \nu \delta(\mathbf{r} - \mathbf{r}_0)$ and ν is real, so

$$\begin{aligned} \text{tr}(\mathcal{K}_{\mathbf{u}_z} \mathcal{Z}) &= \nu K_{\mathbf{u}_z}(\mathbf{r}_0, \mathbf{r}_0), \\ \text{tr}(\mathcal{K}_{\mathbf{u}_z} \mathcal{Z} \mathcal{K}_{\mathbf{u}_z} \mathcal{Z}) &= \nu^2 |K_{\mathbf{u}_z}(\mathbf{r}_0, \mathbf{r}_0)|^2 = [\text{tr}(\mathcal{K}_{\mathbf{u}_z} \mathcal{Z})]^2, \text{ etc.}, \end{aligned} \quad (18.76)$$

and the desired univariate characteristic function is

$$\psi_{I_z(\mathbf{r}_0)}(\nu) = \exp[-2\pi i \nu K_{\mathbf{u}_z}(\mathbf{r}_0, \mathbf{r}_0) - 2\pi^2 \nu^2 [K_{\mathbf{u}_z}(\mathbf{r}_0, \mathbf{r}_0)]^2 + \dots]. \quad (18.77)$$

The exponent is recognized as an expansion for the logarithm, $\ln(1+z) = z - \frac{1}{2}z^2 + \frac{1}{3}z^3 - \dots$, valid for $|z| < 1$; hence

$$\psi_{I_z(\mathbf{r}_0)}(\nu) = \exp\{-\ln[1 + 2\pi i \nu K_{\mathbf{u}_z}(\mathbf{r}_0, \mathbf{r}_0)]\}, \quad (18.78)$$

so

$$\psi_{I_z(\mathbf{r}_0)}(\nu) = \frac{1}{1 + 2\pi i \nu K_{\mathbf{u}_z}(\mathbf{r}_0, \mathbf{r}_0)}, \quad (18.79)$$

which is the characteristic function for a chi-squared random variable with two degrees of freedom as given in (C.139), or equivalently for an exponential random variable as in (C.121).

Bivariate statistics If the irradiance at two points is of interest, the bivariate characteristic function is related to the characteristic functional for the random process by an extension of (18.75):

$$\psi_{I_z(\mathbf{r}_1), I_z(\mathbf{r}_2)}(\nu_1, \nu_2) = \Psi_{\mathbf{I}_z}[\nu_1 \delta(\mathbf{r} - \mathbf{r}_1) + \nu_2 \delta(\mathbf{r} - \mathbf{r}_2)]. \quad (18.80)$$

One way to proceed is to use (18.73) with \mathcal{Z} being the integral operator with kernel

$$Z(\mathbf{r}, \mathbf{r}') = \zeta(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') = [\nu_1 \delta(\mathbf{r} - \mathbf{r}_1) + \nu_2 \delta(\mathbf{r} - \mathbf{r}_2)] \delta(\mathbf{r} - \mathbf{r}'). \quad (18.81)$$

To use (18.73), we first find the eigenvalues of $\mathcal{K}_{\mathbf{u}_z} \mathcal{Z}$; the eigenvalue equation is

$$\int_{\infty} d^2 r'' [\mathcal{K}_{\mathbf{u}_z} \mathcal{Z}](\mathbf{r}, \mathbf{r}'') \phi(\mathbf{r}'') = \lambda \phi(\mathbf{r}). \quad (18.82)$$

⁸The scalar product we intend is in \mathbb{L}_2 , not the one for the reproducing-kernel Hilbert space. While the delta function is not in \mathbb{L}_2 , we can realize the scalar product with a limiting argument.

Writing out the product $\mathcal{K}_{\mathbf{u}_z} \mathcal{Z}$ explicitly and using the kernel for \mathcal{Z} , we get

$$\int_{-\infty}^{\infty} d^2r'' \int_{-\infty}^{\infty} d^2r' K_{\mathbf{u}_z}(\mathbf{r}, \mathbf{r}'') [\nu_1 \delta(\mathbf{r}'' - \mathbf{r}_1) + \nu_2 \delta(\mathbf{r}'' - \mathbf{r}_2)] \delta(\mathbf{r}'' - \mathbf{r}') \phi(\mathbf{r}'') \\ = \nu_1 K_{\mathbf{u}_z}(\mathbf{r}, \mathbf{r}_1) \phi(\mathbf{r}_1) + \nu_2 K_{\mathbf{u}_z}(\mathbf{r}, \mathbf{r}_2) \phi(\mathbf{r}_2) = \lambda \phi(\mathbf{r}). \quad (18.83)$$

It follows that $\phi(\mathbf{r})$ must have the form $\alpha K_{\mathbf{u}_z}(\mathbf{r}, \mathbf{r}_1) + \beta K_{\mathbf{u}_z}(\mathbf{r}, \mathbf{r}_2)$; there are only two linearly independent eigenfunctions and hence the rank of $\mathcal{K}_{\mathbf{u}_z} \mathcal{Z}$ is two in this case.

Since (18.83) must hold for all \mathbf{r} , including \mathbf{r}_1 and \mathbf{r}_2 , we get two equations that can be written in matrix form as

$$\begin{bmatrix} \nu_1 K_{11} - \lambda & \nu_2 K_{12} \\ \nu_1 K_{21} & \nu_2 K_{22} - \lambda \end{bmatrix} \begin{bmatrix} \phi(\mathbf{r}_1) \\ \phi(\mathbf{r}_2) \end{bmatrix} = 0, \quad (18.84)$$

where $K_{jk} \equiv K_{\mathbf{u}_z}(\mathbf{r}_j, \mathbf{r}_k)$. The two possible values for λ in this equation (call them λ_1 and λ_2) are found by setting the determinant of the 2×2 matrix to zero. Though the notation does not show it, these eigenvalues depend on ν_1 and ν_2 .

We can use the eigenvalues of $\mathcal{K}_{\mathbf{u}_z} \mathcal{Z}$ to construct the eigenvalues of the operator in which we are really interested, $\mathcal{I} + 2\pi i \mathcal{K}_{\mathbf{u}_z} \mathcal{Z}$. Two of the eigenvalues of that operator are $1 + 2\pi i \lambda_1$ and $1 + 2\pi i \lambda_2$; there is also an infinite set of eigenvalues equal to unity, but they contribute nothing to the determinant in (18.73). After a bit of algebra we find

$$\psi_{I_z(\mathbf{r}_1), I_z(\mathbf{r}_2)}(\nu_1, \nu_2) = \frac{1}{(1 + 2\pi i \lambda_1)(1 + 2\pi i \lambda_2)} \\ = \frac{1}{[1 + 2\pi i \nu_1 K_{\mathbf{u}_z}(\mathbf{r}_1, \mathbf{r}_1)][1 + 2\pi i \nu_2 K_{\mathbf{u}_z}(\mathbf{r}_2, \mathbf{r}_2)] + 4\pi^2 \nu_1 \nu_2 |K_{\mathbf{u}_z}(\mathbf{r}_1, \mathbf{r}_2)|^2}. \quad (18.85)$$

The corresponding bivariate PDF can be obtained by performing a 2D inverse Fourier transform; the result is given by Goodman (1975) in terms of I_0 Bessel functions. If $K_{\mathbf{u}_z}(\mathbf{r}_1, \mathbf{r}_2) = 0$, (18.85) reduces to the product of two chi-squared characteristic functions, each with two degrees of freedom, so the PDF reduces to the product of two exponentials.

18.3 SPECKLE IN AN IMAGING SYSTEM

Next we turn to speckle in optical imaging, adapting the analysis of Sec. 18.2 by adding a photographic transparency to serve as the object, a lens system to form the image, and a discrete detector array. The objective of the analysis is a statistical description, in the form of a characteristic function, for the detector output. In this section the only random effect we consider is speckle, but in Sec. 18.4 we shall extend the analysis further by bringing in measurement noise and object variation.

The system under consideration is described and analyzed deterministically in Sec. 18.3.1. The statistics are treated with the help of characteristic functionals in Sec. 18.3.2, and the effect of the image detector is discussed in Sec. 18.3.3.

18.3.1 The imaging system

The imaging system considered in this section is shown in Fig. 18.3. The object, consisting of a photographic transparency with amplitude transmittance t_{obj} , is placed directly over a ground glass, which is then illuminated with a normally incident plane wave as in Sec. 18.2. A thin lens is placed a distance $2f$ from the object, and a discrete detector array is placed in the focal plane, a distance $2f$. This system has a magnification of -1 , but we shall avoid annoying minus signs by defining the axes in the image plane oppositely to those in the object plane; thus the x_0 direction in the object plane is pointing upward in Fig. 18.3, but the x direction in the image plane is pointing downward.

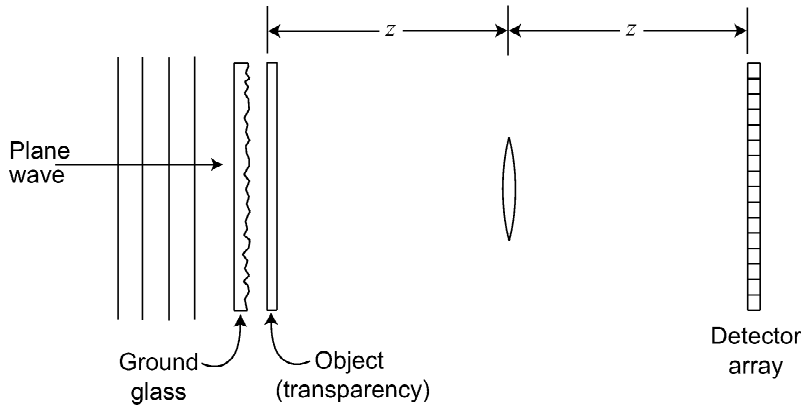

Fig. 18.3 Simple optical system with magnification of -1 .

We can analyze this system in three stages. The first stage is the linear CC mapping from object field to image field, the second is a nonlinear point transformation from image-plane field to image-plane irradiance, and the third is a linear CD mapping from irradiance to the discrete detector outputs.

Coherent CC mapping The first stage is described by the integral transform

$$u_{im}(\mathbf{r}) = \int_{\infty} d^2r_0 p_{coh}(\mathbf{r} - \mathbf{r}_0; \mathbf{r}_0) u_0(\mathbf{r}_0), \quad (18.86)$$

where $u_{im}(\mathbf{r})$ is the field in the image plane, $u_0(\mathbf{r}_0)$ is the field emerging from the object transparency in the plane $z = 0$, and $p_{coh}(\mathbf{r} - \mathbf{r}_0; \mathbf{r}_0)$ is the coherent point spread function (PSF). For the present problem, this PSF is given by (9.227); modified for our inverted coordinate system and $p = q = 2f$, that equation becomes

$$p_{coh}(\mathbf{r}; \mathbf{r}_0) = \frac{1}{(2\lambda f)^2} T_{pupil} \left(\frac{\mathbf{r}}{2\lambda f}; \mathbf{r}_0 \right), \quad (18.87)$$

where $T_{pupil}(\boldsymbol{\rho}; \mathbf{r}_0)$ is the Fourier transform with respect to the first variable of the 2D Fourier transform of the pupil function, $t_{pupil}(\mathbf{r}; \mathbf{r}_0)$. The second variable is needed here if we wish to include the effects of field-dependent aberrations; for more discussion of this point, see Secs. 9.6.3 and 9.7.1. If there are no field-dependent

aberrations, both $T_{pupil}(\boldsymbol{\rho}; \mathbf{r}_0)$ and $p_{coh}(\mathbf{r}; \mathbf{r}_0)$ are independent of the second variable and (18.86) is a convolution.

We can write the mapping of (18.86) in abstract form by defining a coherent imaging operator \mathcal{P}_{coh} , so that

$$\mathbf{u}_{im} = \mathcal{P}_{coh} \mathbf{u}_0. \quad (18.88)$$

Irradiance and CD mapping by the detector The second stage in the analysis is conversion of image-plane field to irradiance, stated simply as

$$I_{im}(\mathbf{r}) = |u_{im}(\mathbf{r})|^2. \quad (18.89)$$

The third stage is the CD mapping by the detector array. For simplicity, we assume that the mean output of each detector element is proportional to the integral of the irradiance over its face, so

$$\bar{g}_m = \int_{\infty} d^2r w_m(\mathbf{r}) I_{im}(\mathbf{r}), \quad (18.90)$$

where $w_m(\mathbf{r})$ is a constant responsivity factor times a rect function describing the spatial extent of the m^{th} detector.

Object transparency The equations above relate the detector output to the field in the plane $z = 0$. To bring in the object transparency explicitly, we write

$$u_0(\mathbf{r}) = u_{GG}(\mathbf{r}) t_{obj}(\mathbf{r}), \quad (18.91)$$

where $t_{obj}(\mathbf{r})$ is the complex amplitude transmission of the object, and $u_{GG}(\mathbf{r})$ is the field emerging from the ground glass and incident on the object; $u_{GG}(\mathbf{r})$ is identical to the amplitude transmission of the ground glass if the initial illumination is a unit-amplitude, normally incident plane wave.

We can put (18.91) into vector form by using the Hadamard notation introduced in Sec. A.2.8, with the convention that an element-by-element product of two vectors is denoted by simple juxtaposition. When the vectors in question are in an \mathbb{L}_2 Hilbert space, the juxtaposition of two vectors connotes the product of the corresponding functions, so (18.91) can be written as

$$\mathbf{u}_0 = \mathbf{u}_{GG} \mathbf{t}_{obj}. \quad (18.92)$$

The CC propagation rule, (18.88), now becomes

$$\mathbf{u}_{im} = \mathcal{P}_{coh} \{ \mathbf{u}_{GG} \mathbf{t}_{obj} \}. \quad (18.93)$$

Where no confusion is likely to result, we may delete the braces and write $\mathbf{u}_{im} = \mathcal{P}_{coh} \mathbf{u}_{GG} \mathbf{t}_{obj}$.

18.3.2 Propagation of characteristic functionals

The formulas in Sec. 18.3.1 describe the deterministic properties of the imaging system. To describe the statistical properties, we use characteristic functionals and basically retrace the steps of Sec. 18.3.1 with appropriate modifications.

Characteristic functional for the input field The characteristic functional for \mathbf{u}_0 can be written as

$$\begin{aligned}\Psi_{\mathbf{u}_0}(\boldsymbol{\xi}) &= \left\langle \exp \left[-2\pi i \int_{\infty} d^2r \xi^*(\mathbf{r}) u_{GG}(\mathbf{r}) t_{obj}(\mathbf{r}) \right] \right\rangle \\ &= \left\langle \exp \left[-2\pi i \int_{\infty} d^2r [\xi(\mathbf{r}) t_{obj}^*(\mathbf{r})]^* u_{GG}(\mathbf{r}) \right] \right\rangle.\end{aligned}\quad (18.94)$$

Thus

$$\Psi_{\mathbf{u}_0}(\boldsymbol{\xi}) = \Psi_{\mathbf{u}_{GG}}(\mathbf{t}_{obj}^* \boldsymbol{\xi}). \quad (18.95)$$

When \mathbf{t}_{obj} is moved to the other side of the scalar product in Hadamard notation, it acquires an asterisk rather than a dagger; regarded as an operator, the Hadamard product functions as scalar multiplication, and the adjoint of scalar multiplication by something is scalar multiplication by its complex conjugate.

Characteristic functional for the image field With (18.20) and (18.95), the characteristic functional for the field in the image plane becomes

$$\Psi_{\mathbf{u}_{im}}(\boldsymbol{\xi}) = \Psi_{\mathbf{u}_0}(\mathcal{P}_{coh}^\dagger \boldsymbol{\xi}) = \Psi_{\mathbf{u}_{GG}}(\mathbf{t}_{obj}^* \mathcal{P}_{coh}^\dagger \boldsymbol{\xi}). \quad (18.96)$$

Thus if we know the characteristic functional for the ground glass (the only random element being considered here), we can transform it to the characteristic functional for the image field.

CLT revisited At this point in the derivation presented in Sec. 18.2, we invoked the central-limit theorem to argue that the field in the observation plane was circular Gaussian provided the ground glass fully randomized the input field. Key to the argument was the assumption that many independent regions on the ground glass contributed the field at any point in the observation plane.

That argument is less persuasive in an imaging context since the width of the coherent PSF defines the contributing region on the ground glass. For well corrected lenses of high numerical aperture, that width is of the order of a wavelength or two, and the correlation length is of order half a wavelength, so it is problematical to assume that the region defined by the PSF encompasses many independent regions. Moreover, even if the width of the PSF were large enough, we would still have to consider the effect of the object transparency. We cannot, for example, consider the object to be a small pinhole with width comparable to a wavelength.

In spite of these caveats, we shall assume here that the image-plane field is circular Gaussian, returning to the subject in Sec. 18.5 where we discuss object models that lead to non-Gaussian fields.

Field in the image plane With the assumption of a circular Gaussian form, the characteristic functional for the field in the image plane becomes

$$\Psi_{\mathbf{u}_{im}}(\boldsymbol{\xi}) = \exp(-\pi^2 \boldsymbol{\xi}^\dagger \mathcal{K}_{\mathbf{u}_{im}} \boldsymbol{\xi}), \quad (18.97)$$

where

$$\mathcal{K}_{\mathbf{u}_{im}} = \mathcal{P}_{coh} \mathbf{t}_{obj} \langle \mathbf{u}_0 \mathbf{u}_0^\dagger \rangle \mathbf{t}_{obj}^* \mathcal{P}_{coh}^\dagger. \quad (18.98)$$

Thus, as with any circular Gaussian, all statistical properties of the image-plane field are determined solely by the autocorrelation function, which is also the autocovariance since the mean is zero.

If we assume that the correlation length of the field emerging from the ground glass is small compared to the width of the coherent PSF and that the object transparency is slowly varying, then we can represent the autocorrelation function of $u_0(\mathbf{r})$ by a delta function as in (18.13). In vector form, that means that $\langle \mathbf{u}_0 \mathbf{u}_0^\dagger \rangle = \ell_c^2 \mathbf{I}$, and we have

$$\mathcal{K}_{\mathbf{u}_{im}} = \ell_c^2 \mathcal{P}_{coh} \mathbf{t}_{obj} \mathbf{t}_{obj}^* \mathcal{P}_{coh}^\dagger = \ell_c^2 \mathcal{P}_{coh} |\mathbf{t}_{obj}|^2 \mathcal{P}_{coh}^\dagger, \quad (18.99)$$

where the last form uses a further embellishment on the Hadamard notation: $|\mathbf{t}_{obj}|^2$ is the \mathbb{L}_2 vector corresponding to the function $|t_{obj}(\mathbf{r})|^2$.

The autocorrelation function of the image-plane field is the kernel of the integral operator (18.99). Using (18.86), we see that

$$K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}') = \ell_c^2 \int d^2 r_0 p_{coh}(\mathbf{r} - \mathbf{r}_0; \mathbf{r}_0) p_{coh}^*(\mathbf{r}' - \mathbf{r}_0; \mathbf{r}_0) |t_{obj}(\mathbf{r}_0)|^2. \quad (18.100)$$

Irradiance in the image plane Though the mean field in the image plane is zero, the mean irradiance is not. In fact, the mean irradiance is obtained at once from (18.100) since

$$\langle I_{im}(\mathbf{r}) \rangle = \langle |u_{im}(\mathbf{r})|^2 \rangle = K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}) = \ell_c^2 \int d^2 r_0 |p_{coh}(\mathbf{r} - \mathbf{r}_0; \mathbf{r}_0)|^2 |t_{obj}(\mathbf{r}_0)|^2. \quad (18.101)$$

This expression agrees with (9.284), which gives the mean irradiance in an incoherent, quasimonochromatic imaging system. On average, a spatially incoherent source and a coherent source modulated with a fine ground glass give the same irradiance, though the meaning of mean is different. In incoherent imaging, the average is over an ensemble of source realizations, and in speckle problems it is over an ensemble of ground glasses. In the incoherent case, however, we can invoke ergodicity and replace the ensemble average with a time average, and the time average is what we observe with a temporally integrating detector (see Sec. 10.1.5). In the speckle problem, on the other hand, the irradiance is a time-independent speckle pattern and time averaging has no effect.

To study the statistics of the image-plane irradiance, we need its characteristic functional. Since we are assuming that the field is circular Gaussian, just as we did in Sec. 18.2.5, we can simply refer back to (18.73) and write

$$\Psi_{I_{im}}(\zeta) = \frac{1}{\det(\mathcal{I} + 2\pi i \mathcal{K}_{\mathbf{u}_{im}} \mathcal{Z})}, \quad (18.102)$$

where \mathcal{Z} is the integral operator with kernel $\zeta(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}')$, and the determinant of an integral operator is interpreted as the product of its eigenvalues.

From this characteristic functional we can derive the univariate or single-point characteristic function and the corresponding univariate PDF just as we did in Sec. 18.2.5. From (18.79) we see that

$$\psi_{I_{im}(\mathbf{r})}(\nu) = \frac{1}{1 + 2\pi i \nu K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r})}, \quad (18.103)$$

from which it follows that $I_{im}(\mathbf{r})$ is a chi-squared random variable with two degrees of freedom, or equivalently an exponentially-distributed random variable (see

Secs. C.5.3 and C.5.5). The mean irradiance at point \mathbf{r} is $K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r})$, or simply $\langle |u_{im}(\mathbf{r})|^2 \rangle$.

The bivariate characteristic function for the image-plane irradiance is given by an expression analogous to (18.85), with the substitution of (18.100) for the autocorrelation function.

The autocorrelation and autocovariance functions for the irradiance can be obtained several different ways. They can be computed from either the bivariate characteristic function (18.85) or the infinite-dimensional characteristic functional (18.102) by suitable differentiation. (In the latter case Fréchet derivatives, defined in Sec. 15.3.5, must be used, but they behave very much like ordinary derivatives.) A simpler route, however, is just to invoke the complex Gaussian moment theorem discussed in Sec. 8.3.6. By (8.250) we find

$$\begin{aligned} \langle I_{im}(\mathbf{r}) I_{im}(\mathbf{r}') \rangle &= \\ \langle |u_{im}(\mathbf{r})|^2 |u_{im}(\mathbf{r}')|^2 \rangle &= K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}) K_{\mathbf{u}_{im}}(\mathbf{r}', \mathbf{r}') + K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}') K_{\mathbf{u}_{im}}(\mathbf{r}', \mathbf{r}) \\ &= \langle I_{im}(\mathbf{r}) \rangle \langle I_{im}(\mathbf{r}') \rangle + |K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}')|^2. \end{aligned} \quad (18.104)$$

Thus the autocovariance of the irradiance is just the squared modulus of the autocovariance of the field:

$$K_{I_{im}}(\mathbf{r}, \mathbf{r}') = \langle I_{im}(\mathbf{r}) I_{im}(\mathbf{r}') \rangle - \langle I_{im}(\mathbf{r}) \rangle \langle I_{im}(\mathbf{r}') \rangle = |K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}')|^2. \quad (18.105)$$

Stationarity, real and quasi To better understand the nature of the field covariance $K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}')$, we can write it out explicitly in terms of the pupil function of the system. As in Sec. 9.6.3, we write the pupil function as [cf. (9.181)]

$$t_{pupil}(\mathbf{r}; \mathbf{r}_0) = \exp[ikW(\mathbf{r}; \mathbf{r}_0)] t_{ap}(\mathbf{r}), \quad (18.106)$$

where $t_{ap}(\mathbf{r})$ is unity inside the clear aperture of the lens and zero outside, and the exponential factor accounts for the aberrations. With (18.87) and (18.100), we now have

$$\begin{aligned} K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}') &= \frac{\ell_c^2}{(2\lambda f)^4} \int_{\infty} d^2 r_0 |t_{obj}(\mathbf{r}_0)|^2 \int_{\infty} d^2 \tilde{\mathbf{r}} \int_{\infty} d^2 \tilde{\mathbf{r}}' t_{ap}(\tilde{\mathbf{r}}) t_{ap}(\tilde{\mathbf{r}}') \\ &\times \exp[ikW(\tilde{\mathbf{r}}; \mathbf{r}_0)] \exp[-ikW(\tilde{\mathbf{r}}'; \mathbf{r}_0)] \exp\left[-i\frac{2\pi}{2\lambda f} \tilde{\mathbf{r}} \cdot (\mathbf{r} - \mathbf{r}_0)\right] \exp\left[i\frac{2\pi}{2\lambda f} \tilde{\mathbf{r}}' \cdot (\mathbf{r}' - \mathbf{r}_0)\right], \end{aligned} \quad (18.107)$$

where all three integrals are formally over the 2D plane, but the integral over \mathbf{r}_0 is constrained to the object support by the factor $|t_{obj}(\mathbf{r}_0)|^2$ and the other two integrals are constrained to the clear aperture by the aperture transmittance factors. This is as far as we can go without further assumptions or approximations (we have already made the Fresnel approximation), but we shall consider several special cases.

First assume that the object transmittance $|t_{obj}(\mathbf{r}_0)|^2$ is a constant, which we set to unity for convenience, and assume further that the system, though aberrated, is shift invariant. This means that there can be field-independent aberrations such as spherical aberration and defocus but not field-dependent ones such as coma and astigmatism (see Sec. 9.6.4). Then $W(\tilde{\mathbf{r}}; \mathbf{r}_0)$ is independent of \mathbf{r}_0 , so we can write it as $W(\tilde{\mathbf{r}})$, and the \mathbf{r}_0 integral becomes

$$\int_{\infty} d^2 r_0 \exp\left[i\frac{2\pi}{2\lambda f} (\tilde{\mathbf{r}} - \tilde{\mathbf{r}}') \cdot \mathbf{r}_0\right] = (2\lambda f)^2 \delta(\tilde{\mathbf{r}} - \tilde{\mathbf{r}}'). \quad (18.108)$$

Now we can use this delta function to perform the integral over $\tilde{\mathbf{r}}'$ in (18.107), and we obtain

$$K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}') = \frac{\ell_c^2}{(2\lambda f)^2} \int_{\infty} d^2\tilde{\mathbf{r}} t_{ap}(\tilde{\mathbf{r}}) \exp\left[-i\frac{2\pi}{2\lambda f}\tilde{\mathbf{r}} \cdot (\mathbf{r} - \mathbf{r}')\right]. \quad (18.109)$$

Two key points are to be noted from this expression. First, the image-plane field is a stationary random process since its autocovariance function depends only on the difference $\mathbf{r} - \mathbf{r}'$. Second, the aberration factors have cancelled. Thus, by comparing (18.109) with (18.87), we see that the autocovariance function of the field in this case is the shift-invariant coherent PSF associated with an unaberrated lens of the same aperture as the actual aberrated one. To get these results, however, we had to assume that the object was a constant over an infinite field and that the optical system was shift-invariant over this field; neither of these assumptions is tenable.

To get a more realistic model, let us assume that the object is not constant but slowly varying, and that the aberrations are field dependent and also slowly varying. It is convenient to transform to sum and difference coordinates as in Sec. 8.2.4 or 13.2.13:

$$\bar{\mathbf{r}} = \frac{1}{2}(\mathbf{r} + \mathbf{r}'), \quad \Delta\mathbf{r} = \mathbf{r} - \mathbf{r}', \quad (18.110)$$

so that

$$\mathbf{r} = \bar{\mathbf{r}} + \frac{1}{2}\Delta\mathbf{r}, \quad \mathbf{r}' = \bar{\mathbf{r}} - \frac{1}{2}\Delta\mathbf{r}. \quad (18.111)$$

Note that the Jacobian of this transformation is unity. A similar transformation is used for $\tilde{\mathbf{r}}$ and $\tilde{\mathbf{r}}'$, and the autocovariance function of the field becomes

$$K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}') = K_{\mathbf{u}_{im}}(\bar{\mathbf{r}} + \frac{1}{2}\Delta\mathbf{r}, \bar{\mathbf{r}} - \frac{1}{2}\Delta\mathbf{r}) \equiv \tilde{K}_{\mathbf{u}_{im}}(\bar{\mathbf{r}}, \Delta\mathbf{r}). \quad (18.112)$$

With these definitions, (18.107) takes the ungainly form,

$$\begin{aligned} \tilde{K}_{\mathbf{u}_{im}}(\bar{\mathbf{r}}, \Delta\mathbf{r}) &= \frac{\ell_c^2}{(2\lambda f)^4} \int_{\infty} d^2r_0 |t_{obj}(\mathbf{r}_0)|^2 \int_{\infty} d^2\tilde{\mathbf{r}} \int_{\infty} d^2\Delta\tilde{\mathbf{r}} \\ &\times t_{ap}(\bar{\mathbf{r}} + \frac{1}{2}\Delta\tilde{\mathbf{r}}) t_{ap}(\bar{\mathbf{r}} + \frac{1}{2}\Delta\tilde{\mathbf{r}}) \exp[ikW(\bar{\mathbf{r}} + \frac{1}{2}\Delta\tilde{\mathbf{r}}; \mathbf{r}_0)] \exp[-ikW(\bar{\mathbf{r}} - \frac{1}{2}\Delta\tilde{\mathbf{r}}; \mathbf{r}_0)] \\ &\times \exp\left[-i\frac{2\pi}{2\lambda f}(\bar{\mathbf{r}} + \frac{1}{2}\Delta\tilde{\mathbf{r}}) \cdot (\mathbf{r} - \mathbf{r}_0)\right] \cdot \exp\left[i\frac{2\pi}{2\lambda f}(\bar{\mathbf{r}} - \frac{1}{2}\Delta\tilde{\mathbf{r}}) \cdot (\mathbf{r}' - \mathbf{r}_0)\right]. \quad (18.113) \end{aligned}$$

As in Sec. 9.6.4 (and, indeed, in most of the optics literature), we neglect all aberrations beyond second order. That means that we can expand $W(\bar{\mathbf{r}} \pm \frac{1}{2}\Delta\tilde{\mathbf{r}}; \mathbf{r}_0)$ in a Taylor series (with respect to its first argument) and truncate the series after the quadratic term. The terms constant and quadratic in $\Delta\tilde{\mathbf{r}}$ neatly cancel in (18.113), and the integral over that variable becomes

$$\begin{aligned} &\int_{\infty} d^2\Delta\tilde{\mathbf{r}} t_{ap}(\bar{\mathbf{r}} + \frac{1}{2}\Delta\tilde{\mathbf{r}}) t_{ap}(\bar{\mathbf{r}} - \frac{1}{2}\Delta\tilde{\mathbf{r}}) \exp[ik\Delta\tilde{\mathbf{r}} \cdot \nabla W(\bar{\mathbf{r}}; \mathbf{r}_0)] \exp\left[-i\frac{2\pi}{2\lambda f}\Delta\tilde{\mathbf{r}} \cdot (\bar{\mathbf{r}} - \mathbf{r}_0)\right] \\ &\approx t_{ap}(\bar{\mathbf{r}}) \int_{\infty} d^2\Delta\tilde{\mathbf{r}} \exp[ik\Delta\tilde{\mathbf{r}} \cdot \nabla W(\bar{\mathbf{r}}; \mathbf{r}_0)] \exp\left[-i\frac{2\pi}{2\lambda f}\Delta\tilde{\mathbf{r}} \cdot (\bar{\mathbf{r}} - \mathbf{r}_0)\right] \\ &= (2\lambda f)^2 t_{ap}(\bar{\mathbf{r}}) \delta[\mathbf{r}_0 - \bar{\mathbf{r}} + 2f\nabla W(\bar{\mathbf{r}}; \mathbf{r}_0)], \quad (18.114) \end{aligned}$$

where the approximation on the second line assumes that the aperture function has a large support and takes on only the values 0 and 1, while the last step involves

some properties of delta functions. Recall from Sec. 9.6.6 that $2f \nabla W(\bar{\mathbf{r}}; \mathbf{r}_0)$ is the aberration-induced displacement of a ray originating from object point \mathbf{r}_0 and passing through point $\bar{\mathbf{r}}$ in the pupil [*cf.* (9.210) and note that q in that equation is $2f$ in the present problem].

We can now use the delta function to perform the integral over \mathbf{r}_0 . This delta function is not immediately in the form where we can invoke the sifting property of delta functions since its argument is a nonlinear function of \mathbf{r}_0 through the term $2f \nabla W(\bar{\mathbf{r}}; \mathbf{r}_0)$, but it is a reasonable approximation to replace $2f \nabla W(\bar{\mathbf{r}}; \mathbf{r}_0)$ with $2f \nabla W(\bar{\mathbf{r}}; \bar{\mathbf{r}})$ if the aberrations are slowly varying. (See Sec. 7.2.7 where we made a similar approximation in discussing shift-variant magnifiers.) If the object is also slowly varying over the scale of the aberration-induced displacement, we get, finally,

$$\begin{aligned} \tilde{K}_{u_{im}}(\bar{\mathbf{r}}, \Delta \mathbf{r}) &\approx \frac{\ell_c^2}{(2\lambda f)^2} |t_{obj}(\bar{\mathbf{r}})|^2 \int_{\infty} d^2 \bar{\mathbf{r}} t_{ap}(\bar{\mathbf{r}}) \exp \left[-i \frac{2\pi}{2\lambda f} (\bar{\mathbf{r}} \cdot \Delta \mathbf{r}) \right] \\ &= \frac{\ell_c^2}{(2\lambda f)^2} |t_{obj}(\bar{\mathbf{r}})|^2 T_{ap} \left(\frac{\Delta \mathbf{r}}{2\lambda f} \right). \end{aligned} \quad (18.115)$$

Again the aberrations play no role; the correlation length under the present approximations is determined solely by the clear aperture of the lens.

In (18.115) we have cast the autocovariance function of the field into the quasistationary form originally encountered in Sec. 8.2.4 [*cf.* (8.119)]. In that section, however, we discussed only the second-order statistics of the random process. Here we can make a much stronger statement. Since all statistical properties of both the field and the irradiance are fully determined by the field autocovariance under the circular Gaussian assumption, (18.115) gives us an approximation through which we can compute the characteristic functionals of the field and irradiance and hence any desired higher-order moments of either.⁹

18.3.3 Effect of the detector

So far we have discussed the image-plane field and irradiance as continuous random processes. In practice the irradiance will be detected with one or more detectors of finite area. In this section we shall learn how to incorporate the detectors into our statistical descriptions of speckle under the assumption that the detection process itself is noise-free. In Sec. 18.4 we shall integrate the results of this section with what we know about measurement noise from previous chapters and get the complete statistics of the output of real, noisy, discrete detector arrays.

Single-element detectors We shall model a detector here as a device that integrates the irradiance over a finite area (see Sec. 10.1.5); real-world effects such as nonuniform response over this area and angular dependences are ignored. For now we consider a single detector element, but the analysis will be extended to arrays below.

⁹One might be tempted to take the approximation a step further and replace $T_{ap}(\Delta \mathbf{r}/2\lambda f)$ by a delta function, but this step is not warranted since (18.115) will be used in integrals where other factors might also be delta functions, as in (18.75). Moreover, we need the fact that the covariance operator is compact and hence has a denumerable set of eigenfunctions. We know from Chap. 1 that an integral operator is compact if its kernel satisfies the Hilbert-Schmidt condition, which $T_{ap}(\Delta \mathbf{r}/2\lambda f)$ does (over a finite support) but $\delta(\Delta \mathbf{r})$ does not.

As discussed qualitatively in Sec. 18.1.2, a key question is whether the detector area is smaller or larger than the speckle blob. If the detector is much smaller than the blob, integration over the detector area is basically point sampling, so the univariate PDF on the detector output (in the absence of measurement noise) will be essentially the single-point PDF of the irradiance field, which is an exponential under our circular-Gaussian assumptions. If the detector is much larger than the blob, on the other hand, we expect the PDF on the detector output to be Gaussian by dint of the central-limit theorem. We shall now learn how to make these qualitative observations quantitative.

Let g_{out} denote the output voltage from a single-element detector of area A_d . This voltage is related to the irradiance by

$$g_{out} = C \int_{A_d} d^2r I_{im}(\mathbf{r}), \quad (18.116)$$

where C is the responsivity of the detector. It will prove useful to rewrite this equation as

$$g_{out} = \int_{\infty} d^2r w(\mathbf{r}) I_{im}(\mathbf{r}) = \mathbf{w}^\dagger \mathbf{I}_{im}, \quad (18.117)$$

where $w(\mathbf{r})$ takes on the value C within the area of the detector and zero otherwise, and \mathbf{w} is the corresponding vector in Hilbert space.

The mapping in (18.117) is linear, and we know from Sec. 8.2.3 how to transform characteristic functionals through linear mappings. Specifically, from (8.95) and (18.117), we can write the characteristic *function* for g_{out} in terms of the characteristic *functional* for \mathbf{I}_{im} as

$$\psi_{g_{out}}(\nu) = \langle \exp(-2\pi i \mathbf{w}^\dagger \mathbf{I}_{im} \nu) \rangle = \Psi_{\mathbf{I}_{im}}(\nu \mathbf{w}). \quad (18.118)$$

To be explicit, we can use (18.102) to write

$$\psi_{g_{out}}(\nu) = \frac{1}{\det(\mathcal{I} + 2\pi i \nu \mathcal{K}_{\mathbf{u}_{im}} \mathcal{W})}, \quad (18.119)$$

where \mathcal{W} is the integral operator with kernel $w(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}')$. Alternatively, we can expand the determinant in traces as in (18.72) and write

$$\psi_{g_{out}}(\nu) = \exp[-2\pi i \nu \text{tr}(\mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}) - 2\pi^2 \nu^2 \text{tr}(\mathcal{K}_{\mathbf{u}_{im}} \mathcal{W} \mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}) + \dots]. \quad (18.120)$$

This series will converge if ν is sufficiently small since the eigenvalues of $2\pi i \nu \mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}$ are all proportional to ν .

Two limits To better understand these characteristic functions, we shall consider the limits of large and small detectors.

If the detector is very small compared to the correlation length of the speckle, we can approximate $w(\mathbf{r})$ by

$$w(\mathbf{r}) \approx C A_d \delta(\mathbf{r} - \mathbf{r}_d), \quad (18.121)$$

where \mathbf{r}_d is the detector location. Thus the kernel of \mathcal{W} is $C A_d \delta(\mathbf{r} - \mathbf{r}_d) \delta(\mathbf{r} - \mathbf{r}')$, which can also be written as $C A_d \delta(\mathbf{r} - \mathbf{r}_d) \delta(\mathbf{r}' - \mathbf{r}_d)$. Since the kernel factors into a function of \mathbf{r} times a function of \mathbf{r}' , it follows that the operator has rank one (see

Sec. 1.5.1), and since the constants are real, \mathbf{W} is Hermitian. Moreover, a product of a rank-one operator with any other operator also has rank one, and rank is the number of nonzero eigenvalues for a Hermitian operator. Thus $\mathcal{K}_{\mathbf{u}_{im}}\mathbf{W}$ has only a single-nonzero eigenvalue. The reader can verify that this eigenvalue is $CA_d\bar{I}_{im}(\mathbf{r}_d)$ and that the corresponding eigenfunction is $\phi(\mathbf{r}) \propto K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}_d)$.

With this information, we can evaluate the determinant in (18.119). Recall that the determinant of an integral operator is defined as the product of its eigenvalues; the operator $\mathcal{I} + 2\pi i\nu\mathcal{K}_{\mathbf{u}_{im}}\mathbf{W}$ has one eigenvalue equal to $1 + 2\pi i CA_d\nu\bar{I}_{im}(\mathbf{r}_d)$ and an infinite set of unity eigenvalues, so

$$\psi_{g_{out}}(\nu) = \frac{1}{1 + 2\pi i CA_d\nu\bar{I}_{im}(\mathbf{r}_d)}. \tag{18.122}$$

This is the characteristic function for an exponentially distributed scalar random variable of mean $CA_d\bar{I}_{im}(\mathbf{r}_d)$. It is no surprise that g_{out} is exponential since, with point sampling and no measurement noise, it merely reflects the single-point statistics of the irradiance.

Now consider the opposite limit of a large detector. This time the expansion in traces, (18.120), is more useful than the determinantal form. For simplicity we assume that the *mean* irradiance is approximately constant over the detector area (even though the detector may cover many speckle blobs). Then, with the help of (18.71) and (18.105),

$$\text{tr}(\mathcal{K}_{\mathbf{u}_{im}}\mathbf{W}) = \int_{\infty} d^2r w(\mathbf{r}) K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}) = CA_d K_{\mathbf{u}_{im}}(\mathbf{r}_d, \mathbf{r}_d) = CA_d\bar{I}_{im}(\mathbf{r}_d) = \bar{g}_{out}; \tag{18.122}$$

$$\begin{aligned} \text{tr}(\mathcal{K}_{\mathbf{u}_{im}}\mathbf{W}\mathcal{K}_{\mathbf{u}_{im}}\mathbf{W}) &= \int_{\infty} d^2r \int_{\infty} d^2r' w(\mathbf{r}) |K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}')|^2 w(\mathbf{r}') \\ &= \int_{\infty} d^2r \int_{\infty} d^2r' w(\mathbf{r}) K_{\mathbf{I}_{im}}(\mathbf{r}, \mathbf{r}') w(\mathbf{r}'). \end{aligned} \tag{18.123}$$

To simplify this last form, let us assume that the irradiance is quasistationary over the detector area so that its autocovariance function can be factored as [*cf.* (18.112) and (18.115)]¹⁰

$$K_{\mathbf{I}_{im}}(\mathbf{r}, \mathbf{r}') = \tilde{K}_{\mathbf{I}_{im}}(\bar{\mathbf{r}}, \Delta\mathbf{r}) = [\bar{I}_{im}(\bar{\mathbf{r}})]^2 a(\Delta\mathbf{r}), \tag{18.124}$$

where $\bar{\mathbf{r}}$ and $\Delta\mathbf{r}$ are defined in (18.110), and the short-range factor is normalized so that $a(0) = 1$; we have also used the fact that the variance of the irradiance is the square of its mean for an exponential law. With this factorization, (18.123) becomes

$$\text{tr}(\mathcal{K}_{\mathbf{u}_{im}}\mathbf{W}\mathcal{K}_{\mathbf{u}_{im}}\mathbf{W}) = \int_{\infty} d^2\bar{r} \int_{\infty} d^2\Delta r w(\bar{\mathbf{r}} + \frac{1}{2}\Delta\mathbf{r}) [\bar{I}_{im}(\bar{\mathbf{r}})]^2 a(\Delta\mathbf{r}) w(\bar{\mathbf{r}} - \frac{1}{2}\Delta\mathbf{r}). \tag{18.125}$$

¹⁰The reader should not confuse the two meanings of the overbar in this equation. When placed over a random variable as in \bar{I}_{im} , the overbar implies an ensemble average, but over a spatial variable as in $\bar{\mathbf{r}}$ it implies a spatial average position as in (18.110).

If the detector is large compared to the range of $a(\Delta\mathbf{r})$ (which is also the blob size), yet $\bar{I}_{im}(\bar{\mathbf{r}})$ is still approximately constant over the detector, we can write

$$\text{tr}(\mathcal{K}_{\mathbf{u}_{im}} \mathcal{W} \mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}) \approx C^2 A_d [\bar{I}_{im}(\mathbf{r}_d)]^2 \int_{\infty} d^2 \Delta r a(\Delta\mathbf{r}). \quad (18.126)$$

The remaining integral defines the blob area A_b , and we can multiply and divide by the detector area to get

$$\text{tr}(\mathcal{K}_{\mathbf{u}_{im}} \mathcal{W} \mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}) \approx \frac{(CA_d)^2}{N_b} [\bar{I}_{im}(\mathbf{r}_d)]^2 = \frac{1}{N_b} (\bar{g}_{out})^2, \quad (18.127)$$

where N_b is the mean number of blobs in the detector area:

$$N_b \equiv \frac{A_d}{\int_{\infty} d^2 \Delta r a(\Delta\mathbf{r})} = \frac{A_d}{A_b}. \quad (18.128)$$

Now we can insert (18.122) and (18.127) into (18.120) to obtain

$$\psi_{g_{out}}(\nu) \approx \exp \left[-2\pi i \bar{g}_{out} \nu - 2\pi^2 \frac{(\bar{g}_{out})^2}{N_b} \nu^2 + \dots \right]. \quad (18.129)$$

If the higher-order terms can be ignored, (18.129) becomes the characteristic function for a univariate normal random variable [*cf.* (C.116)]. This is the expected result since, roughly speaking, each blob represents a patch of the detector with irradiance independent of the irradiance in other patches. The detector sums the outputs from each patch, and hence the total output is normal by the central-limit theorem. It remains, however, to show that the higher-order terms are indeed negligible if the detector is large enough. In lieu of a formal proof, we present a heuristic argument.

The key is the second term in the exponent; since it has a negative, real coefficient, this term corresponds to a Gaussian factor in $\psi_{g_{out}}(\nu)$. As the detector gets larger, $N_b \propto A_d$ but $(\bar{g}_{out})^2 \propto A_d^2$, so the overall coefficient of ν^2 also grows linearly with A_d . Since this coefficient is in the exponent, the Gaussian factor rapidly gets smaller (for any given ν) as the detector gets larger. Conversely, a smaller ν suffices to make the Gaussian factor attain whatever level we deem negligible (say, 0.01). There must therefore be some A_d such that the Gaussian factor has died off to this level before the higher-order terms become appreciable.

The general case To determine the characteristic function and the PDF in the general case where the detector is neither very small nor very large, we must solve the eigenvalue problem for the operator $\mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}$. If we denote the n^{th} eigenvalue of this operator by $\lambda_{\mathcal{KW}}^{(n)}$, then (18.119) becomes

$$\psi_{g_{out}}(\nu) = \prod_{n=1}^{\infty} \left[1 + 2\pi i \nu \lambda_{\mathcal{KW}}^{(n)} \right]^{-1}. \quad (18.130)$$

If the eigenvalues are distinct, the corresponding univariate PDF is (Goodman, 1975):¹¹

$$\text{pr}(g_{out}) = \sum_{n=1}^{\infty} \frac{d_n}{\lambda_{\mathcal{KW}}^{(n)}} \exp\left(-\frac{g_{out}}{\lambda_{\mathcal{KW}}^{(n)}}\right), \quad (g_{out} \geq 0), \quad (18.131)$$

where

$$d_n = \prod_{\substack{m=1 \\ m \neq n}}^{\infty} \left(1 - \frac{\lambda_{\mathcal{KW}}^{(m)}}{\lambda_{\mathcal{KW}}^{(n)}}\right)^{-1}. \quad (18.132)$$

Thus the problem boils down to finding the eigenvalues, which usually must be done numerically.

One example where the eigenvalues can be found analytically uses the quasistationary covariance function of (18.115) and assumes that both the lens aperture and the detector response are described by 1D rect function (see Scribot, 1974 and Goodman, 1975). Thus the Fourier transform of the lens aperture is a sinc function, and the eigenvalue equation simplifies to a 1D problem of the form [cf. (4.64)],

$$\text{const} \cdot \int_{-\frac{1}{2}\epsilon}^{\frac{1}{2}\epsilon} dx' \text{sinc}[B(x-x')] \phi_{\mathcal{KW}}^{(n)}(x') = \lambda_{\mathcal{KW}}^{(n)} \phi_{\mathcal{KW}}^{(n)}(x). \quad (18.133)$$

We know from Sec. 4.1.5 that the solutions to this equation are prolate spheroidal wavefunctions. The abrupt cutoff of the eigenvalue spectrum, as seen in Fig. 4.2, suggests other avenues for approximation, which the inquisitive reader may wish to follow.

SNR on the detector output If $N_b \gg 1$, then the characteristic function of the detector output is given by (18.129). Whether or not the higher-order terms are negligible, we can write that result as

$$\psi_{g_{out}}(\nu) = \exp[-2\pi i \bar{g}_{out} \nu - 2\pi^2 \sigma^2 \nu^2 + \dots], \quad (18.134)$$

where σ^2 is the variance of the output signal, given by

$$\sigma^2 = \frac{(\bar{g}_{out})^2}{N_b}. \quad (18.135)$$

Thus the signal-to-noise ratio, defined here as the mean output divided by the standard deviation, is given by

$$\text{SNR} = \sqrt{N_b}. \quad (18.136)$$

For a small detector, the SNR on the output is unity since the output statistics are just the point statistics of the irradiance, which is exponentially distributed and hence has a standard deviation equal to its mean. For a large detector, however, the SNR is improved since the speckle variations average out.

¹¹The reader who wants to derive (18.131) should note that the eigenvalues are all nonnegative, so the poles are all in the upper half plane, and the contour can be closed on an infinite semicircle in the upper half plane since the exponential factor vanishes rapidly there.

Arrays It is relatively straightforward to extend the derivations above from a single detector to an array. The only difficulty is that we usually cannot assume that the elements in the array are either large or small compared to the blob size. As a numerical example, consider an array of 512×512 elements on a 1 cm^2 detector. The width of each element is thus about $2 \mu\text{m}$. For an F/2 lens operating at a wavelength $\lambda = 0.5 \mu\text{m}$, the correlation length of the speckle (which is also the width of the diffraction-limited PSF), is about $1 \mu\text{m}$, so the element size is comparable to the blob size.

Suppose that the \mathbf{m}^{th} detector element in an array is located at position $\mathbf{r}_{\mathbf{m}}$, where \mathbf{m} is a 2D multi-index with integer components. Generalizing (18.117), the output of the detector element is given by

$$g_{\mathbf{m}} = \int_{\infty} d^2r w_{\mathbf{m}}(\mathbf{r}) I_{im}(\mathbf{r}), \quad (18.137)$$

where

$$w_{\mathbf{m}}(\mathbf{r}) = C \text{rect} \left(\frac{\mathbf{r} - \mathbf{r}_{\mathbf{m}}}{\epsilon} \right). \quad (18.138)$$

Here C is the responsivity of the detector element and ϵ is its width. The set of all detector outputs is a vector \mathbf{g} , and (18.137) defines the discretization operator \mathcal{D}_w in:

$$\mathbf{g} = \mathcal{D}_w \mathbf{I}_{im}. \quad (18.139)$$

Our objective is to understand the statistics of \mathbf{g} .

Multivariate characteristic function The generalizations of (18.118) and (18.119) are

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \langle \exp[-2\pi i (\mathcal{D}_w \mathbf{I}_{im})^\dagger \boldsymbol{\xi}] \rangle = \Psi_{\mathbf{I}_{im}}(\mathcal{D}_w^\dagger \boldsymbol{\xi}) = \frac{1}{\det(\mathcal{I} + 2\pi i \mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}_{\boldsymbol{\xi}})}, \quad (18.140)$$

where $\mathcal{W}_{\boldsymbol{\xi}}$ is an integral operator with kernel

$$W_{\boldsymbol{\xi}}(\mathbf{r}, \mathbf{r}') = [\mathcal{D}_w^\dagger \boldsymbol{\xi}](\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') = \sum_{\mathbf{m}} \xi_{\mathbf{m}} w_{\mathbf{m}}(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'). \quad (18.141)$$

The expansion in traces, (18.120), now becomes

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \exp[-2\pi i \text{tr}(\mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}_{\boldsymbol{\xi}}) - 2\pi^2 \text{tr}(\mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}_{\boldsymbol{\xi}} \mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}_{\boldsymbol{\xi}}) + \dots]. \quad (18.142)$$

Convergence of this expansion requires that all eigenvalues of $2\pi i \mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}_{\boldsymbol{\xi}}$ be < 1 in absolute value, which will occur if $|\boldsymbol{\xi}|$ is small enough.

The first two traces in the expansion are [cf. (18.71), (18.122) and (18.123)]

$$\text{tr}(\mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}_{\boldsymbol{\xi}}) = \sum_{\mathbf{m}} \xi_{\mathbf{m}} \int_{\infty} d^2r w_{\mathbf{m}}(\mathbf{r}) K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}); \quad (18.143)$$

$$\text{tr}(\mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}_{\boldsymbol{\xi}} \mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}_{\boldsymbol{\xi}}) = \sum_{\mathbf{m}} \xi_{\mathbf{m}} \sum_{\mathbf{m}'} \xi_{\mathbf{m}'} \int_{\infty} d^2r \int_{\infty} d^2r' w_{\mathbf{m}}(\mathbf{r}) |K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}')|^2 w_{\mathbf{m}'}(\mathbf{r}'). \quad (18.144)$$

Relation to the object Though (18.140) and (18.142) purport to specify statistical properties of an image, they do not explicitly show the effect of the object. To make that connection, we need to use the operator relation (18.99) or its kernel (18.100). Plugging (18.99) into (18.140) gives

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \frac{1}{\det(\mathcal{I} + 2\pi i \ell_c^2 \mathcal{P}_{coh} |\mathbf{t}_{obj}|^2 \mathcal{P}_{coh}^\dagger \mathcal{W}_{\boldsymbol{\xi}})}. \quad (18.145)$$

Note that only the squared modulus of the amplitude transmittance of the object appears. Recall that the object is a photographic transparency and that it is placed over a ground glass that completely randomizes the phase of the light; any additional phase modulation by the object transparency is irrelevant.

To acknowledge this point, and to put our results here into a notation compatible with previous chapters, we define

$$f(\mathbf{r}) \equiv |\mathbf{t}_{obj}(\mathbf{r})|^2 \quad \text{or} \quad \mathbf{f} = |\mathbf{t}_{obj}|^2. \quad (18.146)$$

Thus the characteristic function is given by

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \frac{1}{\det(\mathcal{I} + 2\pi i \ell_c^2 \mathcal{P}_{coh} \mathbf{f} \mathcal{P}_{coh}^\dagger \mathcal{W}_{\boldsymbol{\xi}})}. \quad (18.147)$$

This characteristic function is conditional on a particular object, and we shall write it as $\psi_{\mathbf{g}|\mathbf{f}}(\boldsymbol{\xi})$ in Sec. 18.4.2 when we consider the object to be random.

Mean vector and covariance matrix The expansion in traces allows us just to read off the mean and covariance of \mathbf{g} . If we can write the characteristic function in the form

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \exp \left[-2\pi i \sum_{\mathbf{m}} b_{\mathbf{m}} \xi_{\mathbf{m}} - 2\pi^2 \sum_{\mathbf{m}} \sum_{\mathbf{m}'} \xi_{\mathbf{m}} A_{\mathbf{m}\mathbf{m}'} \xi_{\mathbf{m}'} + \dots \right], \quad (18.148)$$

then we can show from (8.30) and (8.31) that $b_{\mathbf{m}}$ is the mean of $g_{\mathbf{m}}$ and $A_{\mathbf{m}\mathbf{m}'}$ is the $(\mathbf{m}, \mathbf{m}')$ element of the covariance matrix. Higher terms, which involve cubic and higher powers of $\xi_{\mathbf{m}}$, give no contribution to the mean or covariance after taking the requisite derivatives and setting all $\xi_{\mathbf{m}}$ to 0. Thus

$$\bar{g}_{\mathbf{m}} = \int_{\infty} d^2r w_{\mathbf{m}}(\mathbf{r}) K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}) = \int_{\infty} d^2r w_{\mathbf{m}}(\mathbf{r}) \bar{I}_{im}(\mathbf{r}); \quad (18.149)$$

$$\begin{aligned} [\mathbf{K}_{\mathbf{g}}]_{\mathbf{m}\mathbf{m}'} &= \int_{\infty} d^2r \int_{\infty} d^2r' w_{\mathbf{m}}(\mathbf{r}) |K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}')|^2 w_{\mathbf{m}'}(\mathbf{r}') \\ &= \int_{\infty} d^2r \int_{\infty} d^2r' w_{\mathbf{m}}(\mathbf{r}) K_{\mathbf{I}_{im}}(\mathbf{r}, \mathbf{r}') w_{\mathbf{m}'}(\mathbf{r}'). \end{aligned} \quad (18.150)$$

Neither of these results should be surprising; they are the usual expressions for propagating means and covariances through linear CD mappings.

Reduction to determinant of a matrix We began this section with the characteristic functional for the irradiance in the image plane and converted it to the characteristic function for the discrete data vector by using the rules for linear CD mappings, yet the result was still expressed as the determinant of an integral operator. We shall now show that it is possible to transform the characteristic function so that it involves the determinant of a matrix rather than an integral operator, at least for small detectors. The procedure is an extension of one we used in Sec. 18.2.5 to derive the bivariate point statistics of the irradiance.

A detector element is considered small for this purpose if its width ϵ is much less than the speckle blob size, which is approximately the width of the coherent PSF. In that case we can write [cf. (18.138)]

$$w_{\mathbf{m}}(\mathbf{r}) \approx C\epsilon^2 \delta(\mathbf{r} - \mathbf{r}_{\mathbf{m}}), \quad (18.151)$$

and hence [cf. (18.138)]

$$W_{\xi}(\mathbf{r}, \mathbf{r}') \approx C\epsilon^2 \sum_{\mathbf{m}'} \xi_{\mathbf{m}'} \delta(\mathbf{r} - \mathbf{r}_{\mathbf{m}'}) \delta(\mathbf{r} - \mathbf{r}'). \quad (18.152)$$

The key point is that the rank of \mathcal{KW}_{ξ} (where we have deleted the subscript on \mathcal{K} for notational simplicity) is less than or equal to the number of detector elements with this approximation; to see this, let $\phi_{\mathcal{KW}}^{(n)}(\mathbf{r})$ be an eigenfunction of \mathcal{KW}_{ξ} with eigenvalue $\lambda_{\mathcal{KW}}^{(n)}$ and write

$$\left[\mathcal{KW}_{\xi} \phi_{\mathcal{KW}}^{(n)} \right](\mathbf{r}) \approx C\epsilon^2 \sum_{\mathbf{m}'} \xi_{\mathbf{m}'} K(\mathbf{r}, \mathbf{r}_{\mathbf{m}'}) \phi_{\mathcal{KW}}^{(n)}(\mathbf{r}_{\mathbf{m}'}) = \lambda_{\mathcal{KW}}^{(n)} \phi_{\mathcal{KW}}^{(n)}(\mathbf{r}). \quad (18.153)$$

Thus any eigenfunction of \mathcal{KW}_{ξ} with nonzero eigenvalue is a linear combination of the functions $\{K(\mathbf{r}, \mathbf{r}_{\mathbf{m}'})\}$. For an $M \times M$ detector array, there are M^2 functions in this set, and they are all linearly independent, so the rank of \mathcal{KW}_{ξ} is $\leq M^2$, with equality if and only if all $\xi_{\mathbf{m}'} \neq 0$.

If we evaluate (18.153) at $\mathbf{r} = \mathbf{r}_{\mathbf{m}}$, we obtain

$$\left[C\epsilon^2 \mathbf{K}\Xi - \lambda_{\mathcal{KW}}^{(n)} \mathbf{I} \right] \Phi_{\mathcal{KW}}^{(n)} = \mathbf{0}, \quad (18.154)$$

where $\Phi_{\mathcal{KW}}^{(n)}$ is an $M^2 \times 1$ vector with components $\{\phi_{\mathcal{KW}}^{(n)}(\mathbf{r}_{\mathbf{m}})\}$, and \mathbf{K} and Ξ are $M^2 \times M^2$ matrices defined by

$$[\mathbf{K}]_{\mathbf{m}\mathbf{m}'} \equiv K(\mathbf{r}_{\mathbf{m}}, \mathbf{r}_{\mathbf{m}'}), \quad [\Xi]_{\mathbf{m}\mathbf{m}'} \equiv \xi_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'}. \quad (18.155)$$

The eigenvalues are determined by solving

$$\det \left[C\epsilon^2 \mathbf{K}\Xi - \lambda_{\mathcal{KW}}^{(n)} \mathbf{I} \right] = 0. \quad (18.156)$$

Since the rank of the integral operator \mathcal{KW}_{ξ} is $\leq M^2$, we can be assured that all nonzero eigenvalues will be found by solving this equation.

The original characteristic function from (18.140) is thus given by

$$\psi_{\mathbf{g}}(\xi) = \frac{1}{\det(\mathcal{I} + 2\pi i \mathcal{KW}_{\xi})} = \prod_{n=1}^{M^2} \frac{1}{1 + 2\pi i C\epsilon^2 \lambda_{\mathcal{KW}}^{(n)}} = \frac{1}{\det(\mathbf{I} + 2\pi i C\epsilon^2 \mathbf{K}\Xi)}, \quad (18.157)$$

where \mathbf{I} is an $M^2 \times M^2$ unit matrix.

The matrix-determinant form is particularly useful if we want to know the joint characteristic function for only a few detector outputs. For example, to get the bivariate statistics for any two $g_{\mathbf{m}}$, we need only two nonzero $\xi_{\mathbf{m}}$, so (18.156) requires evaluation of just a 2×2 determinant. We remind the reader, however, that the matrix form applies only with small detectors that provide essentially point sampling of the speckle irradiance.

18.4 NOISE AND IMAGE QUALITY

Though speckle is a form of noise, we still need to consider measurement noise (Gaussian or Poisson) as well as object randomness. In all, coherent imaging is triply (or even quadruply) stochastic: the image is a random vector conditional on the irradiance pattern, the irradiance pattern is a random process conditional on the object, and the object itself is another random process. If we consider both kinds of measurement noise — Gaussian electronic noise and Poisson photon-counting statistics — there are altogether four random processes in the problem.

Before trying to express these ideas mathematically, let us recall the meaning of randomness for each of these components. When we regard the object as random, we are envisioning drawing many objects from some ensemble and imaging each in turn. It may be difficult or even impossible to specify this ensemble, but in principle we are thinking in frequentist terms about sampling from an infinite set of possible objects. The objects discussed so far in this chapter have been photographic transparencies, and we imagine laying one after the other over an illuminated ground glass and imaging the emerging field. For each object, however, the irradiance pattern is also random because we can consider an ensemble of ground glasses; indeed, all statistical properties derived in Sec. 18.3 were for one object transparency and infinitely many ground glasses. Finally, if we use one object transparency and one ground glass but take repeated images, the data vector will be random because of photon statistics and electronic noise.

The goal of this section is to incorporate measurement noise and object randomness into our statistical analysis and then to use the results to discuss objective assessment of image quality in coherent imaging. We shall continue to consider a 2D imaging system where the object is a photographic transparency, but more general situations will be treated in Sec. 18.5.

18.4.1 Measurement noise

In Chap. 11 we presented a detailed account of Poisson random variables and processes, and in Chap. 12 we applied that knowledge to the analysis of photon noise in optical detectors. We also saw in Chap. 12, however, that numerous electronic noise processes could lead to Gaussian statistics instead of Poisson. We shall consider both of these kinds of noise in a detector array sensing a speckle distribution.

Photon noise As the starting point for discussing combined speckle and photon noise, we shall use (8.339), which expresses the transformation of the characteristic functional of a random process through a CD mapping, with the output of that mapping serving as the mean of a Poisson random vector. In the present discussion,

the random process in question is the irradiance incident on the detector array, and the CD mapping is the discretization operator \mathcal{D}_w . Thus (8.339) becomes

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \Psi_{\mathbf{I}_{im}}[\mathcal{D}_w^\dagger \boldsymbol{\Gamma}(\boldsymbol{\xi})], \tag{18.158}$$

where the operator $\boldsymbol{\Gamma}$ is defined by (8.338) as

$$[\boldsymbol{\Gamma}(\boldsymbol{\xi})]_{\mathbf{m}} = \frac{-1 + \exp(-2\pi i \xi_{\mathbf{m}})}{-2\pi i}. \tag{18.159}$$

With this transformation, (18.140) becomes

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \frac{1}{\det(\mathcal{I} + 2\pi i \mathcal{K}_{u_{im}} \mathcal{W}_{\boldsymbol{\Gamma}\boldsymbol{\xi}})} = \frac{1}{\det(\mathcal{I} + 2\pi i \ell_c^2 \mathcal{P}_{coh} \mathbf{f} \mathcal{P}_{coh}^\dagger \mathcal{W}_{\boldsymbol{\Gamma}\boldsymbol{\xi}})}, \tag{18.160}$$

where $\mathcal{W}_{\boldsymbol{\Gamma}\boldsymbol{\xi}}$ is an integral operator with kernel [cf. (18.141)]

$$W_{\boldsymbol{\Gamma}\boldsymbol{\xi}}(\mathbf{r}, \mathbf{r}') = \sum_{\mathbf{m}} \left[\frac{-1 + \exp(-2\pi i \xi_{\mathbf{m}})}{-2\pi i} \right] w_{\mathbf{m}}(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'). \tag{18.161}$$

After a bit of manipulation, the kernel of the operator inside the determinant in (18.160) takes the form

$$[\mathcal{I} + 2\pi i \mathcal{K}_{u_{im}} \mathcal{W}_{\boldsymbol{\Gamma}\boldsymbol{\xi}}](\mathbf{r}, \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}') + K_{u_{im}}(\mathbf{r}, \mathbf{r}') \sum_{\mathbf{m}} [1 - \exp(-2\pi i \xi_{\mathbf{m}})] w_{\mathbf{m}}(\mathbf{r}'). \tag{18.162}$$

The expansion in traces, (18.142), is still valid if it converges, but $\xi_{\mathbf{m}}$ must be replaced by $[\boldsymbol{\Gamma}(\boldsymbol{\xi})]_{\mathbf{m}}$ in (18.143) and (18.144); the result is

$$\begin{aligned} \psi_{\mathbf{g}}(\boldsymbol{\xi}) &= \exp \left\{ -2\pi i \sum_{\mathbf{m}} [\boldsymbol{\Gamma}(\boldsymbol{\xi})]_{\mathbf{m}} \bar{g}_{\mathbf{m}} - 2\pi^2 \sum_{\mathbf{m}, \mathbf{m}'} [\boldsymbol{\Gamma}(\boldsymbol{\xi})]_{\mathbf{m}} \left[\mathbf{K}_{\mathbf{g}}^{(nf)} \right]_{\mathbf{m}\mathbf{m}'} [\boldsymbol{\Gamma}(\boldsymbol{\xi})]_{\mathbf{m}'} + \dots \right\} \\ &= \exp \left\{ \sum_{\mathbf{m}} [-1 + \exp(-2\pi i \xi_{\mathbf{m}})] \bar{g}_{\mathbf{m}} \right. \\ &\quad \left. + \frac{1}{2} \sum_{\mathbf{m}, \mathbf{m}'} [-1 + \exp(-2\pi i \xi_{\mathbf{m}})] \left[\mathbf{K}_{\mathbf{g}}^{(nf)} \right]_{\mathbf{m}\mathbf{m}'} [-1 + \exp(-2\pi i \xi_{\mathbf{m}'})] + \dots \right\}, \tag{18.163} \end{aligned}$$

where we have used (18.149) and (18.150). Recall, however, that (18.150) did not include the effects of Poisson noise, so the double integral in that equation is the covariance of \mathbf{g} with speckle but without Poisson noise, hence the superscript (nf) for *noise-free*. With proper choice of the responsivity C , $g_{\mathbf{m}}$ is measured in units of detected events or counts, so $\bar{g}_{\mathbf{m}}$ can be interpreted as the mean number of counts in element \mathbf{m} during the measurement time.

The multivariate characteristic function given in (18.160) or (18.163) contains all possible statistical information about the detector output when both speckle and photon noise are present. It applies to an arbitrary array of detector elements of arbitrary size. We shall now investigate several special cases and limits of this general result.

Mean vector and covariance matrix As we noted in Sec. 18.3.3, we can read off the mean and covariance of a random vector if we can express its characteristic function in the form (18.148). The characteristic function in (18.163) is not immediately in that form since the coefficients of successive terms are nonlinear functions of the frequency variables $\xi_{\mathbf{m}}$. We can, however, expand the exponentials to obtain

$$-1 + \exp(-2\pi i \xi_{\mathbf{m}}) = -2\pi i \xi_{\mathbf{m}} - 2\pi^2 \xi_{\mathbf{m}}^2 + \dots \quad (18.164)$$

Thus, through terms quadratic in the frequencies, we have

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \exp \left\{ \sum_{\mathbf{m}} (-2\pi i \xi_{\mathbf{m}'} - 2\pi^2 \xi_{\mathbf{m}}^2) \bar{g}_{\mathbf{m}} - 2\pi^2 \sum_{\mathbf{m}, \mathbf{m}'} \xi_{\mathbf{m}} [\mathbf{K}_{\mathbf{g}}^{(n,f)}]_{\mathbf{m}\mathbf{m}'} \xi_{\mathbf{m}'} + \dots \right\}. \quad (18.165)$$

Comparison with (18.148) shows that $\bar{g}_{\mathbf{m}}$ is indeed the mean, and the covariance matrix is given by

$$[\mathbf{K}_{\mathbf{g}}]_{\mathbf{m}\mathbf{m}'} = \bar{g}_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'} + [\mathbf{K}_{\mathbf{g}}^{(n,f)}]_{\mathbf{m}\mathbf{m}'}. \quad (18.166)$$

This result is familiar from earlier chapters; it expresses the universal form for the covariance matrix of doubly stochastic Poisson noise, as first derived¹² in Sec. 11.2.2.

Large detector elements When we considered large detector elements with no Poisson noise in Sec. 18.3.3, we argued that the expansion in traces could be truncated after the second term in the exponent since that term was quadratic in the frequency variable and had a negative, real coefficient that increased with the detector area [see (18.129)]. As a result, the speckle statistics approached Gaussian. The coefficient of the first term in the exponent of the characteristic function was pure imaginary and gave the mean of the Gaussian.

With Poisson noise, all of this changes. It is no longer true that the coefficient of the first term is pure imaginary and that of the second term is pure real. In fact, both terms are complex and periodic in $\xi_{\mathbf{m}}$ with period 1, which tells us immediately that $g_{\mathbf{m}}$ can have only integer values. (We know from Sec. 3.3.8 that periodicity of a function restricts its Fourier transform to a discrete set of points.) Moreover, as noted above, we can no longer identify each term in the exponent with a specific power of $\boldsymbol{\xi}$; the Γ operator mixes the powers.

We can, however, terminate the series in the exponent of (18.163) with the single-sum term if the detector is large enough. The noise-free part of the covariance matrix approaches zero as N_b (the mean number of blobs across the detector) gets large [cf. (18.135)], so the double-sum term in (18.163) becomes negligible if N_b is large enough. In that case (18.163) becomes

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \exp \left\{ \sum_{\mathbf{m}} [-1 + \exp(-2\pi i \xi_{\mathbf{m}})] \bar{g}_{\mathbf{m}} \right\} = \prod_{\mathbf{m}} \exp \{ [-1 + \exp(-2\pi i \xi_{\mathbf{m}})] \bar{g}_{\mathbf{m}} \}. \quad (18.167)$$

This expression is recognized from (C.171) as the product of characteristic functions for Poisson random variables. Thus the speckle averages out and the detector

¹²In those previous results, we would have written $\bar{\bar{g}}_{\mathbf{m}}$ where we have $\bar{g}_{\mathbf{m}}$ here, but the first average, over the speckle irradiances, is already implicit in the definition of $\bar{g}_{\mathbf{m}}$ in (18.149). We shall reserve the double overbar for Sec. 18.4.2, where we consider the triply stochastic problem of combined speckle, Poisson noise and object randomness.

outputs revert to independent Poisson random variables as the detector gets large.

We encountered an analogous situation in Sec. 11.3.7 when we discussed photon-counting statistics with incoherent light [see especially the discussion below (11.128)]. In that case we also had two covariance terms, but one of them averaged out when we integrated over a long observation time, leaving us with just the Poisson component. The same thing happens with speckle except that the averaging is spatial. *Large detectors give Poisson statistics in spite of speckle.*

Gaussian limit of the Poisson If we insert (18.164) into (18.167), we get

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \prod_{\mathbf{m}} \exp [-2\pi i \xi_{\mathbf{m}} \bar{g}_{\mathbf{m}} - 2\pi^2 \xi_{\mathbf{m}}^2 \bar{g}_{\mathbf{m}} + \cdots] . \quad (18.168)$$

If $\bar{g}_{\mathbf{m}}$ is large enough, we can truncate this series after the first real term, the one quadratic in $\xi_{\mathbf{m}}$. Thus, if the detector elements are large and the mean counts per element are also large, the statistics approach independent Gaussian with the variance of each output equal to the mean.

Small detector elements, univariate statistics We can compute the univariate characteristic function for a single output $g_{\mathbf{m}}$ simply by setting $\xi_{\mathbf{m}'} = 0$ for all $\mathbf{m}' \neq \mathbf{m}$. Then (18.160) becomes

$$\psi_{g_{\mathbf{m}}}(\xi_{\mathbf{m}}) = \frac{1}{\det [\mathcal{I} + 2\pi i \mathcal{K}_{\mathbf{u}_{im}} \mathcal{W}_{\Gamma\xi}^{\mathbf{m}}]} , \quad (18.169)$$

where $\mathcal{W}_{\Gamma\xi}^{\mathbf{m}}$ is $\mathcal{W}_{\Gamma\xi}$ with the summation sign in (18.161) omitted.

If the detector is much smaller than a blob and can be approximated with a delta function as in (18.121), the operator in the determinant has rank 1, and the determinant can be evaluated just as in Sec. 18.3.3. The univariate characteristic function becomes [cf. (18.122)]

$$\psi_{g_{\mathbf{m}}}(\xi_{\mathbf{m}}) = \frac{1}{1 + [1 - \exp(-2\pi i \xi_{\mathbf{m}})] \bar{g}_{\mathbf{m}}} = \frac{1}{1 + \bar{g}_{\mathbf{m}} - \bar{g}_{\mathbf{m}} \exp(-2\pi i \xi_{\mathbf{m}})} . \quad (18.170)$$

We can get the corresponding univariate PDF by taking an inverse Fourier transform. Temporarily dropping the subscript \mathbf{m} for convenience, we must evaluate:

$$\text{pr}(g) = \int_{-\infty}^{\infty} d\xi \frac{\exp(2\pi i g \xi)}{1 + \bar{g} - \bar{g} \exp(-2\pi i \xi)} . \quad (18.171)$$

Contour integration suggests itself. The exponential factor is analytic in the upper half plane and vanishes at infinity in that half plane (for $g > 0$). Thus we can close the contour with an arc of infinite radius crossing the positive imaginary axis. It remains to find the poles in the upper half plane and evaluate their residues.

The denominator vanishes when

$$\xi = n + \frac{i}{2\pi} \ln \left(\frac{1 + \bar{g}}{\bar{g}} \right) \equiv \xi_n , \quad n \text{ integer} . \quad (18.172)$$

We can demonstrate that this singularity is a simple pole and find its residue by use of (B.47) and L'Hôpital's rule:

$$\lim_{\xi \rightarrow \xi_n} \frac{\xi - \xi_n}{1 + \bar{g} - \bar{g} \exp(-2\pi i \xi)} = \frac{1}{2\pi i \bar{g} \exp(-2\pi i \xi_n)} = \frac{1}{2\pi i (1 + \bar{g})} . \quad (18.173)$$

The residue of the integrand at the n^{th} pole is thus

$$\text{res}_n = \frac{\exp(2\pi i \xi_n g)}{2\pi i (1 + \bar{g})}. \quad (18.174)$$

There are an infinite number of poles within the contour; with (B.48) and a little algebra, the integral becomes

$$\oint_C d\xi \frac{\exp(2\pi i g \xi)}{1 + \bar{g} - \bar{g} \exp(-2\pi i \xi)} = 2\pi i \sum_{n=-\infty}^{\infty} \text{res}_n = \sum_{n=-\infty}^{\infty} \exp(2\pi i n g) \frac{\bar{g}^n}{(1 + \bar{g})^{1+g}}. \quad (18.175)$$

The sum will be recognized from (2.50) as a comb function, so

$$\text{pr}(g_{\mathbf{m}}) = \sum_{k=0}^{\infty} \frac{\bar{g}_{\mathbf{m}}^k}{(1 + \bar{g}_{\mathbf{m}})^{1+k}} \delta(g_{\mathbf{m}} - k), \quad (18.176)$$

where we have now reinstated the \mathbf{m} subscript, and we have deleted all negative- k terms from the sum since $g_{\mathbf{m}}$ cannot be negative and hence $\delta(g_{\mathbf{m}} - k) = 0$ for $k < 0$. By (C.24), the coefficient of the delta function is the probability of occurrence of the discrete value $g_{\mathbf{m}} = k$, or

$$\text{Pr}(g_{\mathbf{m}} = k) = \frac{\bar{g}_{\mathbf{m}}^k}{(1 + \bar{g}_{\mathbf{m}})^{1+k}}. \quad (18.177)$$

This probability is the *Bose-Einstein law*, and we know from Sec. 11.1.4 that the Poisson transform of an exponential is a Bose-Einstein [see also (11.314)]. In the present problem, the irradiance at a single point is exponential, and the small detector samples the irradiance at a point and uses the result as the mean for a Poisson, with the resulting photon-counting distribution being, therefore, Bose-Einstein. It must be remembered, however, that this law applies only with small detectors and even then only to the univariate statistics.

Electronic noise If there is an array of noisy amplifiers or other noise sources, one for each detector element, then we can write

$$\mathbf{v} = \mathbf{g} + \mathbf{n}, \quad (18.178)$$

where \mathbf{v} is the vector of amplifier output voltages and \mathbf{n} is the corresponding vector of noise values. If \mathbf{n} and \mathbf{g} are statistically independent, we know from Sec. 8.5.3 that [cf. (8.335)]

$$\psi_{\mathbf{v}}(\boldsymbol{\xi}) = \psi_{\mathbf{n}}(\boldsymbol{\xi}) \psi_{\mathbf{g}}(\boldsymbol{\xi}). \quad (18.179)$$

If we neglect the Poisson noise and suppose that the electronic noise is the only noise process associated with the detection of a speckle pattern, then we have [cf. (18.140)]:

$$\psi_{\mathbf{v}}(\boldsymbol{\xi}) = \psi_{\mathbf{n}}(\boldsymbol{\xi}) \Psi_{\mathbf{I}_{im}}(\mathcal{D}_w^\dagger \boldsymbol{\xi}). \quad (18.180)$$

To account for both electronic and Poisson noise, we write [cf. (18.158)]:

$$\psi_{\mathbf{v}}(\boldsymbol{\xi}) = \psi_{\mathbf{n}}(\boldsymbol{\xi}) \Psi_{\mathbf{I}_{im}}[\mathcal{D}_w^\dagger \boldsymbol{\Gamma}(\boldsymbol{\xi})]. \quad (18.181)$$

The usual model (see Chap. 12) is that the electronic noise \mathbf{n} is zero-mean i.i.d. Gaussian, so

$$\psi_{\mathbf{n}}(\boldsymbol{\xi}) = \prod_{\mathbf{m}} \exp(-2\pi^2 \sigma_{el}^2 \xi_{\mathbf{m}}^2). \quad (18.182)$$

If we use the expansion in traces to cast $\psi_{\mathbf{g}}(\boldsymbol{\xi})$ into the form (18.148), then

$$\psi_{\mathbf{v}}(\boldsymbol{\xi}) = \exp \left[-2\pi i \sum_{\mathbf{m}} \bar{g}_{\mathbf{m}} \xi_{\mathbf{m}} - 2\pi^2 \sum_{\mathbf{m}} \sum_{\mathbf{m}'} \xi_{\mathbf{m}} [\mathbf{K}_{\mathbf{v}}]_{\mathbf{m}\mathbf{m}'} \xi_{\mathbf{m}'} + \dots \right], \quad (18.183)$$

where

$$\mathbf{K}_{\mathbf{v}} = \mathbf{K}_{\mathbf{g}} + \sigma_{el}^2 \mathbf{I}. \quad (18.184)$$

Thus, given the characteristic function in the standard form (18.148), we need only add a multiple of the unit matrix to the covariance in order to account for Gaussian electronic noise; there is no implication that the statistics of \mathbf{g} itself are Gaussian.

18.4.2 Random objects

All of the statistical analysis to this point has been for a fixed object, but we know from Chaps. 13 and 14, that object variability is an important factor limiting task performance. In this section we shall see how to extend the analysis to include random objects.

Overall characteristic function Formally, the characteristic function of the data vector in the presence of speckle, Poisson noise and object variability is given by

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \langle \psi_{\mathbf{g}|\mathbf{f}}(\boldsymbol{\xi}) \rangle_{\mathbf{f}} = \left\langle \frac{1}{\det(\mathcal{I} + 2\pi i \ell_c^2 \mathcal{P}_{coh} \mathbf{f} \mathcal{P}_{coh}^\dagger \mathcal{W}_{\Gamma} \boldsymbol{\xi})} \right\rangle_{\mathbf{f}}. \quad (18.185)$$

For purposes of computing moments, the expansion in traces (18.163) is useful:

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \left\langle \exp \left\{ -2\pi i \sum_{\mathbf{m}} [\Gamma(\boldsymbol{\xi})]_{\mathbf{m}} \bar{g}_{\mathbf{m}} - 2\pi^2 \sum_{\mathbf{m}, \mathbf{m}'} [\Gamma(\boldsymbol{\xi})]_{\mathbf{m}} [\mathbf{K}_{\mathbf{g}|\mathbf{f}}^{(nf)}]_{\mathbf{m}\mathbf{m}'} [\Gamma(\boldsymbol{\xi})]_{\mathbf{m}'} + \dots \right\} \right\rangle_{\mathbf{f}}, \quad (18.186)$$

where the superscript (nf) has been added to indicate that this covariance matrix is computed without consideration of the Poisson noise, though of course it includes speckle; specifically, it is given by (18.150).

If we wanted also to incorporate electronic noise into the characteristic function, we would use (18.179) and (18.185) to write

$$\psi_{\mathbf{v}}(\boldsymbol{\xi}) = \psi_{\mathbf{n}}(\boldsymbol{\xi}) \psi_{\mathbf{g}}(\boldsymbol{\xi}) = \psi_{\mathbf{n}}(\boldsymbol{\xi}) \left\langle \frac{1}{\det(\mathcal{I} + 2\pi i \ell_c^2 \mathcal{P}_{coh} \mathbf{f} \mathcal{P}_{coh}^\dagger \mathcal{W}_{\Gamma} \boldsymbol{\xi})} \right\rangle_{\mathbf{f}}. \quad (18.187)$$

Since the electronic noise is assumed to be independent of the object, the factor $\psi_{\mathbf{n}}(\boldsymbol{\xi})$ is outside the average over \mathbf{f} . For simplicity, we shall omit any further discussion of electronic noise.

Mean and covariance In order to compute the overall mean vector and covariance matrix, we must carry out the expansion of the exponent in (18.186) through terms quadratic in the $\xi_{\mathbf{m}}$ and then compute first and second derivatives. Cubic and higher terms in the exponent will make no contribution to the mean and covariance.

The requisite expansion is [*cf.* (18.165)]

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \left\langle \exp \left\{ \sum_{\mathbf{m}} (-2\pi i \xi_{\mathbf{m}'} - 2\pi^2 \xi_{\mathbf{m}}^2) \bar{g}_{\mathbf{m}} - 2\pi^2 \sum_{\mathbf{m}, \mathbf{m}'} \xi_{\mathbf{m}} [\mathbf{K}_{\mathbf{g}}^{(nf)}]_{\mathbf{m}\mathbf{m}'} \xi_{\mathbf{m}'} + \dots \right\} \right\rangle_{\mathbf{f}}, \quad (18.188)$$

and the first two derivatives are

$$\frac{\partial}{\partial \xi_{\mathbf{m}}} \psi_{\mathbf{g}}(\boldsymbol{\xi}) = \left\langle \left[-2\pi i \bar{g}_{\mathbf{m}} - 4\pi^2 \xi_{\mathbf{m}} \bar{g}_{\mathbf{m}} - 4\pi^2 \sum_{\mathbf{m}'} [\mathbf{K}_{\mathbf{g}|\mathbf{f}}^{(nf)}]_{\mathbf{m}\mathbf{m}'} \xi_{\mathbf{m}'} \right] \psi_{\mathbf{g}|\mathbf{f}}(\boldsymbol{\xi}) \right\rangle_{\mathbf{f}}; \quad (18.189)$$

$$\frac{\partial^2}{\partial \xi_{\mathbf{m}} \partial \xi_{\mathbf{m}'}} \psi_{\mathbf{g}}(\boldsymbol{\xi}) = -4\pi^2 \left\langle \left[\bar{g}_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'} + [\mathbf{K}_{\mathbf{g}|\mathbf{f}}^{(nf)}]_{\mathbf{m}\mathbf{m}'} + \bar{g}_{\mathbf{m}} \bar{g}_{\mathbf{m}'} \right] \psi_{\mathbf{g}|\mathbf{f}}(\boldsymbol{\xi}) \right\rangle_{\mathbf{f}}. \quad (18.190)$$

The overall mean is obtained by evaluating the first derivative at the origin:

$$\langle g_{\mathbf{m}} \rangle = -\frac{1}{2\pi i} \left[\frac{\partial}{\partial \xi_{\mathbf{m}}} \psi_{\mathbf{g}}(\boldsymbol{\xi}) \right]_{\mathbf{0}} = \langle \bar{g}_{\mathbf{m}} \rangle_{\mathbf{f}} \equiv \bar{\bar{g}}_{\mathbf{m}}. \quad (18.191)$$

The unsubscripted angle brackets on the left and the double overbar on the right imply an average over all random effects—speckle, Poisson noise and object variability—but the single overbar implies an average over only speckle and Poisson noise. Thus, as before, $\bar{g}_{\mathbf{m}}$ is the mean of $g_{\mathbf{m}}$ conditional on \mathbf{f} .

The second moment is

$$\langle g_{\mathbf{m}} g_{\mathbf{m}'} \rangle = \frac{1}{-4\pi^2} \left[\frac{\partial^2}{\partial \xi_{\mathbf{m}} \partial \xi_{\mathbf{m}'}} \psi_{\mathbf{g}}(\boldsymbol{\xi}) \right]_{\mathbf{0}} = \bar{\bar{g}}_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'} + \left\langle [\mathbf{K}_{\mathbf{g}|\mathbf{f}}^{(nf)}]_{\mathbf{m}\mathbf{m}'} \right\rangle_{\mathbf{f}} + \langle \bar{g}_{\mathbf{m}} \bar{g}_{\mathbf{m}'} \rangle_{\mathbf{f}}. \quad (18.192)$$

The overall covariance matrix is given by

$$[\mathbf{K}_{\mathbf{g}}]_{\mathbf{m}\mathbf{m}'} \equiv \langle g_{\mathbf{m}} g_{\mathbf{m}'} \rangle - \bar{\bar{g}}_{\mathbf{m}} \bar{\bar{g}}_{\mathbf{m}'} = \bar{\bar{g}}_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'} + \overline{K}_{\mathbf{m}\mathbf{m}'}^{(nf)} + [\mathbf{K}_{\bar{\mathbf{g}}}]_{\mathbf{m}\mathbf{m}'}, \quad (18.193)$$

where

$$\overline{K}_{\mathbf{m}\mathbf{m}'}^{(nf)} \equiv \left\langle [\mathbf{K}_{\mathbf{g}|\mathbf{f}}^{(nf)}]_{\mathbf{m}\mathbf{m}'} \right\rangle_{\mathbf{f}}, \quad (18.194)$$

and

$$[\mathbf{K}_{\bar{\mathbf{g}}}]_{\mathbf{m}\mathbf{m}'} \equiv \langle \bar{g}_{\mathbf{m}} \bar{g}_{\mathbf{m}'} \rangle_{\mathbf{f}} - \bar{\bar{g}}_{\mathbf{m}} \bar{\bar{g}}_{\mathbf{m}'}. \quad (18.195)$$

Thus we now have three terms in the covariance matrix for this triply stochastic random process. The diagonal term $\bar{\bar{g}}_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'}$ comes from the Poisson noise averaged over all objects and all speckle realizations. The “noise-free” term, (18.194), comes just from the speckle but is averaged over all objects.

The final term, (18.195), represents the variations of the object function as transferred through to the discrete data domain. It is identical to the covariance one would get for this same optical system operated with a long exposure time to average out the Poisson noise and a moving ground glass to average out the speckle. Equivalently, it is the covariance for the system used with an incoherent source and long exposure time, so that the only randomness left is the object variability.

18.4.3 Task performance

In this section we survey methods for computing observer performance on various tasks of interest. We rely heavily on Chap. 14, with the present goal being to see how the techniques described there can be applied specifically to speckle problems.

Discrimination between known objects The simplest of discrimination tasks is when the object must be either \mathbf{f}_1 or \mathbf{f}_2 , both of which are nonrandom and known precisely to the observer. For example, \mathbf{f}_1 could refer to a known background and \mathbf{f}_2 to that same background plus a known signal, and in that case we refer to the task as SKE/BKE. The only noise source we consider here is speckle.

We have already examined one special case of this problem in Sec. 13.2.9. As an illustration of the ideal observer with non-Gaussian statistics, we considered a simplified (but not uncommon) model of speckle in which the measurements are statistically independent and exponentially distributed [see (13.136)]. We now know that this model is applicable only when the detector elements are small compared to the speckle blob size, yet separated by a distance large compared to the blob size. We found in that case that the log-likelihood ratio (13.137) yielded a linear discriminant, given in (13.217), though not the Hotelling discriminant, which for comparison was given in (13.218). For later reference, we rewrite (13.137) here in our multi-index notation as

$$\lambda(\mathbf{g}) = \sum_{\mathbf{m}} \left(\frac{1}{\bar{g}_{1\mathbf{m}}} - \frac{1}{\bar{g}_{2\mathbf{m}}} \right) g_{\mathbf{m}}. \quad (18.196)$$

We shall now revisit the SKE/BKE detection problem in speckle noise without these unrealistic assumptions. As in Sec. 13.2.12, we pose two questions: Is the log-likelihood ratio a linear discriminant? What is the optimal linear discriminant in the sense of maximizing the AUC? For background on these questions, see Sec. 13.2.12 and especially (13.219)–(13.226).

When is the log-likelihood ratio linear? The general answer to this question is that the log-likelihood ratio is a linear discriminant of the form [cf. (13.221)]

$$\lambda(\mathbf{g}) = \ln \left[\frac{\text{pr}(\mathbf{g}|H_2)}{\text{pr}(\mathbf{g}|H_1)} \right] = \mathbf{a}^t \mathbf{g} + c \quad (18.197)$$

if and only if the characteristic functions satisfy (13.226):

$$\psi_{\mathbf{g}|H_2}(\boldsymbol{\xi}) = \text{const} \cdot \psi_{\mathbf{g}|H_1} \left(\boldsymbol{\xi} + \frac{i}{2\pi} \mathbf{a} \right). \quad (18.198)$$

If we can put the characteristic functions in this form, we can read off the linear discriminant \mathbf{a} by inspection.

If the only noise present is speckle, then the characteristic function of the data under the j^{th} hypothesis ($j = 1, 2$) is given from (18.147) as

$$\psi_{\mathbf{g}|H_j}(\boldsymbol{\xi}) = \frac{1}{\det(\mathcal{I} + 2\pi i \ell_c^2 \mathcal{P}_{\text{coh}} \mathbf{f}_j \mathcal{P}_{\text{coh}}^\dagger \mathcal{W}_{\boldsymbol{\xi}})} \equiv \frac{1}{\det(\mathcal{I} + 2\pi i \mathcal{K}_j \mathcal{W}_{\boldsymbol{\xi}})}, \quad (18.199)$$

where \mathcal{K}_j is the covariance operator for the image-plane field under hypothesis j .

The following manipulations will lead us in the direction of (18.198):

$$\begin{aligned}\psi_{\mathbf{g}|H_2}(\boldsymbol{\xi}) &= \frac{1}{\det [(\boldsymbol{\mathcal{K}}_2 \boldsymbol{\mathcal{K}}_1^{-1}) (\boldsymbol{\mathcal{K}}_1 \boldsymbol{\mathcal{K}}_2^{-1} + 2\pi i \boldsymbol{\mathcal{K}}_1 \boldsymbol{\mathcal{W}}_{\boldsymbol{\xi}})]} \\ &= \frac{1}{\det (\boldsymbol{\mathcal{K}}_2 \boldsymbol{\mathcal{K}}_1^{-1}) \det (\boldsymbol{\mathcal{I}} + 2\pi i \boldsymbol{\mathcal{K}}_1 \boldsymbol{\mathcal{W}}_{\boldsymbol{\xi}} + \boldsymbol{\mathcal{K}}_1 \boldsymbol{\mathcal{K}}_2^{-1} - \boldsymbol{\mathcal{I}})} \\ &= \text{const} \cdot \frac{1}{\det \left\{ \boldsymbol{\mathcal{I}} + 2\pi i \boldsymbol{\mathcal{K}}_1 \left[\boldsymbol{\mathcal{W}}_{\boldsymbol{\xi}} + \frac{i}{2\pi} (\boldsymbol{\mathcal{K}}_1^{-1} - \boldsymbol{\mathcal{K}}_2^{-1}) \right] \right\}},\end{aligned}\quad (18.200)$$

where, as a reminder [see (18.141)], $\boldsymbol{\mathcal{W}}_{\boldsymbol{\xi}}$ has the kernel

$$[\boldsymbol{\mathcal{W}}_{\boldsymbol{\xi}}](\mathbf{r}, \mathbf{r}') = \sum_{\mathbf{m}} \xi_{\mathbf{m}} w_{\mathbf{m}}(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'). \quad (18.201)$$

For comparison, the right-hand side of (18.198) can be written as

$$\psi_{\mathbf{g}|H_1} \left(\boldsymbol{\xi} + \frac{i}{2\pi} \mathbf{a} \right) = \frac{1}{\det \left\{ \boldsymbol{\mathcal{I}} + 2\pi i \boldsymbol{\mathcal{K}}_1 \left[\boldsymbol{\mathcal{W}}_{\boldsymbol{\xi}} + \frac{i}{2\pi} \boldsymbol{\mathcal{W}}_{\mathbf{a}} \right] \right\}}, \quad (18.202)$$

where

$$[\boldsymbol{\mathcal{W}}_{\mathbf{a}}](\mathbf{r}, \mathbf{r}') = \sum_{\mathbf{m}} a_{\mathbf{m}} w_{\mathbf{m}}(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'). \quad (18.203)$$

Thus the log-likelihood ratio is a linear discriminant if

$$\det \left\{ \boldsymbol{\mathcal{I}} + 2\pi i \boldsymbol{\mathcal{K}}_1 \left[\boldsymbol{\mathcal{W}}_{\boldsymbol{\xi}} + \frac{i}{2\pi} \boldsymbol{\mathcal{W}}_{\mathbf{a}} \right] \right\} = \det \left\{ \boldsymbol{\mathcal{I}} + 2\pi i \boldsymbol{\mathcal{K}}_1 \left[\boldsymbol{\mathcal{W}}_{\boldsymbol{\xi}} + \frac{i}{2\pi} (\boldsymbol{\mathcal{K}}_1^{-1} - \boldsymbol{\mathcal{K}}_2^{-1}) \right] \right\}. \quad (18.204)$$

If the detector elements are small compared to the speckle blob size, then the determinants of integral operators reduce to determinants of matrices as discussed in Sec. 18.3.3 [see (18.157)]. In that case the log-likelihood ratio is a linear discriminant if

$$\det \left\{ \mathbf{I} + 2\pi i C \epsilon^2 \mathbf{K}_1 \left[\boldsymbol{\Xi} + \frac{i}{2\pi} \mathbf{A} \right] \right\} = \det \left\{ \mathbf{I} + 2\pi i C \epsilon^2 \mathbf{K}_1 \left[\boldsymbol{\Xi} + \frac{i}{2\pi C \epsilon^2} (\mathbf{K}_1^{-1} - \mathbf{K}_2^{-1}) \right] \right\}, \quad (18.205)$$

where \mathbf{K}_j and $\boldsymbol{\Xi}$ were defined in (18.155), and

$$[\mathbf{A}]_{\mathbf{m}\mathbf{m}'} = a_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'}. \quad (18.206)$$

Linear log-likelihoods: Example 1 As a first example of the use of this formalism, suppose that the detectors are small compared to a speckle blob, but sufficiently far apart that the measurements are uncorrelated. In that case we know already that the log-likelihood ratio is given by (18.196), but it is instructive to rederive that result from (18.205).

For uncorrelated measurements, we can write¹³

$$C \epsilon^2 [\mathbf{K}_j]_{\mathbf{m}\mathbf{m}'} = \bar{g}_{j\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'}. \quad (18.207)$$

¹³The reader who was expecting a variance instead of a mean on the right-hand side of (18.207) should recall that \mathbf{K}_j is the covariance of the field, not the covariance of the data. Thus $[\mathbf{K}_j]_{\mathbf{m}\mathbf{m}'} = \langle |u(\mathbf{r}_{\mathbf{m}})|^2 \rangle_j$, and the factor of $C \epsilon^2$ accounts for integration across the detector face and conversion of the result to an output signal.

Thus (18.205) is satisfied if $\mathbf{A} = (\mathbf{K}_1^{-1} - \mathbf{K}_2^{-1}) / (C\epsilon^2)$, or

$$a_{\mathbf{m}} = \frac{1}{\bar{g}_{1\mathbf{m}}} - \frac{1}{\bar{g}_{2\mathbf{m}}}, \quad (18.208)$$

in agreement with (18.196).

Linear log-likelihoods: Example 2 Next we consider small detectors without assuming they are widely spaced compared to a blob size. In this case the measurements are correlated, and we cannot satisfy (18.205) by taking $\mathbf{A} \propto \mathbf{K}_1^{-1} - \mathbf{K}_2^{-1}$ since the former is diagonal by definition but the latter is not diagonal. We can, however, show that the determinants are equal even though the operators are not if we assume that the difference signal is slowly varying on the spatial scale of the correlations, so we can use the quasistationary approximation of (18.115).

To be specific, suppose the lens has a square aperture of side L_{ap} , so that (18.115) becomes

$$K_j(\mathbf{r}, \mathbf{r}') \approx \ell_c^2 f_j(\mathbf{r}) \beta^2 \text{sinc}[\beta(\mathbf{r} - \mathbf{r}')] , \quad (18.209)$$

where the sinc function with a vector argument is just a product of two 1D sinc functions, and

$$\beta \equiv \frac{L_{ap}}{2\lambda f}. \quad (18.210)$$

Note that the argument of $f_j(\cdot)$ is written as \mathbf{r} in (18.209) and $\bar{\mathbf{r}}$ in (18.115); this difference is insignificant if $f_j(\mathbf{r})$ is slowly varying on the scale of the lens resolution, as it must be for (18.115) to be valid in the first place.

For detectors that are small compared to the blob size, the argument of the operator $\mathcal{K}_j \mathcal{W}_\xi$ becomes

$$[\mathcal{K}_j \mathcal{W}_\xi](\mathbf{r}, \mathbf{r}') \approx \ell_c^2 C \epsilon^2 \sum_{\mathbf{m}} \xi_{\mathbf{m}} f_j(\mathbf{r}_{\mathbf{m}}) \beta^2 \text{sinc}[\beta(\mathbf{r} - \mathbf{r}')] \delta(\mathbf{r}' - \mathbf{r}_{\mathbf{m}}). \quad (18.211)$$

Applied to an arbitrary image-plane irradiance $I_{im}(\mathbf{r})$, this operator yields

$$[\mathcal{K}_j \mathcal{W}_\xi \mathbf{I}_{im}](\mathbf{r}) = \ell_c^2 C \epsilon^2 \sum_{\mathbf{m}} \xi_{\mathbf{m}} f_j(\mathbf{r}_{\mathbf{m}}) \beta^2 \text{sinc}[\beta(\mathbf{r} - \mathbf{r}_{\mathbf{m}})] I_{im}(\mathbf{r}_{\mathbf{m}}). \quad (18.212)$$

This expression is a linear combination of the sinc functions, so the range of $\mathcal{K}_j \mathcal{W}_\xi$ is spanned by the set of functions $\{v_{\mathbf{m}}(\mathbf{r})\}$, where

$$v_{\mathbf{m}}(\mathbf{r}) \equiv \beta \text{sinc}[\beta(\mathbf{r} - \mathbf{r}_{\mathbf{m}})] . \quad (18.213)$$

The orthonormality of this set,

$$(v_{\mathbf{m}}, v_{\mathbf{m}'}) \equiv \int_{\infty} d^2 r v_{\mathbf{m}}(\mathbf{r}) v_{\mathbf{m}'}(\mathbf{r}) = \delta_{\mathbf{m}\mathbf{m}'}, \quad (18.214)$$

can be verified by use of Parseval's theorem. (It helps to assume that $\beta\epsilon$ is an integer, though it suffices to say that $\beta\epsilon$ is large.)

Since $\text{sinc}[\beta(\mathbf{r} - \mathbf{r}_{\mathbf{m}})]$ is reproduced by convolving it with $\beta^2 \text{sinc}(\beta\mathbf{r})$, the range of $\mathcal{K}_j \mathcal{W}_\xi$ is a finite-dimensional reproducing-kernel Hilbert space (see Sec. 1.8), which we shall denote by \mathbb{K} . The projector onto \mathbb{K} is given by

$$\mathcal{P}_{\mathbb{K}} = \sum_{\mathbf{m}} \mathbf{v}_{\mathbf{m}} \mathbf{v}_{\mathbf{m}}^\dagger, \quad [\mathcal{P}_{\mathbb{K}}](\mathbf{r}, \mathbf{r}') = \beta^2 \sum_{\mathbf{m}} \text{sinc}[\beta(\mathbf{r} - \mathbf{r}_{\mathbf{m}})] \text{sinc}[\beta(\mathbf{r}' - \mathbf{r}_{\mathbf{m}})] . \quad (18.215)$$

Thus (18.199) becomes

$$\psi_{\mathbf{g}|H_j}(\boldsymbol{\xi}) = \frac{1}{\det(\mathcal{I} + 2\pi i \mathcal{P}_{\mathbb{K}} \mathcal{K}_j \mathcal{W}_{\boldsymbol{\xi}})} = \frac{1}{\det(\mathcal{I} + 2\pi i \mathcal{P}_{\mathbb{K}} \mathcal{K}_j \mathcal{W}_{\boldsymbol{\xi}} \mathcal{P}_{\mathbb{K}})}, \quad (18.216)$$

where the last step follows from (A.85) and the fact that $\mathcal{P}_{\mathbb{K}}^2 = \mathcal{P}_{\mathbb{K}}$.

Retracing the steps leading up to (18.204), we see that the log-likelihood ratio is a linear discriminant in the present problem if

$$\mathcal{P}_{\mathbb{K}} \mathcal{K}_1 \mathcal{W}_{\mathbf{a}} \mathcal{P}_{\mathbb{K}} = \mathcal{P}_{\mathbb{K}} \mathcal{K}_1 [(\mathcal{P}_{\mathbb{K}} \mathcal{K}_1)^{-1} - (\mathcal{P}_{\mathbb{K}} \mathcal{K}_2)^{-1}]. \quad (18.217)$$

The kernel of the left-hand side of this equation is

$$[\mathcal{P}_{\mathbb{K}} \mathcal{K}_1 \mathcal{W}_{\mathbf{a}} \mathcal{P}_{\mathbb{K}}](\mathbf{r}, \mathbf{r}') = \ell_c^2 C \epsilon^2 \beta^4 \sum_{\mathbf{m}} a_{\mathbf{m}} f_1(\mathbf{r}_{\mathbf{m}}) \text{sinc}[\beta(\mathbf{r} - \mathbf{r}_{\mathbf{m}})] \text{sinc}[\beta(\mathbf{r}' - \mathbf{r}_{\mathbf{m}})]. \quad (18.218)$$

To find the kernel of the right-hand side, note that

$$\begin{aligned} & [\mathcal{P}_{\mathbb{K}} \mathcal{K}_j](\mathbf{r}, \mathbf{r}') \\ &= \ell_c^2 C \epsilon^2 \beta^4 \sum_{\mathbf{m}} \text{sinc}[\beta(\mathbf{r} - \mathbf{r}_{\mathbf{m}})] \int d^2 r'' \text{sinc}[\beta(\mathbf{r}'' - \mathbf{r}_{\mathbf{m}})] f_j(\mathbf{r}'') \text{sinc}[\beta(\mathbf{r}'' - \mathbf{r}')] \\ &\approx \ell_c^2 C \epsilon^2 \beta^2 \sum_{\mathbf{m}} f_j(\mathbf{r}_{\mathbf{m}}) \text{sinc}[\beta(\mathbf{r} - \mathbf{r}_{\mathbf{m}})] \text{sinc}[\beta(\mathbf{r}' - \mathbf{r}_{\mathbf{m}})]. \end{aligned} \quad (18.219)$$

It follows from the orthonormality of the basis functions that

$$\left[(\mathcal{P}_{\mathbb{K}} \mathcal{K}_j)^{-1} \right](\mathbf{r}, \mathbf{r}') = \frac{\beta^2}{\ell_c^2 C \epsilon^2} \sum_{\mathbf{m}} \frac{1}{f_j(\mathbf{r}_{\mathbf{m}})} \text{sinc}[\beta(\mathbf{r} - \mathbf{r}_{\mathbf{m}})] \text{sinc}[\beta(\mathbf{r}' - \mathbf{r}_{\mathbf{m}})], \quad (18.220)$$

with the obvious assumption that $f_j(\mathbf{r}_{\mathbf{m}}) \neq 0$.

With these kernels, (18.217) becomes

$$\sum_{\mathbf{m}} \left[\ell_c^2 C \epsilon^2 a_{\mathbf{m}} f_1(\mathbf{r}_{\mathbf{m}}) - 1 + \frac{f_1(\mathbf{r}_{\mathbf{m}})}{f_2(\mathbf{r}_{\mathbf{m}})} \right] \text{sinc}[\beta(\mathbf{r} - \mathbf{r}_{\mathbf{m}})] \text{sinc}[\beta(\mathbf{r}' - \mathbf{r}_{\mathbf{m}})] = 0. \quad (18.221)$$

Thus

$$a_{\mathbf{m}} = \frac{1}{\ell_c^2 C \epsilon^2} \left[\frac{1}{f_1(\mathbf{r}_{\mathbf{m}})} - \frac{1}{f_2(\mathbf{r}_{\mathbf{m}})} \right], \quad (18.222)$$

which is equivalent to (18.208) since $\bar{g}_{j\mathbf{m}} = \ell_c^2 C \epsilon^2 f_j(\mathbf{r}_{\mathbf{m}})$ for a slowly varying object.

Thus the log-likelihood ratio is obtained by a simple matched filter, but matched to the difference in the reciprocal objects rather than the difference object itself. If the object has low contrast, so that $f_2(\mathbf{r}_{\mathbf{m}}) - f_1(\mathbf{r}_{\mathbf{m}})$ is small and $f_1(\mathbf{r}_{\mathbf{m}})$ and $f_2(\mathbf{r}_{\mathbf{m}})$ are approximately constant over the signal region, then the log-likelihood is a simple non-prewhitening (NPW) matched filter. Perhaps surprisingly, no prewhitening is needed in spite of the correlations, basically because a sinc correlation corresponds to a flat power spectrum.

For examples of the use of NPW matched filters in SKE/BKE detection problems in speckle, see Smith *et al.* (1983) and Silverstein and O'Donnell (1988).

Gaussian approximations As we have just seen, it can be quite difficult to manipulate the expressions for speckle characteristic functions when the detectors are pointlike and there is no electronic or photon noise. Fortunately, the problems get easier, not harder, when some of these other effects are included, mainly because Gaussian statistics rapidly become applicable. We saw in Sec. 18.3.3 that the statistics of the detector output approach Gaussian when the detector area is much larger than the speckle blob size, essentially because the detector averages over many independent regions. In this same limit, as we saw in Sec. 18.4.1, the photon-counting statistics become Poisson, but Poissons are well approximated by Gaussians if the mean number of counts in an observation time is large. Finally, if we consider additive electronic noise as in Sec. 18.4.2, there is an additional Gaussian PDF to be convolved with the PDF of the detector output, making the overall PDF more nearly Gaussian.

Thus, the main use of the elegant characteristic functions presented here may be nothing more than providing expressions for the covariance matrix in many practical circumstances. Much further work is needed, however, to determine when more detailed statistical knowledge is useful in task performance.

Hotelling observer When the data statistics are Gaussian and the signal is weak enough that the covariance is the same under both hypotheses, we know that the ideal observer is the linear Hotelling observer, and the relevant figure of merit is the Hotelling trace or SNR. As we have seen in earlier chapters, however, we often use the Hotelling observer even when we cannot argue convincingly that the data are Gaussian. In the speckle context, that situation could arise with small detectors or short exposure times, and it almost certainly arises when object variability is considered.

If the BKE statistics are Gaussian but the objects demonstrate complicated, non-Gaussian statistics, then we must have recourse to sampling methods as discussed in Sec. 14.3.2. In applying these methods to speckle problems, the decomposition of the covariance matrix in (18.193) is useful since the Poisson term in that expression is diagonal and will usually be known analytically. Similarly, the second term in (18.193)—the so-called noise-free covariance—can often be analyzed by the methods of this chapter; though it is not diagonal, it will have only short-range correlations. That leaves the object-variability term to be estimated by sampling methods. There is nothing special about applying these methods to speckle problems, and they will not be discussed further here.

Channelized observer models As we know from Sec. 14.3.2, estimation of computation of the performance of the Hotelling observer (or optimal linear discriminant function) purely by sampling methods is difficult if the dimensionality of the data vector is large, as when the input to the discriminant is the output of a large detector array. Similarly, as we discussed in Sec. 14.3.3, computation of the performance of the ideal observer is difficult in high-dimensional problems since huge multivariate probability density functions are required. In both cases, dimensionality reduction or feature extraction is very helpful. Linear features derived from channels are particularly useful since the statistics of the channel outputs are readily related to the statistics of the data or even the underlying object.

In particular, (14.88) gives the transformation law for determining the characteristic function of a channel output vector when the characteristic functional for

the objects is known and the system is linear. How this transformation rule is used in speckle problems depends on whether the detector integrates amplitude or irradiance. In the optical case, with irradiance-sensitive detectors, we can transform a characteristic function like (18.216) through the linear channels. With amplitude-sensitive detectors like the ones to be discussed in more detail in Sec. 18.6, we can go from the characteristic functional for the field distribution at the detector face all the way to the channel outputs.

In either case we can use the statistics of the channel outputs to compute the performance of channelized Hotelling or channelized ideal observers. Though this program has not yet been implemented, it appears to be an excellent way of taking advantage of the analytical results of this chapter.

Hybrid estimation-classification tasks As we discussed in Secs. 13.1.1 and 13.3.8, classification tasks are often performed with estimated object parameters as features. In many pattern-recognition problems, we are interested in small-scale features or texture of the object, but it is not obvious how coherent imagery can give us that kind of information. Indeed, as far as our analysis to this point goes, all rough objects are essentially equivalent. They all fully randomize the phase of the transmitted or reflected wave, and they all give rise to circular Gaussian statistics for the field.

Nevertheless, there is a huge literature on extracting texture information from coherent imagery, especially in the context of medical ultrasound or synthetic-aperture radar. The key to that endeavor is to recognize the limitations of the circular-Gaussian models. As we shall see in Sec. 18.5, many interesting new statistical distributions arise when we do not assume that the number of independent scattering elements within the area of the coherent PRF is large.

18.5 POINT-SCATTERING MODELS AND NON-GAUSSIAN SPECKLE

The development in this chapter so far has been based on the assumption that a ground glass completely randomizes the phase of a light wave and that the autocovariance function of the ground-glass transmittance is sharply peaked and can be approximated as a delta function. In other words, we have regarded the transmittance as a white-noise random process, and we haven't been very specific about the point statistics of that process. We were able to avoid being more specific about the ground glass since we invoked the central-limit theorem to argue that the field in an observation plane was always circular Gaussian. As we noted, however, that argument is suspect in an imaging system if the area of the PSF encompasses only a few correlation lengths of the ground glass.

In this section we shall adopt a different view of the object, assuming that it consists of a set of discrete point scatterers at random locations and possibly with random scattering amplitudes. A natural mathematical description of the object is thus a random point process, a topic we discussed at considerable length in Chap. 11. If we assume that the scattering points are statistically independent, we are led to describe the object as a Poisson point process, though necessarily a nonstationary one in interesting imaging situations. As in Chap. 11, however, there is also considerable interest in doubly stochastic point processes where the density of points is itself a random process.

Point-scattering models may be more applicable to reflection imaging than to transmission through a ground glass. Consider, for example, airborne imaging of a field of grass with a laser illuminator or microwave radar. Most of the radiation emitted from the aircraft will be forward scattered and eventually absorbed in the grass. Occasionally, however, a blade of grass will be oriented approximately normal to the incident direction and reflect the radiation back towards the imaging system in the aircraft. The object being imaged thus consists effectively of bright points or *glints*, and the amplitude and phase of each glint depend on the random position and orientation of the blade of grass.

Point-scattering models are also frequently used in medical ultrasound of soft organs. Red blood cells and liver lobules, for example, might be modeled as scattering points if they are small compared to the ultrasound wavelength. Phantoms consisting of small, dense points in gelatinous media can produce ultrasound speckle patterns that mimic well the speckle seen in actual tissue.

Our goal in this section is to recapitulate Sec. 18.3 but with point-scattering models in place of the delta-correlated ground glass assumed there. The result will be that the speckle field is not circular Gaussian, so we refer to the subject of this section as non-Gaussian speckle. Another common term is non-Rayleigh speckle, which refers to the fact that the square root of the irradiance does not follow a Rayleigh law, so the irradiance itself is not exponentially distributed.

Sec. 18.5.1 provides a general point-process description of the object field, states some statistical assumptions and derives the characteristic functional for the field. In Sec. 18.5.2 we propagate this object field to an image plane and determine its characteristic functional, but without the Gaussian approximation used in Sec. 18.3.2. Sec. 18.5.3 specializes the infinite-dimensional statistical description of the field in the previous section to univariate statistics of the field and irradiance at a single point.

18.5.1 Object fields and objects

All treatments of point-scattering models in the speckle literature express the object field as

$$u_{obj}(\mathbf{r}) = \sum_{n=1}^N a_n \exp(i\phi_n) \delta(\mathbf{r} - \mathbf{r}_n), \quad (18.223)$$

but different physical situations require different mechanistic justifications of the model and different interpretation of the parameters. Key to all interpretations, however, is the realization that the delta function does not represent literally an object of infinitesimal width but merely something small compared to the resolution of the imaging system.

Consider, for example, a reflecting surface consisting of small flats or facets as shown in Fig. 18.4. For simplicity, we assume that all facets are parallel to the plane $z = 0$ and that the n^{th} facet is a distance h_n from that reference plane. If this surface is illuminated by a unit-amplitude plane wave at normal incidence, then the wave propagates a distance $2h_n$ from $z = 0$ to the facet and back to $z = 0$. The phase shift relative to the phase of the incident wave at $z = 0$ is thus

$$\phi_n = \frac{2\pi}{\lambda} 2h_n, \quad (18.224)$$

where λ is the free-space wavelength of the radiation. Comparing this result to (18.7) we see that the phase shift in reflection is several times larger than in transmission for the same surface relief; in reflection the light travels twice as far, and in transmission the phase shift is reduced by a factor of $n_g - 1$ (with n_g being the refractive index of the glass, a number around 1.5) since phase is measured relative to what it would be in the absence of the ground glass.

Fig. 18.4 Facet model for a reflecting surface.

If each facet is small compared to the resolution of the imaging system, then the field reflected from the facet can be treated as a spatial delta function. The amplitude a_n can then be interpreted as the amplitude reflectivity of the facet times its area. If the facets are at different angles, then a_n can also include the fraction of the light reflected towards the detector.

Another common situation where the point-scattering model of (18.223) is invoked is in scattering from aerosol particles in the atmosphere. In this case the phase shift arises, at least in part, from the random position of the aerosol particle in the illuminating field. We can write

$$u_{obj}(\mathbf{r}) = u_{inc}(\mathbf{r}) \sum_{n=1}^N a_n \delta(\mathbf{r} - \mathbf{r}_n) = \sum_{n=1}^N a_n \exp[i\Phi(\mathbf{r}_n)] \delta(\mathbf{r} - \mathbf{r}_n), \quad (18.225)$$

where we have assumed that the incident wave is described by the pure-phase function $u_{inc}(\mathbf{r}) = \exp[i\Phi(\mathbf{r})]$ and used a property of delta functions, (2.119). Thus the phase ϕ_n in this view is simply the phase of the illumination at the scattering point.

Defining the object Whatever the interpretation of the parameters in the object field, we must still specify just what we mean by “the object.” One approach would be to identify $f(\mathbf{r})$ as the mean number of scattering points per unit area, which we

denoted in Chap. 11 as $b(\mathbf{r})$. From (11.83), we know that $b(\mathbf{r})$ is the mean of the random sum of delta functions with unit weights:

$$b(\mathbf{r}) = \left\langle \sum_{n=1}^N \delta(\mathbf{r} - \mathbf{r}_n) \right\rangle. \quad (18.226)$$

In the present problem with complex weights, even if we define the object by $f(\mathbf{r}) = b(\mathbf{r})$, we cannot say that it is the mean of the object field; in fact, $\langle u_{obj}(\mathbf{r}) \rangle = 0$ if the phases are uniformly distributed on $(-\pi, \pi)$.

An alternative is to associate the object with the squared modulus of the scattering amplitude. Then the object field would take the form,

$$u_{obj}(\mathbf{r}) = \sum_{n=1}^N \sqrt{f(\mathbf{r}_n)} \exp(i\phi_n) \delta(\mathbf{r} - \mathbf{r}_n) = \sqrt{f(\mathbf{r})} \sum_{n=1}^N \exp(i\phi_n) \delta(\mathbf{r} - \mathbf{r}_n). \quad (18.227)$$

This definition is appealing since it expresses the object field as something associated with the object of interest times a random point process that we want to regard as noise; exactly this motivation led us in Sec. 18.3 to think of the object as a transparency placed over a ground glass. A disadvantage of (18.227), however, is that the object is independent of the density of scatterers, which might be of considerable interest.

We can combine the ideas behind (18.226) and (18.227) by defining the object as the mean density of scattering points times the average of the square of the scattering amplitude: $f(\mathbf{r}) \equiv b(\mathbf{r}) \langle a_n^2 \rangle$, where the expectation is defined with respect to a spatially varying PDF so it is a function of \mathbf{r} . As we shall see in Sec. 18.5.2, this quantity arises naturally when we study the statistics of the image field.

A more general way of modeling an object as a random point process is to give up on the scalar description and say that more than one characteristic of the object at each point is of interest, in which case the object is a vector-valued function (see Sec. 7.1.1). We could, for example, consider both the density of scattering points and the mean scattering amplitude as object characteristics of interest and define the components of an object vector by $f_1(\mathbf{r}) \equiv b(\mathbf{r})$ and $f_2(\mathbf{r}) \equiv \langle a_n \rangle$.

We shall not pursue the idea of a vector-valued object further, but instead focus on the scalar object field in what follows.

Statistical assumptions Since the object field is a complex random process, its characteristic functional is defined as in (18.19) by

$$\Psi_{\mathbf{u}_{obj}}(\boldsymbol{\xi}) \equiv \left\langle \exp \left[-i\pi \left(\boldsymbol{\xi}^\dagger \mathbf{u}_{obj} + \mathbf{u}_{obj}^\dagger \boldsymbol{\xi} \right) \right] \right\rangle, \quad (18.228)$$

where the average in its most general form is over $\{\mathbf{r}_n\}$, $\{a_n\}$, $\{\phi_n\}$, N itself, and the density $b(\mathbf{r})$. Once we have this characteristic functional, we can get the one for the image-plane field by use of (18.96), so our immediate task is to specify probability laws for the random variables and carry out the average in (18.228).

As usual in dealing with point processes, we assume that the points are statistically independent and identically distributed. If we assume further that the parameters of an individual point, \mathbf{r}_n , a_n and ϕ_n are independent of each other,¹⁴

¹⁴The assumption that ϕ_n is independent of \mathbf{r}_n does not hold if the phase is determined simply by the position of the scattering point in the illumination field. In that case it might be valid to

the conditional density on these variables for a fixed N becomes

$$\text{pr}[\{\mathbf{r}_n\}, \{a_n\}, \{\phi_n\} | N] = \prod_{n=1}^N \text{pr}(\mathbf{r}_n) \text{pr}(a_n) \text{pr}(\phi_n). \quad (18.229)$$

The joint density on all variables, including N , is thus

$$\begin{aligned} & \text{pr}[\{\mathbf{r}_n\}, \{a_n\}, \{\phi_n\}, N] \\ &= \text{pr}[\{\mathbf{r}_n\}, \{a_n\}, \{\phi_n\} | N] \text{Pr}(N) = \text{Pr}(N) \prod_{n=1}^N \text{pr}(\mathbf{r}_n) \text{pr}(a_n) \text{pr}(\phi_n). \end{aligned} \quad (18.230)$$

To specify the problem fully, we need to give the component PDFs in this product. From (11.84), we know that $b(\mathbf{r})$, with proper normalization, is the PDF for the locations of the scattering points, so

$$\text{pr}(\mathbf{r}_n) = \frac{b(\mathbf{r}_n)}{\int_{\mathbf{S}} d^2r' b(\mathbf{r}')} = \frac{1}{\overline{N}} b(\mathbf{r}_n), \quad (18.231)$$

where \mathbf{S} is the support of the object.

If we assume that the phases are fully randomized on $(-\pi, \pi)$, we can write

$$\text{pr}(\phi_n) = \frac{1}{2\pi} \text{rect}\left(\frac{\phi_n}{2\pi}\right). \quad (18.232)$$

Various forms might be used for $\text{pr}(a_n)$, but since a_n is the magnitude of a complex scattering amplitude, we must choose one that is defined for $0 \leq a_n < \infty$; log-normal, gamma and K-Bessel densities are possibilities. If the object is a collection of identical particles with scattering cross section σ , we would take $\text{pr}(a_n) = \delta(a_n - \sqrt{\sigma})$.

A natural choice for $\text{Pr}(N)$ is a Poisson of mean \overline{N} , but for more generality we can treat \overline{N} as random and write $\text{Pr}(N)$ in the form of a Poisson transform as defined in (11.25):

$$\text{Pr}(N) = \int_0^\infty d\overline{N} \text{Pr}(N|\overline{N}) \text{pr}(\overline{N}) = \frac{1}{N!} \int_0^\infty d\overline{N} \exp(-\overline{N}) \overline{N}^N \text{pr}(\overline{N}). \quad (18.233)$$

Like $\text{pr}(a_n)$, $\text{pr}(\overline{N})$ must be defined on $(0, \infty)$. The Poisson is recovered by taking $\text{pr}(\overline{N})$ as a delta function.

Characteristic functional for the object field Having assembled the needed probability laws, we turn next to computation of the characteristic functional for the object field. The development is similar to that in Sec. 11.3.10 but with the added complication of random amplitudes and phases.

In full generality, (18.228) can be written in the nested form,

$$\Psi_{\mathbf{u}_{obj}}(\boldsymbol{\xi}) \equiv \left\langle \left\langle \exp\left[-i\pi \left(\boldsymbol{\xi}^\dagger \mathbf{u}_{obj} + \mathbf{u}_{obj}^\dagger \boldsymbol{\xi}\right)\right] \right\rangle_{\{a_n\}, \{\phi_n\}, \{\mathbf{r}_n\} | N} \right\rangle_{N|\overline{N}} \Big/ \overline{N}. \quad (18.234)$$

assume that the actual position of the point was $\mathbf{r}_n + \Delta\mathbf{r}_n$, where $\Delta\mathbf{r}_n$ was several wavelengths but nevertheless small compared to the system resolution. Then the independence of ϕ_n and \mathbf{r}_n would be a reasonable model.

By use of the delta function in (18.223), we can rewrite the quantity being averaged as

$$\begin{aligned} \exp\left[-i\pi\left(\boldsymbol{\xi}^\dagger \mathbf{u}_{obj} + \mathbf{u}_{obj}^\dagger \boldsymbol{\xi}\right)\right] &= \prod_{n=1}^N \exp\left\{-i\pi a_n \left[\exp(i\phi_n) \xi^*(\mathbf{r}_n) + \exp(-i\phi_n) \xi(\mathbf{r}_n)\right]\right\} \\ &= \prod_{n=1}^N \exp\left\{-2\pi i a_n |\xi(\mathbf{r}_n)| \cos[\phi_n - \phi_\xi(\mathbf{r}_n)]\right\}, \end{aligned} \quad (18.235)$$

where $\xi(\overline{\mathbf{r}_n}) = |\xi(\mathbf{r}_n)| \exp[i\phi_\xi(\mathbf{r}_n)]$.

Since we are assuming that the point parameters are independent and identically distributed, the innermost expectation in (18.234) becomes

$$\begin{aligned} &\left\langle \exp\left[-i\pi\left(\boldsymbol{\xi}^\dagger \mathbf{u}_{obj} + \mathbf{u}_{obj}^\dagger \boldsymbol{\xi}\right)\right] \right\rangle_{\{a_n\}, \{\phi_n\}, \{\mathbf{r}_n\} | N} \\ &= \left[\left\langle \exp\left\{-2\pi i a_n |\xi(\mathbf{r}_n)| \cos[\phi_n - \phi_\xi(\mathbf{r}_n)]\right\} \right\rangle_{a_n, \phi_n, \mathbf{r}_n} \right]^N. \end{aligned} \quad (18.236)$$

This step does not imply that the process is stationary in any sense, just that the individual scatterers are indistinguishable; in other words, $\text{pr}(\mathbf{r}_n)$ is not necessarily constant over the support.

With (18.232) and a change of variables, the average over ϕ_n yields

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} d\phi \exp(-2\pi i a_n |\xi(\mathbf{r}_n)| \cos \phi) = J_0(2\pi a_n |\xi(\mathbf{r}_n)|), \quad (18.237)$$

where $J_0(\cdot)$ is the zeroth-order Bessel function of the first kind. Note that the phase of $\xi(\mathbf{r}_n)$ has disappeared.

With (18.231) as the PDF on \mathbf{r}_n and a generic PDF for a_n , we can now write

$$\begin{aligned} &\left\langle \exp\left\{-2\pi i a_n |\xi(\mathbf{r}_n)| \cos[\phi_n - \phi_\xi(\mathbf{r}_n)]\right\} \right\rangle_{a_n, \phi_n, \mathbf{r}_n} \\ &= \frac{1}{N} \int_0^\infty da_n \text{pr}(a_n) \int_{\mathbf{S}} d^2 r_n b(\mathbf{r}_n) J_0(2\pi a_n |\xi(\mathbf{r}_n)|). \end{aligned} \quad (18.238)$$

Combining (18.234), (18.236) and (18.238), we obtain

$$\Psi_{\mathbf{u}_{obj}}(\boldsymbol{\xi}) = \left\langle \left\langle \left[\frac{1}{N} \int_0^\infty da_n \text{pr}(a_n) \int_{\mathbf{S}} d^2 r_n b(\mathbf{r}_n) J_0(2\pi a_n |\xi(\mathbf{r}_n)|) \right]^N \right\rangle_{N|\overline{N}} \right\rangle_{\overline{N}}. \quad (18.239)$$

The expectation over N for fixed \overline{N} can be performed as in Sec. 11.3.10, with the result

$$\begin{aligned} &\left\langle \left\{ \frac{1}{\overline{N}} \int_0^\infty da_n \text{pr}(a_n) \int_{\mathbf{S}} d^2 r_n b(\mathbf{r}_n) J_0[2\pi a_n |\xi(\mathbf{r}_n)|] \right\}^N \right\rangle_{N|\overline{N}} \\ &= \exp\left\{-\overline{N} + \int_0^\infty da_n \text{pr}(a_n) \int_{\mathbf{S}} d^2 r_n b(\mathbf{r}_n) J_0[2\pi a_n |\xi(\mathbf{r}_n)|]\right\}. \end{aligned} \quad (18.240)$$

Since \bar{N} is determined by the integral of the density of scatterers [see (18.231)], the remaining expectation is really over realizations of $b(\mathbf{r})$, so we can write

$$\Psi_{\mathbf{u}_{obj}}(\boldsymbol{\xi}) = \left\langle \exp \left\{ - \int_{\mathbf{S}} d^2r b(\mathbf{r}) + \int_0^\infty da_n \text{pr}(a_n) \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) J_0[2\pi a_n |\boldsymbol{\xi}(\mathbf{r}_n)|] \right\} \right\rangle_{\mathbf{b}}. \quad (18.241)$$

Sometimes we want to regard $b(\mathbf{r})$ as nonrandom; for example, if we define the object by $f(\mathbf{r}) = b(\mathbf{r})$ and consider just a single object, the average over \mathbf{b} in (18.241) is not needed. In those cases, we shall use a conditional characteristic functional given by

$$\begin{aligned} \Psi_{\mathbf{u}_{obj}|\mathbf{b}}(\boldsymbol{\xi}) &= \exp \left\{ - \int_{\mathbf{S}} d^2r b(\mathbf{r}) + \int_0^\infty da_n \text{pr}(a_n) \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) J_0[2\pi a_n |\boldsymbol{\xi}(\mathbf{r}_n)|] \right\} \\ &= \exp \left\{ -\bar{N} + \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) \langle J_0[2\pi a_n |\boldsymbol{\xi}(\mathbf{r}_n)|] \rangle_{a_n} \right\}. \end{aligned} \quad (18.242)$$

This form should be compared to the characteristic functional for a Poisson point process with constant weights, given in (11.150) and rewritten here as

$$\Psi_{\mathbf{g}}(\mathbf{s}) = \exp \left\{ -\bar{N} + \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) \exp[-2\pi i s(\mathbf{r}_n)] \right\}. \quad (18.243)$$

The key differences are the additional average over a_n in (18.242), the appearance there of the Bessel function rather than the complex exponential, and the use of a complex argument $\boldsymbol{\xi}(\mathbf{r})$ in place of the real function $s(\mathbf{r})$ in (18.243). Curiously, (18.242) is pure real even though $\boldsymbol{\xi}(\mathbf{r})$ is complex, and (18.243) is complex even though $s(\mathbf{r})$ is real.

18.5.2 Image fields

Since coherent imaging is a linear transformation of the object field to the image field, the characteristic functional for the latter can be found from a transformation rule like (18.96). For an arbitrary coherent imaging system with space-variant PSF $p_{coh}(\mathbf{r} - \mathbf{r}'; \mathbf{r}')$, we can write

$$u_{im}(\mathbf{r}) = \int_{\mathbf{S}} d^2r' p_{coh}(\mathbf{r} - \mathbf{r}'; \mathbf{r}') u_{obj}(\mathbf{r}') = \sum_n a_n \exp(i\phi_n) p_{coh}(\mathbf{r} - \mathbf{r}_n; \mathbf{r}_n). \quad (18.244)$$

In terms of the coherent imaging operator \mathcal{P}_{coh} , we have

$$\mathbf{u}_{im} = \mathcal{P}_{coh} \mathbf{u}_{obj} \quad \text{or} \quad u_{im}(\mathbf{r}) = [\mathcal{P}_{coh} \mathbf{u}_{obj}](\mathbf{r}). \quad (18.245)$$

With this operator and (18.96), we see that

$$\Psi_{\mathbf{u}_{im}}(\boldsymbol{\xi}) = \Psi_{\mathbf{u}_{obj}}(\mathcal{P}_{coh}^\dagger \boldsymbol{\xi}). \quad (18.246)$$

Explicitly, with (18.241),

$$\Psi_{\mathbf{u}_{im}}(\boldsymbol{\xi}) = \left\langle \exp \left\{ -\bar{N} + \int_0^\infty da_n \text{pr}(a_n) \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) J_0 \left[2\pi a_n |[\mathcal{P}_{coh}^\dagger \boldsymbol{\xi}](\mathbf{r}_n)| \right] \right\} \right\rangle_{\mathbf{b}}. \quad (18.247)$$

This result is our most general statement of the statistics of the image-plane field. It is a modest extension of an expression obtained by Zardecki and Delisle (1977), who considered only free-space propagation and not an imaging system. In what follows we shall consider some additional approximations and special cases of this result.

The Gaussian limit In Sec. 18.2.4 we went through a lengthy derivation of the central-limit theorem for a coherently illuminated ground glass. The result was that the image-plane field approached a circular Gaussian random process if the ground glass had many independent regions within the area defined by the coherent PSF. A similar derivation for the present object model would show that the image field was circular Gaussian if the number of scattering points within the PSF area was large. Rather than presenting that derivation, however, we give here a heuristic argument which will suffice to determine the form of the circular Gaussian.

The starting point for the heuristic argument is that $\Psi_{\mathbf{u}_{im}}(\boldsymbol{\xi})$, like all characteristic functionals, must be unity when $\boldsymbol{\xi}(\mathbf{r}) = 0$ for all \mathbf{r} . To see this point for (18.247), note that the Bessel function is identically one if $\boldsymbol{\xi}(\mathbf{r}) = 0$ and hence $[\mathcal{P}_{coh}\boldsymbol{\xi}](\mathbf{r}) = 0$. Then the integral over a_n yields unity and the one over \mathbf{r}_n yields \bar{N} , neatly cancelling the other \bar{N} in the exponent. If there are some regions for which $[\mathcal{P}_{coh}\boldsymbol{\xi}](\mathbf{r}) \neq 0$, however, the cancellation is not exact, and in that case the exponential rapidly approaches zero as \bar{N} gets large. Thus, as in our previous treatments of the central-limit theorem (see Secs. 8.3.4 and 18.2.4), the basic calculation is to expand the exponent in a power series and retain terms linear and quadratic in the frequency variable.

The requisite expansion for the present problem is

$$J_0(z) = \sum_{k=0}^{\infty} \frac{\left(-\frac{1}{4}z^2\right)^k}{(k!)^2} = 1 - \frac{1}{4}z^2 + \dots \tag{18.248}$$

If we truncate this expansion, then the conditional characteristic functional of the image field for fixed \mathbf{b} , *i.e.*, (18.247) without the final average, becomes

$$\begin{aligned} \Psi_{\mathbf{u}_{im}|\mathbf{b}}(\boldsymbol{\xi}) &= \exp \left\{ -\bar{N} + \int_0^{\infty} da_n \text{pr}(a_n) \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) \left[1 - \pi^2 a_n^2 |[\mathcal{P}_{coh}^\dagger \boldsymbol{\xi}](\mathbf{r}_n)|^2 \right] \right\} \\ &= \exp \left\{ -\pi^2 \langle a_n^2 \rangle \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) |[\mathcal{P}_{coh}^\dagger \boldsymbol{\xi}](\mathbf{r}_n)|^2 \right\}, \end{aligned} \tag{18.249}$$

where in the last step we have used the fact that $b(\mathbf{r}_n)$ is the mean number of points per unit area, so its integral over the whole field is just \bar{N} . The integral in the exponent can be written in detail as

$$\begin{aligned} &\int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) |[\mathcal{P}_{coh}^\dagger \boldsymbol{\xi}](\mathbf{r}_n)|^2 \\ &= \int_{\mathbf{S}} d^2r \xi^*(\mathbf{r}) \int_{\mathbf{S}} d^2r' \xi(\mathbf{r}') \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) p_{coh}(\mathbf{r}-\mathbf{r}_n; \mathbf{r}_n) p_{coh}^*(\mathbf{r}'-\mathbf{r}_n; \mathbf{r}_n). \end{aligned} \tag{18.250}$$

Thus (18.249) becomes [*cf.* (18.97)]

$$\Psi_{\mathbf{u}_{im}|\mathbf{b}}(\boldsymbol{\xi}) = \exp \left(-\pi^2 \boldsymbol{\xi}^\dagger \mathcal{K}_{\mathbf{u}_{im}} \boldsymbol{\xi} \right), \tag{18.251}$$

where $\mathcal{K}_{\mathbf{u}_{im}}$ is the autocovariance operator for the image field, with a kernel given by

$$K_{\mathbf{u}_{im}}(\mathbf{r}, \mathbf{r}') = \langle a_n^2 \rangle \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) p_{coh}(\mathbf{r} - \mathbf{r}_n; \mathbf{r}_n) p_{coh}^*(\mathbf{r}' - \mathbf{r}_n; \mathbf{r}_n). \quad (18.252)$$

This result is identical with (18.100) if we replace $\ell_c^2 |t_{obj}(\mathbf{r})|^2$ with $\langle a_n^2 \rangle b(\mathbf{r})$. Thus a natural quantity to call an object is the mean density of scattering points times the average of the square of the scattering amplitude.

For a more formal discussion of the Gaussian limit, see Zardecki and Delisle (1977); they in turn cite Lord Rayleigh (1919).

Gaussian mixtures To get the full characteristic functional for the field in the limit of a large number of scatterers, we must still average (18.252) over realizations of the density \mathbf{b} . Since \mathbf{u}_{im} has zero mean for each \mathbf{b} , we are averaging zero-mean Gaussian characteristic functionals with respect to variations in their covariance matrices. We encountered this situation in Sec. 8.4.3 where we argued that the output of high-pass or band-pass filters applied to many kinds of images could be viewed as mixtures of zero-mean Gaussians, and we showed that the resulting PDFs had long tails and cusps at the origin. A similar behavior can be expected for the field PDFs in speckle problems without the need for overt filtration since the speckle field naturally has zero mean.

In summary, if the density of scatters, $b(\mathbf{r})$, is nonrandom and large so that $\overline{N_0} \rightarrow \infty$, then a circular Gaussian is expected for the field regardless of the statistics of a_n . If $b(\mathbf{r})$ and hence $\overline{N_0}$ are themselves random, however, then non-Gaussian fields can be expected. Moreover, as cautioned by Jakeman and Pusey (1976), large variations in a_n can lead to non-Gaussian behavior if $\overline{N_0}$ is large but not approaching infinity since then only a small fraction of the scatterers may contribute to the image field.

18.5.3 Univariate statistics of the image field and irradiance

If we evaluate the random process $u_{im}(\mathbf{r})$ at a particular point $\mathbf{r} = \mathbf{R}_0$, the resulting complex number is a random variable described by the univariate characteristic function $\psi_{u_{im}(\mathbf{R}_0)}(\nu)$ rather than the infinite-dimensional characteristic functional $\Psi_{\mathbf{u}_{im}}(\boldsymbol{\xi})$. We know from the discussion in Sec. 18.2.5, however, that the univariate characteristic function for $u_{im}(\mathbf{R}_0)$ is obtained from the characteristic functional by setting $\boldsymbol{\xi}(\mathbf{r}) = \nu \delta(\mathbf{r} - \mathbf{R}_0)$ [cf. (18.75)]. Making this substitution in (18.247) and performing an integral with the delta function, we obtain

$$\begin{aligned} & \psi_{u_{im}(\mathbf{R}_0)}(\nu) \\ &= \left\langle \exp \left\{ -\overline{N} + \int_0^\infty da_n \text{pr}(a_n) \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) J_0[2\pi a_n |\nu p_{coh}(\mathbf{R}_0 - \mathbf{r}_n; \mathbf{r}_n)|] \right\} \right\rangle_{\mathbf{b}}. \end{aligned} \quad (18.253)$$

We can get all moments of the field at point \mathbf{R}_0 from this equation, and we can also get all moments of the irradiance since $\langle [I_{im}(\mathbf{R}_0)]^n \rangle = \langle [u_{im}(\mathbf{R}_0)u_{im}^*(\mathbf{R}_0)]^n \rangle$. For ways of handling the complicated Fréchet derivatives involved in the moment calculations, see the appendix in Zardecki and Delisle (1977).

Micro-area approximation It is difficult to derive analytical results from the general expression (18.253), or even to gain qualitative insights, without further approximation. One common approach is the *micro-area approximation* suggested by Jakeman and Pusey in the 1970s. (For a review, see Jakeman and Tough, 1988.) Zardecki and Delisle (1977) go so far as to say that this model “appears to be the only feasible way of dealing with higher-order statistics.”

The essence of the micro-area approximation is to ignore the detailed structure of the coherent PSF and replace $|p_{coh}(\mathbf{R}_0 - \mathbf{r}_n; \mathbf{r}_n)|$ in (18.253) by a uniform disc or cylinder function. The main statistical effect is then fluctuations of the number of point scatterers in the disc area.

To be more precise, we approximate the PSF as

$$|p_{coh}(\mathbf{R}_0 - \mathbf{r}_n; \mathbf{r}_n)| \approx |p_{coh}(\mathbf{0}; \mathbf{R}_0)| \text{cyl} \left[\frac{|\mathbf{R}_0 - \mathbf{r}_n|}{D(\mathbf{R}_0)} \right], \quad (18.254)$$

where the cylinder function is defined in (3.257), and the diameter of the disc is determined such that

$$\int_{\mathbf{S}} d^2r_n |p_{coh}(\mathbf{R}_0 - \mathbf{r}_n; \mathbf{r}_n)| \text{cyl} \left[\frac{|\mathbf{R}_0 - \mathbf{r}_n|}{D(\mathbf{R}_0)} \right] = |p_{coh}(\mathbf{0}; \mathbf{R}_0)| \frac{\pi D^2(\mathbf{R}_0)}{4}. \quad (18.255)$$

Using this approximation and noting that $J_0(0) = 1$, we can write the integral over \mathbf{r}_n in (18.253) as

$$\begin{aligned} & \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) J_0[2\pi a_n |\nu p_{coh}(\mathbf{R}_0 - \mathbf{r}_n; \mathbf{r}_n)|] \\ & \approx \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) + \{J_0[2\pi a_n |\nu p_{coh}(\mathbf{0}; \mathbf{R}_0)|] - 1\} \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) \text{cyl} \left[\frac{|\mathbf{R}_0 - \mathbf{r}_n|}{D(\mathbf{R}_0)} \right] \\ & = \bar{N} + \bar{N}_0 \{J_0[2\pi a_n |\nu p_{coh}(\mathbf{0}; \mathbf{R}_0)|] - 1\}, \end{aligned} \quad (18.256)$$

where

$$\bar{N} \equiv \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n), \quad \bar{N}_0 \equiv \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) \text{cyl} \left[\frac{|\mathbf{R}_0 - \mathbf{r}_n|}{D(\mathbf{R}_0)} \right]. \quad (18.257)$$

Thus \bar{N} is the mean number of scatterers in the entire object support, and \bar{N}_0 is the mean number in the disc centered on point \mathbf{R}_0 . Though the notation does not show it, \bar{N}_0 can be a function of \mathbf{R}_0 in general.

With (18.256), the univariate characteristic function of (18.253) becomes

$$\begin{aligned} \psi_{u_{im}}(\mathbf{R}_0)(\nu) &= \left\langle \exp \left\{ -\bar{N}_0 + \bar{N}_0 \int_0^\infty da_n \text{pr}(a_n) J_0[2\pi a_n |\nu p_{coh}(\mathbf{0}; \mathbf{R}_0)|] \right\} \right\rangle_{\mathbf{b}} \\ &= \left\langle \exp \left\{ -\bar{N}_0 + \bar{N}_0 \bar{J}_0[2\pi a_n |\nu p_{coh}(\mathbf{0}; \mathbf{R}_0)|] \right\} \right\rangle_{\bar{N}_0}, \end{aligned} \quad (18.258)$$

where the overbar on the Bessel function implies an average over the only remaining random variable in its argument, the scattering amplitude a_n . Note that the total number of scatterers, \bar{N} , no longer appears; it cannot since scatterers outside the disc defined by the PSF make no contribution to the field at the observation point \mathbf{R}_0 . Moreover, the average over \mathbf{b} is now equivalent to an average over \bar{N}_0 , and the notation has been changed accordingly on the last line of (18.258).

The micro-area approximation can also be applied to multi-point statistics. To get the joint characteristic function for the field at K points, $\{\mathbf{r} = \mathbf{R}_k, k = 1, \dots, K\}$, we set

$$\xi(\mathbf{r}) = \sum_{k=1}^K \nu_k \delta(\mathbf{r} - \mathbf{R}_k) \tag{18.259}$$

and then apply the micro-area approximation to each of the K disc areas. If the discs do not overlap, the scatterers in the individual micro-areas are statistically independent, and the joint characteristic function is a product of factors like (18.258). If they do overlap, we must take account of a sum within the argument of the Bessel function. For example, for $K = 2$ [cf. (18.253)],

$$\begin{aligned} & \psi_{u_{im}(\mathbf{R}_1), u_{im}(\mathbf{R}_2)}(\nu_1, \nu_2) \\ &= \left\langle \exp \left\{ -\bar{N} + \int_{\mathbf{S}} d^2r_n b(\mathbf{r}_n) \bar{J}_0 \left[2\pi a_n \left| \sum_{k=1}^2 \nu_k p_{coh}(\mathbf{0}; \mathbf{R}_k) \text{cyl} \left(\frac{|\mathbf{R}_k - \mathbf{r}_n|}{D(\mathbf{R}_k)} \right) \right| \right] \right\} \right\rangle_{\mathbf{b}} \end{aligned} \tag{18.260}$$

There is no difficulty in principle in computing moments from this expression, but the required derivatives are tedious.

PDF of the irradiance The image-plane irradiance at a single point is related to the field at that point by $I_{im}(\mathbf{R}_0) = |u_{im}(\mathbf{R}_0)|^2$. The PDF for the irradiance can be found by the same procedure used in Sec. 8.3.6 to derive the exponential law for speckle irradiance, (8.232); we use (C.104) to transform the PDF on the real and imaginary parts of the field to the joint PDF on the irradiance and the phase angle of the field, then marginalize over the latter variable. Dropping the subscripts *im* and the spatial arguments temporarily for notational convenience, we write

$$\text{pr}(I, \phi) = |J| \text{pr}(u', u''), \tag{18.261}$$

where prime and double-prime denote real and imaginary parts, respectively,

$$u' = \sqrt{I} \cos \phi, \quad u'' = \sqrt{I} \sin \phi, \tag{18.262}$$

and J is a Jacobian given by

$$J = \det \begin{bmatrix} \frac{\partial u'}{\partial I} & \frac{\partial u''}{\partial I} \\ \frac{\partial u'}{\partial \phi} & \frac{\partial u''}{\partial \phi} \end{bmatrix} = \frac{1}{2}. \tag{18.263}$$

Thus

$$\text{pr}(I, \phi) = \frac{1}{2} \text{pr}(u', u'') \Big|_{u'=\sqrt{I} \cos \phi, u''=\sqrt{I} \sin \phi}. \tag{18.264}$$

We can now express $\text{pr}(u', u'')$ as the inverse Fourier transform of its characteristic function and take advantage of the fact that ϕ is uniformly distributed on $(0, 2\pi)$, so that

$$\begin{aligned} \text{pr}(I, \phi) &= \frac{1}{2\pi} \text{pr}(I) \\ &= \frac{1}{2} \int_{-\infty}^{\infty} d\nu' \int_{-\infty}^{\infty} d\nu'' \psi_u(\nu', \nu'') \exp \left[2\pi i \left(\nu' \sqrt{I} \cos \phi + \nu'' \sqrt{I} \sin \phi \right) \right]. \end{aligned} \tag{18.265}$$

Since the characteristic function is rotationally symmetric in the complex plane, we can express the 2D inverse Fourier transform as a Hankel transform, yielding

$$\text{pr}(I) = 2\pi^2 \int_0^\infty |\nu|d|\nu| J_0 \left(2\pi|\nu|\sqrt{I} \right) \psi_u(|\nu|) . \tag{18.266}$$

Using (18.258) and reinserting the subscripts and arguments, we obtain

$$\begin{aligned} \text{pr}[I_{im}(\mathbf{R}_0)] &= 2\pi^2 \int_0^\infty |\nu|d|\nu| J_0 \left[2\pi|\nu|\sqrt{I_{im}(\mathbf{R}_0)} \right] \\ &\times \left\langle \exp \left\{ -\bar{N}_0 + \bar{N}_0 \bar{J}_0 [2\pi a_n |\nu| p_{coh}(\mathbf{0}; \mathbf{R}_0)] \right\} \right\rangle_{\bar{N}_0} . \end{aligned} \tag{18.267}$$

This form is valid in the micro-area approximation when the number of scatterers in the disc area centered at \mathbf{R}_0 , denoted N_0 , is a doubly stochastic Poisson random variable with random mean \bar{N}_0 . An alternative and slightly more general form can be obtained by omitting the intermediate conditional average over N_0 for fixed \bar{N}_0 ; in that case we can write [cf. (18.240)]

$$\begin{aligned} &\text{pr}[I_{im}(\mathbf{R}_0)] \\ &= 2\pi^2 \int_0^\infty |\nu|d|\nu| J_0 \left[2\pi|\nu|\sqrt{I_{im}(\mathbf{R}_0)} \right] \left\langle \left\{ \bar{J}_0 [2\pi a_n |\nu| p_{coh}(\mathbf{0}; \mathbf{R}_0)] \right\}^{N_0} \right\rangle_{N_0} . \end{aligned} \tag{18.268}$$

This result (without the averages over a_n and N_0) was derived by Kluyver (1906) in response to a paper on random walks by Pearson (1905), and it was generalized to three dimensions by Rayleigh (1919). For a summary of these historical contributions, see Mardia (1972).

The Poisson case To evaluate (18.267) or (18.268) and get the PDF on the irradiance at a single point, we must specify PDFs for a_n and \bar{N}_0 . The simplest case is when both \bar{N}_0 and a_n are nonrandom (and the latter has the same value for all n , so we can drop the subscript). With these assumptions, neither the average over \bar{N}_0 nor the one over a (signified by the overbar on \bar{J}_0) is needed, and (18.268) becomes

$$\begin{aligned} \text{pr}[I_{im}(\mathbf{R}_0)] &= 2\pi^2 \sum_{N_0=0}^\infty \frac{\bar{N}_0^{N_0}}{N_0!} \\ &\times \exp(-\bar{N}_0) \int_0^\infty |\nu|d|\nu| J_0 \left[2\pi|\nu|\sqrt{I_{im}(\mathbf{R}_0)} \right] \left\{ J_0 [2\pi a |\nu| p_{coh}(\mathbf{0}; \mathbf{R}_0)] \right\}^{N_0} . \end{aligned} \tag{18.269}$$

To evaluate this integral, Lord Rayleigh (1919) suggested the approximation

$$[J_0(x)]^{N_0} \approx \exp \left(-\frac{1}{4} N_0 x^2 \right) , \tag{18.270}$$

which works fairly well even for N_0 as small as 3 or 4. The two sides of (18.270) agree for small x , and raising the Bessel function to a power causes it to fall off rapidly and suppresses the oscillatory sidelobes.

With Rayleigh's approximation, the integral in (18.269) is simply the Hankel transform of a Gaussian, and we find that

$$\text{pr}[I_{im}(\mathbf{R}_0)] \approx \sum_{N_0=0}^\infty \frac{\bar{N}_0^{N_0}}{N_0!} \exp(-\bar{N}_0) \frac{1}{N_0 a^2 |p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2} \exp \left[-\frac{I_{im}(\mathbf{R}_0)}{N_0 a^2 |p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2} \right] . \tag{18.271}$$

We can go further if \bar{N}_0 is large. Then the Poisson probability is sharply peaked around $N_0 = \bar{N}_0$, and we obtain

$$\text{pr}[I_{im}(\mathbf{R}_0)] \approx \frac{1}{\bar{I}_{im}(\mathbf{R}_0)} \exp \left[-\frac{I_{im}(\mathbf{R}_0)}{\bar{I}_{im}(\mathbf{R}_0)} \right], \quad (18.272)$$

where

$$\bar{I}_{im}(\mathbf{R}_0) = \bar{N}_0 a^2 |p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2. \quad (18.273)$$

This exponential density should come as no surprise; when there are many scatterers with random phase, the real and imaginary parts of the field are i.i.d. normal by the central-limit theorem and hence the irradiance is exponentially distributed [see (8.232)].

Doubly stochastic Poissons and the K density More interesting results are obtained when \bar{N}_0 is random. Since \bar{N}_0 can, in principle, take any value between 0 and ∞ , we need a PDF defined on the positive real line for $\text{pr}(\bar{N}_0)$. Candidate densities include the exponential, Rayleigh and log-normal, but much attention in the speckle literature has centered on using a gamma distribution (see Sec. C.5.4). With its two free parameters α and β , the gamma law allows considerable flexibility in constructing approximate PDFs on $(0, \infty)$.

Jakeman and Pusey (1978) used the gamma law for $\text{pr}(\bar{N}_0)$ in speckle statistics. Since the Poisson transform of a gamma is a negative binomial, their model is equivalent to saying that N_0 obeys a negative binomial. Specifically, if

$$\text{pr}(\bar{N}_0) = \frac{\bar{N}_0^{\alpha-1} \exp(-\bar{N}_0/\beta)}{\beta^\alpha \Gamma(\alpha)}, \quad (18.274)$$

then (Saleh, 1978)¹⁵

$$\text{Pr}(N_0) = \binom{N_0 + \alpha - 1}{N_0} \frac{\beta^{N_0}}{(1 + \beta)^{N_0 + \alpha}}. \quad (18.275)$$

The corresponding moment-generating function is (Abramowitz and Stegun, 1965, formula 26.1.23)

$$M_{N_0}(t) \equiv \langle \exp(N_0 t) \rangle_{N_0} = \frac{1}{(1 + \beta - \beta e^t)^\alpha}. \quad (18.276)$$

By differentiating the moment-generating function, we can show that the mean number of scatterers is $\alpha\beta$ and the variance is $\alpha\beta(1 + \beta)$.

To apply the negative-binomial law to speckle, we use (18.268) in conjunction with the Rayleigh approximation (18.270). The relevant expectation is

$$\begin{aligned} & \left\langle \{J_0[2\pi a|\nu p_{coh}(\mathbf{0}; \mathbf{R}_0)|]\}^{N_0} \right\rangle_{N_0} \approx \left\langle \exp[-\pi^2 N_0 a^2 |p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2 |\nu|^2] \right\rangle_{N_0} \\ &= \frac{1}{\{1 + \beta - \beta \exp[-\pi^2 a^2 |p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2 |\nu|^2]\}^\alpha} \approx \frac{1}{[1 + \beta \pi^2 a^2 |p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2 |\nu|^2]^\alpha}, \end{aligned} \quad (18.277)$$

¹⁵The negative binomial is often written as a binomial coefficient times $p^N(1 - p)^\alpha$; to get the form in (18.274), we must identify p as $\beta/(1 + \beta)$. If α is not an integer, the binomial coefficient must be expressed in terms of gamma functions.

where the penultimate step follows from (18.276). The last step is valid when $\alpha\beta \gg 1$, in which case only small values of $|\nu|^2$ are important; recall that $\alpha\beta$ is the mean of the original negative binomial distribution, so large $\alpha\beta$ is equivalent to large N_0 , an assumption that was already used in the Rayleigh approximation.

To get an approximate expression for the univariate density on the irradiance, we substitute the last form of (18.277) into (18.268) and use a tabulated integral (Gradshteyn and Ryzhik, 1980, formula 6.565.4); the result is (Jakeman and Pusey, 1978; Jakeman, 1980)

$$\begin{aligned} & \text{pr}[I_{im}(\mathbf{R}_0)] \\ = & \frac{2}{\Gamma(\alpha)} \frac{1}{a^2 |p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2 \beta} \left[\frac{I_{im}(\mathbf{R}_0)}{a^2 |p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2 \beta} \right]^{\frac{\alpha-1}{2}} K_{\alpha-1} \left[2 \sqrt{\frac{I_{im}(\mathbf{R}_0)}{a^2 |p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2 \beta}} \right]. \end{aligned} \tag{18.278}$$

This PDF, known as the *K distribution*, is defined in (C.142) and plotted in Fig. C.7. It reduces to the exponential distribution of (18.272) as $\alpha \rightarrow \infty$.

K-distributed scattering amplitudes As we have just shown, the K distribution arises in point-scattering speckle models when the scattering amplitudes are nonrandom but the number of scatterers in a micro-area obeys a negative-binomial distribution. In fact, it also arises when the number of scatterers is nonrandom but the amplitudes a_n themselves obey a K distribution.

Jakeman and Pusey (1976) considered the effect of scattering from the ocean surface the performance of microwave radars operating over the sea. They noted that the magnitude of the scattered signal is observed to follow Rayleigh statistics when a large area of the sea is illuminated, but with narrow beams and short pulses the micro-area to which the receiver is sensitive at any one time may have dimensions comparable to the longer wavelengths on the sea surface. The temporal signals from the clutter may then have a spiky “target-like” appearance, especially when the beam propagates nearly parallel to the ocean surface and the back-scatter is observed. Since these spikes or glints can give rise to false positives in a radar detection task, it is important to characterize the clutter statistics.

Jakeman and Pusey neglected the fluctuations in the number of scatterers in the micro-area and focused on fluctuations in the radar scattering cross section, which is included in the amplitude a_n . They provided arguments showing that a K distribution for a_n is both physically reasonable and analytically tractable. Specifically, they assumed that

$$\text{pr}(a_n) = \frac{2b}{\Gamma(1 + \nu)} \left(\frac{ba_n}{2} \right)^{\nu+1} K_{\nu}(ba_n), \quad \nu > -1, \tag{18.279}$$

where ν can be viewed as a skewness parameter; if $\nu \rightarrow -1$, this expression approaches a log-normal, and if $\nu \rightarrow \infty$ it approaches a Rayleigh density (Shankar, 1995).

With this density on the amplitudes and the assumption that N_0 is a nonrandom constant, Jakeman and Pusey (1976) find that (in our notation)

$$\text{pr}[I_{im}(\mathbf{R}_0)] = \frac{b|p_{coh}(\mathbf{0}; \mathbf{R}_0)|}{\sqrt{I_{im}(\mathbf{R}_0)} \Gamma(M)} \left[\frac{b}{2} \sqrt{\frac{I_{im}(\mathbf{R}_0)}{|p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2}} \right]^M K_{M-1} \left[b \sqrt{\frac{I_{im}(\mathbf{R}_0)}{|p_{coh}(\mathbf{0}; \mathbf{R}_0)|^2}} \right], \tag{18.280}$$

where

$$M = N_0(1 + \nu). \tag{18.281}$$

The remarkable similarity of (18.280) to (18.278) should be noted; when K distributions are observed experimentally, there may be no good way of deciding whether they arise from variations in N_0 or a_n . Nevertheless, the parameters of the distribution as estimated from empirical data might be useful features for pattern recognition (Joughin *et al.*, 1993).

The K distribution of scattering amplitudes has also been used to describe ultrasonic scattering from tissue (Shankar *et al.*, 1993; Narayanan *et al.*, 1994; Shankar, 1995; Molthen *et al.*, 1995; Molthen *et al.*, 1998).

Generalized K distributions Various generalizations of the K distribution have appeared in the literature. A common generalization is to consider weak scattering where the phases are not uniformly random and (18.232) does not hold. A useful model in that case is the *von Mises density*,

$$\text{pr}(\phi_n) = [2\pi I_0(\gamma)]^{-1} \exp[\gamma \cos(\phi_n)] \text{rect}\left(\frac{\phi_n}{2\pi}\right), \tag{18.282}$$

where γ is a nonnegative constant and $I_0(\cdot)$ is a modified Bessel function. This PDF is bell-shaped and peaked at $\phi_n = 0$; for large γ it is approximately Gaussian with a variance equal to $1/\gamma$, and it approaches $\delta(\phi_n)$ as $\gamma \rightarrow \infty$.

Using the von Mises PDF on the phases, taking the amplitudes a_n as nonrandom and assuming a negative-binomial distribution for N_0 , Barakat (1986) derived a generalized PDF on the single-point irradiance and showed that it reduced to (18.278) as $\gamma \rightarrow 0$. He also showed that this PDF agreed well with experimental moments of atmospheric laser-scattering data obtained in central Florida.

Jakeman and Tough (1987) reinterpreted Barakat's model in terms of a random walk with a directional bias specified by the density of the phases. With the negative-binomial model for N_0 , they showed that Barakat's generalized K density is obtained in the limit of large $\alpha\beta$, even without the specific von Mises density on the phases. They also extended Barakat's results to higher dimensions, along the way obtaining an n -dimensional generalization of the Rician density.

There has also been some attention to multivariate generalizations of the K distribution. A multivariate model accounting for polarization was developed by Yueh *et al.* (1989). Correlated K-distributed clutter was considered by Oliver (1985) and Marier (1995), and simulation methods were reported by Oliver and Tough (1986).

An interesting way of including spatial correlations in the K distribution was presented by Pentini *et al.* (1992). They considered a correlated circular Gaussian random process for the field, where, for example, the correlation function might be given by (18.100). They sampled the field on a grid of N points to get a correlated circular Gaussian random vector with PDF [*cf.* (8.245)]

$$\text{pr}(\mathbf{u}|\tau) = \frac{1}{\pi^N \tau^N \det(\mathbf{K}_\mathbf{u})} \exp\left(-\frac{1}{\tau} \mathbf{u}^\dagger \mathbf{K}_\mathbf{u}^{-1} \mathbf{u}\right), \tag{18.283}$$

where the nonnegative scalar τ can be interpreted as an overall power level or mean reflectivity of the object. If τ is a random variable independent of \mathbf{u} , then the overall density on \mathbf{u} is a Gaussian mixture. Specifically, if τ follows a gamma law,

Pentini *et al.* show that $\text{pr}(\mathbf{u})$ has the form

$$\text{pr}(\mathbf{u}) = \int_0^\infty d\tau \text{pr}(\mathbf{u}|\tau) \text{pr}(\tau) \propto [\mathbf{u}^\dagger \mathbf{K}_\mathbf{u}^{-1} \mathbf{u}]^{\frac{\nu-N}{2}} K_{\nu-N} \left(\mu \sqrt{\mathbf{u}^\dagger \mathbf{K}_\mathbf{u}^{-1} \mathbf{u}} \right), \quad (18.284)$$

where ν and μ are constants related to the PDF on τ . Thus once again a K distribution arises, this time without recourse to a point-scattering model at all. The argument of the Bessel function is real (since $\mathbf{K}_\mathbf{u}^{-1}$ is Hermitian and positive-semidefinite), but the different components of \mathbf{u} can have arbitrary correlations so long as they are consistent with the circular-Gaussian assumption.

Relation to Ricians Experimental histograms of $\sqrt{I_{im}(\mathbf{R}_0)}$ in coherent imaging are often well approximated by the Rician or Rice-Nakagami law defined in (C.141). Though originally derived by Rice for analysis of a known, nonrandom signal of amplitude A in Gaussian noise, this law is commonly used in speckle problems with A and σ^2 treated as adjustable parameters. This law would apply to speckle with interferometric or homodyne detection, but it does not seem to describe the non-interferometric systems we are analyzing in this chapter, so its mechanistic justification is not clear.

In one sense there is no need for a mechanistic justification of the Rician law; if it fits the data and if the parameters of the fit are useful features for pattern recognition, that is justification enough. Nevertheless, it is interesting to see how an approximate Rician might arise from different physical assumptions.

As we noted in Sec. 18.1.1, the Rician could occur in transmission imaging when the phase of the transmitted wave is not completely randomized, so that there is a nonrandom plane-wave component superimposed on the scattered field. Similarly, in reflection, something akin to a Rician could arise when the phases are not fully randomized, as in (18.282) with large γ . The generalized K distribution of Jakeman and Tough (1987) often approximates a Rician when expressed as a density on $\sqrt{I_{im}(\mathbf{R}_0)}$ rather than $I_{im}(\mathbf{R}_0)$.

The Rician density can also be obtained by assuming that there is a single strong point scatterer or specular reflector present, but there are two difficulties in this view. The first is the (often implicit) assumption that this strong scatterer, unlike the rest of the points in the object, is nonrandom. The second difficulty is that point scatterers outside the support of the coherent PSF of the imaging system make no contribution to the image-plane field at any given point; for the Rician density to be obtained exactly, therefore, one would have to assume that there is always exactly one point scatterer within the PSF no matter where one looks in the image.

Another model that leads to a Rician is an array of point scatterers with partial periodicity (Wagner *et al.*, 1986; Wagner *et al.*, 1987; Shankar, 1995). The wave diffracted from such an array consists of a coherent part, as if the array were perfectly periodic, and a diffuse part resulting from random displacement of the scatterers from the ideal lattice positions. The coherent part can serve as the nonrandom coherent signal envisioned in Rice's original work. Since the coherent component is the result of volume diffraction from a periodic structure, strong diffraction will occur only if the Bragg condition is satisfied (see Sec. 9.8.3). Thus the relative strength of the two components will depend not only on the degree of periodicity, but also on the directions of the incident and diffracted waves as well as the area (or volume) associated with the PSF. If one wished to test the validity

of this model, the dependence of the empirical PDF could be studied as a function of these parameters.

Other densities for N_0 We have emphasized point-scattering models where N_0 follows a negative binomial law (or equivalently, \bar{N}_0 follows a gamma), but many other probability laws can be used for the number of scatterers in a micro-area. Delignon and Pieczynski (2002) summarize the possibilities and discuss ways of choosing among them in describing empirical data from synthetic-aperture radar.

Texture synthesis with speckle In Sec. 8.4 we discussed several parametric models for texture statistics. For example, the clustered lumpy background is a flexible model with a few free parameters that can be adjusted to mimic the textures seen in mammograms. With our current understanding of speckle statistics, it now appears feasible to use speckle fields as models of texture patterns that have nothing to do with coherent imaging. Suppose, for example, that we start with a nonstationary, doubly stochastic Poisson point process and image it—in a computer—through a coherent imaging system with a specified, possibly space-variant PSF. When we then form the irradiance—still in the computer—we will have a nonnegative random field that should be capable of mimicking many different natural textures. To make the synthesis realistic, we can adjust the parameters of the initial point process as well as those of the coherent PSF.

18.6 COHERENT RANGING

To this point we have considered speckle in 2D systems, but we have noted at several points that speckle is important in various forms of radar and ultrasound imaging. These methods have in common that they use amplitude-sensitive detectors, they are used to image 3D objects, and they use time of flight to encode the third dimension. In order to use time of flight, the radiation must be modulated in some way. The simplest option is just to pulse the radiation source, but much research has gone into chirp signals and other waveforms.

In spite of the modulation, radar and ultrasound systems are still coherent, so they exhibit speckle. In this section we shall analyze these systems both deterministically and stochastically and show how the speckle formalism developed earlier in the chapter can be extended to pulsed imaging.

We begin in Sec. 18.6.1 with a qualitative overview of the systems, treating radar and ultrasound in parallel to emphasize their similarities. The serious analytical effort begins in Sec. 18.6.2 by elucidating the linear operator that maps the 3D object to electrical signals from the amplitude-sensitive detectors. In Sec. 18.6.3 we develop a general characteristic functional to describe the statistics of speckle as manifest in the electrical signals. In Sec. 18.6.4 we consider issues in task performance and image quality.

18.6.1 System configurations

As shown in Fig. 18.5, the key elements in a radar or ultrasound system are an RF (radio-frequency) generator, a modulator, a transmitting element, a receiving element and a signal-processing system. Application of an electrical signal to the

transmitting element produces a wave that propagates into space, reflects from some target and returns to the receiving element where it is converted back to an electrical signal. When the transmitting and receiving elements are identical as in Fig. 18.5 (or at least at essentially the same location), the system is said to be *monostatic*. When the transmitter and receiver are at different locations, the system is *bistatic*, and when multiple transmitters and/or receivers are used, the system is *multistatic*. Only monostatic systems will be discussed here.

The transmitted waves are highly directional or beam-like, so only targets within the beam receive radiation. If the targets are small, then they reradiate over a wide angular range, but only a small portion of the wave gets to the receiving element. For monostatic configurations, the receiver is sensitive to back-scattered radiation from the same beam-like region where the transmitted wave propagated.

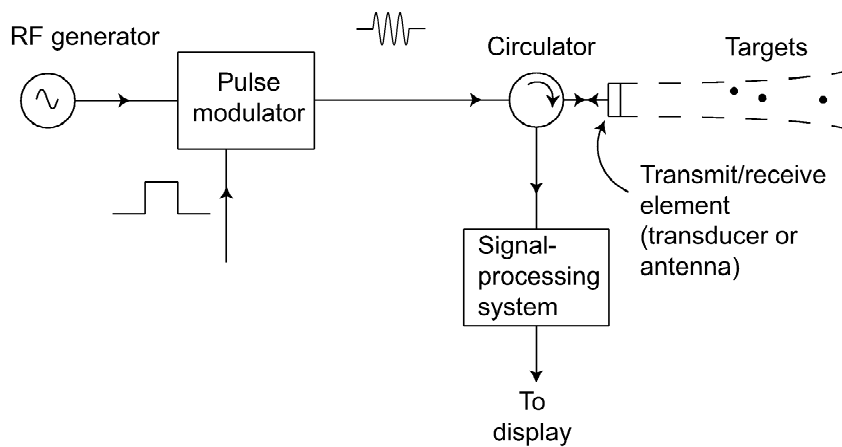

Fig. 18.5 Monostatic and bistatic radar systems.

Transducers We shall use the word *transducer* to describe the elements that convert the electrical signal to a propagating wave and back again. For radar the transducer is a microwave antenna, and for ultrasound it is a piezoelectric element.

The simplest (and most common) ultrasound transducer is a flat piezoelectric plate, usually in the form of a disc as shown in Fig. 18.6a. A high-frequency voltage is applied to electrodes on opposite sides of the disc, and the piezoelectric effect causes the material to vibrate at the same frequency. Maximum vibration amplitude is obtained when the thickness of the transducer is equal to half of the acoustic wavelength in the material.

If the vibrating transducer is placed in contact with a patient's body or other medium, it will induce a vibrational wave in the medium. For medical applications the vibrations are normal to the face of the transducer, so the induced wave is a compressional or density wave, similar to ordinary sound waves in air. Transverse or shear waves can be generated in some solid media, but they do not propagate in air, liquids or soft tissue. For medical use, the frequency of the wave is typically 5–10 MHz, corresponding to a wavelength in tissue of 0.15–0.3 mm.

Since all points on the transducer surface vibrate in phase, the generated wave has a planar wavefront over the surface of the disc. As it propagates, this plane wave diffracts, just as a monochromatic light wave would after passing through a disc aperture.

To avoid the diffraction spread and put maximum energy on a target at a known distance from the transducer, a curved ultrasound transducer can be used as shown in Fig. 18.6b. In this case the wave generated is a converging spherical wave, analogous to light after passing through a lens. In fact, actual acoustic lenses can be used with planar transducers to achieve the same result.

A microwave transducer is a reflecting dish illuminated with a feed horn as shown in Fig. 18.7. The dish is ideally parabolic but may be spherical in practice. If its radius of curvature is R , then it functions as a focusing element with focal length $f = R/2$. If the feed horn is one focal length from the dish, a plane electromagnetic wave is formed immediately after the reflection, and it then diffracts as it propagates just as the ultrasonic wave does. A converging spherical wave can be generated by moving the feed horn so that it is more than one focal length from the dish.

Radar systems operate over a wide variety of frequencies, from a few hundred MHz to tens of GHz. A common choice, referred to as *X band*, is 8–12 GHz. A 10 GHz radio wave in free space has a wavelength of 3 cm.

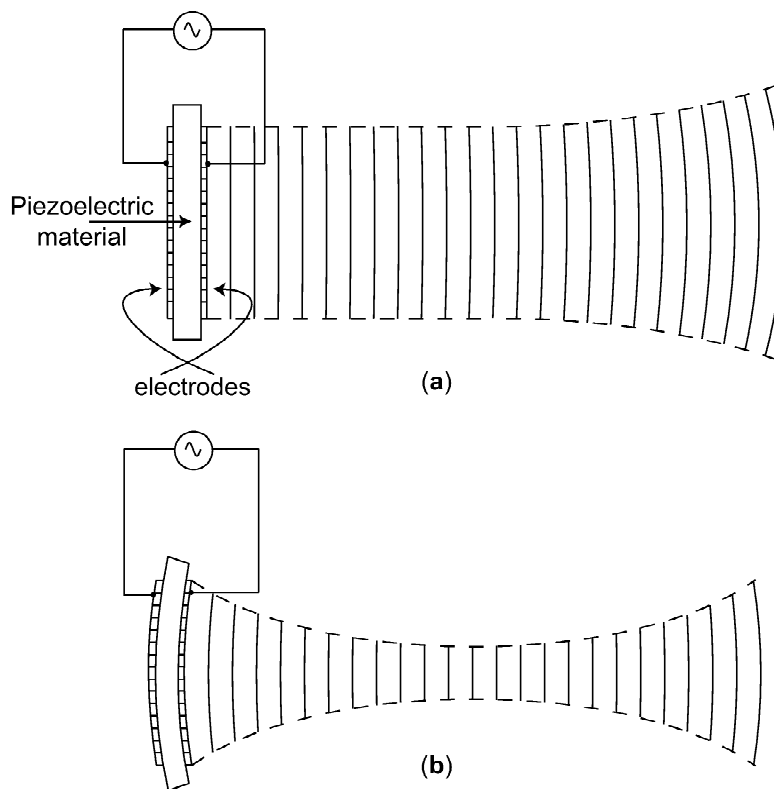

Fig. 18.6 Transducers for use in medical ultrasound. (a) Planar transducer produces a plane wave that eventually diffracts into a diverging spherical wave. (b) Curved transducer produces a converging spherical wave that comes to a focus at the center of curvature of the transducer.

Scanning methods If a pulsed RF signal is transmitted from a transducer in a given location, a wave packet propagates to a reflecting target, and part of the reflected wave returns to the transducer and is reconverted to an electrical signal. If the

received electrical signal is displayed on an oscilloscope, an echo or *blip* is seen at a time corresponding to the round trip propagation time from transducer to target and back again. If there are many targets in the beam, there is an echo for each. The oscilloscope display is referred to as an *A-scan*, where A refers to the amplitude of the return signal. For our purposes, an A-scan can be regarded as a 1D image, with time delay corresponding to the range to the target.

To form a 2D image, the transducer can be tilted or rotated to produce beams in different directions. In radar it is common to rotate the antenna continuously, and in ultrasound the transducer is commonly swept over some angular arc, either mechanically or by hand. Conceptually it may be easier to think of the transducer as being pointed to a discrete set of positions, where a pulsed signal is transmitted and received at each position. The result is a 2D map of target locations in polar coordinates. Commonly, this information is displayed on a monitor with echo strength converted to brightness; this display is called a *B-scan* (B for brightness).

In a B-scan with different angular directions for the beam, information is obtained from the object along a fan of rays. In Chap. 17 we encountered fan-beam and cone-beam tomographic systems that also collect information along many rays passing through a single point. The key difference is that the tomographic systems collect *integrals* of some object property, while radar and ultrasound systems take advantage of time of flight to get information about where along the ray a target lies. Time of flight has been used in some PET systems to get similar information, and if the temporal resolution were adequate, PET images could be obtained without tomographic reconstruction. In practice, however, available gamma-ray detectors limit the time-of-flight resolution to about 10 cm, which is far from adequate for medical applications.

Fig. 18.7 Illustration of microwave transducer. The microwave input is located a distance $R/2$ from the reflector; the result is a plane wave.

Phased arrays Angular scanning of the beam is essential for obtaining a 2D image with a monostatic system, and focusing the beam can be useful to avoid diffraction spread. We know from Chap. 9 that an angular deviation corresponds to a 2D linear phase factor, $\exp(2\pi i \boldsymbol{\rho}_0 \cdot \mathbf{r})$ across a beam, and focusing corresponds to a quadratic phase factor, $\exp(-i\pi r^2/\lambda f)$. In essence, angular scanning and focusing are equivalent to imposing phase variations on the transducer.

The same phase variations can be imposed electronically rather than mechanically if the transducer is divided into many small elements that can be excited independently with different phases. The more elements used, the better the approximation to the desired continuous phase distribution but the more hardware needed to provide the requisite signals to each element. Ideally, the element spacing should be a half wavelength or less to give Nyquist sampling of any real (non-evanescent) plane-wave component of a general propagating beam (Macovski, 1979).

Phased arrays are commonly used in radar for rapid scanning, target tracking and beam forming. 1D phased arrays are also common in medical ultrasound. Rectangular elements are used, where one dimension, say L_x , of the rectangle is comparable to a wavelength but the other, L_y , is much larger than a wavelength. The result is a beam confined to be near the y - z plane but capable of being focused or scanned in that plane. Two-dimensional piezoelectric arrays with small square elements are also being developed; they permit arbitrary monostatic scanning and hence 3D imaging without mechanical motion.

Resolution As with any imaging system, spatial resolution is critical in pulsed ranging systems. We must distinguish lateral resolution (transverse to the beam) from longitudinal resolution (along the beam, in the range direction). Lateral resolution is computed just as in optics; a transducer of diameter D , for example, produces an angular divergence of λ/D in the Fraunhofer zone. Longitudinal resolution, on the other hand, is determined entirely by the modulation of the beam. For example, if we use a simple pulse of duration T , it produces a travelling wave packet of length vT , where v is the speed of propagation. The longitudinal resolution is thus about $vT/2$ (the factor of 2 arising since the delay is doubled for round-trip propagation).

To get good longitudinal resolution, therefore, we should use short pulses. The problem is that the pulse amplitude is usually constrained by engineering considerations such as electrical breakdown, so a shorter pulse has smaller energy, which makes it more difficult to detect weak echoes.

Pulse coding During World War II and since, many methods have been developed for getting good longitudinal resolution without sacrificing pulse energy and hence detectability (see Sec. 18.6.4). Klauder *et al.* (1960) classify the methods as chirp, bang and hiss. Bang refers to the use of simple pulse modulation as just discussed. Chirp refers to use of a temporal quadratic phase factor as the modulation. We know from Sec. 5.1.3 that a quadratic phase variation corresponds to a linear variation of local frequency with time, so the chirp is linear frequency modulation. Hiss refers to the use of noise as the modulation.

The principle of chirp radar is illustrated in Fig. 18.8. As shown there, the transmitted signal is a chirp where the lowest frequency is transmitted first. The received signal is sent through a dispersive delay line where the delay varies linearly with frequency and the lowest frequency is delayed the most. If the dispersion rate of the delay line is matched to the chirp of the signal, then all frequency components come out of the delay line at the same time, yielding a pulse of much higher amplitude and shorter duration. As we shall see in Sec. 18.6.2, the width of the compressed pulse is the reciprocal of the bandwidth of the chirp, while the total energy is determined by its width before compression. Thus chirps allow good detectability and also good longitudinal resolution.

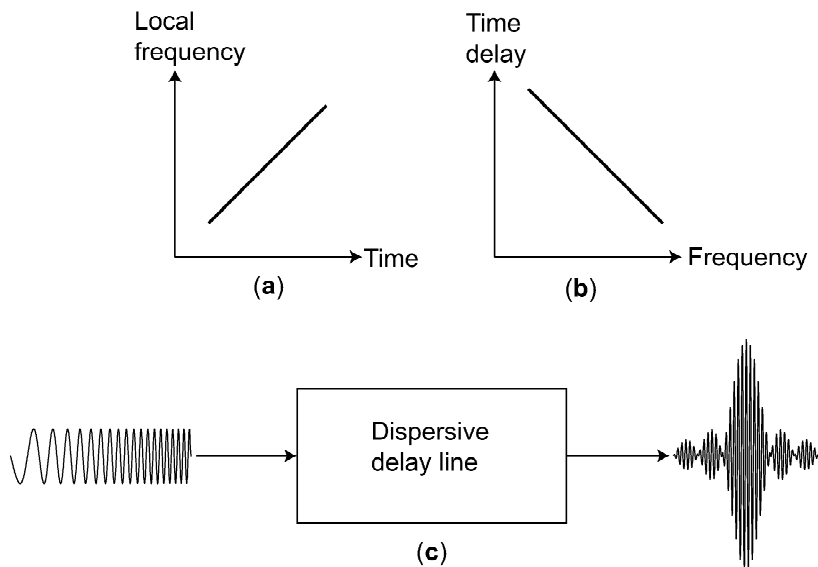

Fig. 18.8 Principle of chirp radar.

As we shall see in Sec. 18.6.2, the delay line is a matched filter for the chirp signal. That means that the delay line serves to cross-correlate the noisy received signal with a replica of the noise-free transmitted signal. If the target is a point, the noisy signal itself contains a replica of the transmitted signal, and the reason chirp radar works is that the correlation of a chirp with itself is sharply peaked, approaching a delta function as the width of the chirp increases.

Many other codes also have sharply peaked autocorrelations. The possibilities include nonlinear frequency modulation, frequency-jump chirp, step chirp and various phase-modulation patterns such as Barker codes. For details see Sullivan (2000).

Optical coherence tomography Although chirp signals are commonly used in modern radar, noise-modulated or hiss signals are not, having been superseded by sophisticated pulse codes. The principle of hiss radar is, however, the foundation for an optical ranging system called *optical coherence tomography* or *OCT*.

The basic system for OCT is shown in Fig. 18.9. The broadband optical source emits a wave that we can represent as $\tilde{u}(\mathbf{r}, t) \exp(-2\pi i\nu_0 t)$, where $\tilde{u}(\mathbf{r}, t)$ is a random process that can be regarded for present purposes as a noise modulation. The wave bounces off a target and returns to the system, where it is interfered with a delayed replica of itself. As we know from Sec. 9.7.4, interference occurs only when the path difference is less than the coherence length, given by $c/\Delta\nu$, where $\Delta\nu$ is the bandwidth of the source. Scanning in the range direction is accomplished by varying the delay, and fringes are observed only if the two path lengths match within the coherence length. Longitudinal or range resolution is thus $c/2\Delta\nu$ and can be improved, just as with a chirp, by increasing the bandwidth of the source.

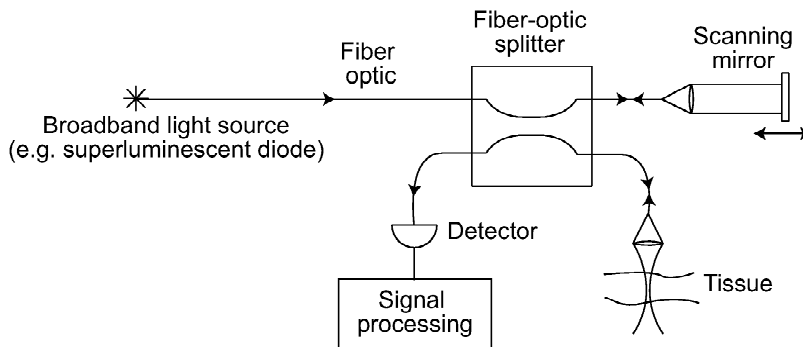

Fig. 18.9 Basic system for optical coherence tomography.

Doppler Often the targets in radar and medical ultrasound are in motion, and the reflected wave undergoes a Doppler shift. If the Doppler shift is measured, the system becomes a 4D imaging system, localizing the target in x , y , z and v_z , where x and y are transverse to the beam, z is along the beam and v_z is the component of \mathbf{v} parallel to z . Resolution in x and y is determined by the transducer size and the wavelength; resolution in z is determined by the duration of the pulse after compression of other processing, and resolution in range is determined by our ability to measure the Doppler shift.

There is, however, a conflict between range resolution and Doppler resolution. If we choose a short pulse that contains only a few cycles of the center frequency, then we get good range resolution but poor Doppler resolution; since the pulse consists of a broad spectrum of frequencies, small frequency shifts are hard to discern. Conversely, a long pulse gives good Doppler resolution. The use of a chirp does not help appreciably in this case, as we can see by looking again at Fig. 18.8a. A change in range z of a target causes a shift of the diagonal line in that figure along the horizontal axis, while a change in v_z causes a shift along the vertical axis. Except for what happens at the ends of the line, these two shifts are indiscernible, and range and Doppler shifts causes ambiguous variations in the received signal. The Woodward ambiguity function, introduced in Sec. 5.2.2, is a way of quantifying this ambiguity.

Synthetic-aperture radar Radar systems in aircraft or satellites can be used to get high-resolution images of the ground. The airborne antenna is generally small and a large area on the ground is illuminated, so these systems do not rely on λ/D to get the spatial resolution. Instead, many images are recorded as the aircraft flies along, and these images are coherent with respect to one another. They can, in effect, be made to interfere in the computer, and the result is that the resolution is determined by the distance the aircraft flies while a particular point on the ground is illuminated. Calling this distance L , we see that the angular resolution is λ/L rather than λ/D , so we have synthesized a much larger aperture, hence the name *synthetic-aperture radar* or *SAR*.¹⁶

¹⁶SAR is a second-order acronym; one of the letters stands for an acronym. Third-order acronyms are also possible; for example, ASF stands for Alaska SAR Facility.

The resolution properties of SAR images are quite counterintuitive. Consider a point target at range R from the aircraft. An antenna of diameter D illuminates a patch of length given by $R\lambda/D$, and this is also the length L of the synthesized aperture. After image reconstruction the linear resolution in the direction of the flight path is $R\lambda/L = (R\lambda)/(R\lambda/D)$ or simply D . Thus the resolution is the antenna size D , independent of both wavelength λ and range R . A smaller antenna is better since it illuminates a larger patch on the ground, and the size of the patch is the length of the synthesized aperture. Resolution in the range direction is determined by pulse width or pulse coding as with other forms of radar.

We shall not explicitly analyze SAR systems in what follows, but the formalism is general enough to include it. In particular, we shall consider multiple antenna configurations, which can include multiple positions along a flight path.

For excellent reviews of the mathematics of SAR, see Borden (1999) and Cheney (2001), and for a comprehensive treatment see Sullivan (2000).

18.6.2 Deterministic analysis

In this section we analyze a basic coherent ranging system deterministically; the corresponding stochastic analysis is presented in Sec. 18.6.3. Both analyses apply equally to microwave or ultrasound systems.

The system we shall analyze is monostatic, with the transducer lying in the plane $z = 0$ (or just behind it if the transducer is curved). The transducer is scanned either laterally by moving it in x and y , or angularly by tilting it physically or by controlling the linear phase factor in a phased array. In either case we use the discrete index j to denote the transducer configuration. For lateral scanning that index specifies the center coordinates of the transducer, (x_j, y_j) , and for angular scanning it specifies the beam direction in polar coordinates, (θ_j, ϕ_j) . For airborne SAR systems, j denotes the position of the antenna along the flight path, which can be taken as the x axis.

The transducer acts as a pulsed source, producing a beam-like wave packet in the space $z > 0$. The wave packet is reflected by inhomogeneities in the refractive index in the medium, and some of it returns to the transducer where it is reconverted to an electrical signal. For each j the transducer output is a function of time, so the collected data are denoted $g_j(t)$. We shall consider the refractive-index inhomogeneities to be functions of the continuous spatial variable $\mathbf{r} = (x, y, z)$ (with $z > 0$), so the system under consideration is a mixed CC-CD system in the terminology of Sec. 7.3.5. It is mixed in data space since $g_j(t)$ has both continuous and discrete indices, but it is continuous in object space since the object is a function of a continuous variable.

There are situations where the system is mixed in object space as well. If we consider polarized electromagnetic radiation, and the object has different scattering properties for the two polarizations, then the object is a 2D vector field and we need a discrete index on the object function. Similarly, in ultrasound the scattering is determined by both the object density and its compressibility, so again the object is a 2D vector field.

For simplicity, however, we shall forgo this generality and consider only scalar objects. Thus we are seeking an expression for a linear operator \mathcal{L} that maps a function of (x, y, z) to a function of j and t . In order to make the analysis tractable, we assume weak scattering and apply the first Born approximation, as introduced in

Sec. 9.8.1. In that section, however, we assumed perfectly monochromatic radiation and solved the Helmholtz equation; here we must use the time-dependent wave equation in order to account for the pulse modulation.

The Born approximation in time-dependent problems We know from (9.23) that scalar waves in a homogeneous medium, where the speed of propagation is c_m , must satisfy

$$\left(\nabla^2 - \frac{1}{c_m^2} \frac{\partial^2}{\partial t^2}\right)u(\mathbf{r}, t) = s(\mathbf{r}, t), \quad (18.285)$$

where $s(\mathbf{r}, t)$ describes the radiation source. We shall be interested in solutions of this equation in situations where the speed of propagation varies with space and time. Perhaps surprisingly, the wave equation (18.285) still holds if we replace the constant c_m by the general function $c_m(\mathbf{r}, t)$ so long as $u(\mathbf{r}, t)$ varies much more rapidly with time than does $c_m(\mathbf{r}, t)$; in other words, the Doppler shifts must be small compared to the mean frequency of the radiation. For simplicity, we assume in what follows that c_m is independent of time (thereby ruling out moving targets in radar).

To accommodate a speed of propagation that varies with \mathbf{r} , we define the refractive index as

$$n(\mathbf{r}) = \frac{c}{c_m(\mathbf{r})}, \quad (18.286)$$

where c is some reference speed, usually taken as the speed of light in vacuum for electromagnetic waves. For medical ultrasound, however, the reference speed is often taken as the speed of sound in water, about 1500 m/s; tissue is very similar to water acoustically, so the refractive index defined this way is near one.

Derivation of the Born approximation now parallels the treatment given in Sec. 9.8.1 for the monochromatic case. Equation (18.285) can be rewritten as

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}\right)u(\mathbf{r}, t) = \frac{n^2(\mathbf{r}) - 1}{c^2} \frac{\partial^2}{\partial t^2} u(\mathbf{r}, t) + \mathbf{s}(\mathbf{r}, t). \quad (18.287)$$

We define $u_{inc}(\mathbf{r})$ as the field that would exist at point (\mathbf{r}, t) in the absence of the inhomogeneous index distribution. Specifically, as in (9.329), $u_{inc}(\mathbf{r}, t)$ is the solution to

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}\right)u_{inc}(\mathbf{r}, t) = s(\mathbf{r}, t). \quad (18.288)$$

We then write the total field as

$$u(\mathbf{r}, t) = u_{inc}(\mathbf{r}, t) + u_{sc}(\mathbf{r}, t), \quad (18.289)$$

where $u_{sc}(\mathbf{r}, t) \equiv u(\mathbf{r}, t) - u_{inc}(\mathbf{r}, t)$ can be interpreted as the field scattered by the index inhomogeneities.

With these definitions, (18.287) in a source-free region ($z > 0$) becomes

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}\right)u_{sc}(\mathbf{r}, t) = \frac{n^2(\mathbf{r}) - 1}{c^2} \frac{\partial^2}{\partial t^2} u(\mathbf{r}, t). \quad (18.290)$$

Notice that the unknown scattered field is hidden in $u(\mathbf{r}, t)$ on the right.

The first Born approximation regards the scattered field as small compared to the incident field, so the wave equation (still in the source-free region) becomes

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}\right) u_{sc}(\mathbf{r}, t) \approx \frac{n^2(\mathbf{r}) - 1}{c^2} \frac{\partial^2}{\partial t^2} u_{inc}(\mathbf{r}, t) \approx k_0^2 [1 - n^2(\mathbf{r})] u_{inc}(\mathbf{r}, t), \quad (18.291)$$

where the last step follows if the incident field is narrowband with center frequency ν_0 , and $k_0 \equiv 2\pi\nu_0/c$.

The equation for the scattered field, (18.291), is now identical to (18.288) except that the real source has been replaced by an effective source: the incident field modulated by the index inhomogeneities.

The object For purposes of deterministic analysis, we can identify “the object” as the scattering potential, defined as in (9.328) by

$$V(\mathbf{r}) \equiv k_0^2 [1 - n^2(\mathbf{r})]. \quad (18.292)$$

When we get to stochastic analysis in Sec. 18.6.3, we shall see that it is by no means so simple to say what the word “object” means.

The incident field Since multiple scattering is neglected in the first Born approximation, the incident field is found by solving the time-dependent wave equation, (18.288), with the transducer acting as a source but with no index inhomogeneities. All of the work in finding the solution was done in Sec. 9.3, and we can just appropriate the basic result here; from (9.66) we know that the incident field is given by

$$u_{inc}^{(j)}(\mathbf{r}, t) = -\frac{1}{4\pi} \int_{\infty} d^3\mathbf{r}' \frac{1}{|\mathbf{r} - \mathbf{r}'|} s_j\left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right), \quad (18.293)$$

where $s_j(\mathbf{r}, t)$ is the source function for the j^{th} transducer configuration. In essence, the field at an observation point is the sum (integral) of the fields from all source points, delayed by the propagation time and reduced in amplitude by the $1/|\mathbf{r} - \mathbf{r}'|$ factor.

Spatially, the source function $s_j(\mathbf{r}, t)$ contains a factor of $\delta(z)$ since the transducer lies in the plane $z = 0$, so the integral in (18.293) is really over the x - y plane. Also, $s_j(\mathbf{r}, t)$ vanishes when the point (x, y) lies outside the physical boundaries of the transducer in the j^{th} configuration. The remaining function of (x, y) may include linear phase factors to describe tilt of the transducer or quadratic phase factors to describe focusing; either of these factors can be created mechanically, by tilting or curving the transducer, or electronically by programming the phase shifters in a phased array appropriately. For example, if

$$s_j(\mathbf{r}) \propto \delta(z) \exp\left[\frac{2\pi i}{\lambda_0} (\alpha_j x + \beta_j y) - \frac{\pi i}{\lambda_0 z_j} (x^2 + y^2)\right], \quad (18.294)$$

it means that the beam is aimed in the direction specified by the direction cosines α_j and β_j (see Sec. 9.2.1) and focused in the plane $z = z_j$ (see Sec. 9.6.1).

Temporally, the source function consists of a carrier-frequency factor times a factor specifying the pulse modulation. If we assume that the carrier frequency and the pulse modulation are the same for every transducer configuration, we can write

$$s_j(\mathbf{r}, t) = m(t) \exp(-2\pi i\nu_0 t) s_j(\mathbf{r}), \quad (18.295)$$

where $m(t)$ is the modulation function. Thus

$$u_{inc}^{(j)}(\mathbf{r}, t) = -\frac{1}{4\pi} \exp(-2\pi i\nu_0 t) \int_{\infty} d^3\mathbf{r}' \frac{\exp(ik_0|\mathbf{r}-\mathbf{r}'|)}{|\mathbf{r}-\mathbf{r}'|} s_j(\mathbf{r}') m\left(t - \frac{|\mathbf{r}-\mathbf{r}'|}{c}\right), \quad (18.296)$$

where $k_0 \equiv 2\pi\nu_0/c$, and the real parts of all complex fields are to be taken. If $m(t)$ is a constant, (18.296) reduces to (9.67), which expresses the solution of the inhomogeneous Helmholtz equation with a prescribed source.

If $m(t)$ is slowly varying compared to the variation in propagation times from different points on the transducer to the scattering point \mathbf{r} , then we can approximate (18.296) by

$$u_{inc}^{(j)}(\mathbf{r}, t) = -\frac{1}{4\pi} \exp(-2\pi i\nu_0 t) m\left(t - \frac{|\mathbf{r}-\mathbf{r}_{0j}|}{c}\right) \int_{\infty} d^3\mathbf{r}' \frac{\exp(ik_0|\mathbf{r}-\mathbf{r}'|)}{|\mathbf{r}-\mathbf{r}'|} s_j(\mathbf{r}'), \quad (18.297)$$

where \mathbf{r}_{0j} is the center of the transducer in the j^{th} configuration. In this form the result is identical to the Helmholtz expression, (9.67), except for an envelope function that moves along the beam at speed c . For later convenience we define

$$h_j(\mathbf{r}) \equiv -\frac{1}{4\pi} \int_{\infty} d^3\mathbf{r}' \frac{\exp(ik_0|\mathbf{r}-\mathbf{r}'|)}{|\mathbf{r}-\mathbf{r}'|} s_j(\mathbf{r}'). \quad (18.298)$$

Since the source is confined to the plane $z = 0$, $h_j(\mathbf{r})$ is the monochromatic diffraction pattern of the transducer.

The scattered field The scattered field is also given by (18.293), but with the real source $s_j(\mathbf{r}, t)$ replaced by the effective one:

$$\begin{aligned} u_{sc}^{(j)}(\mathbf{r}'', t) &= -\frac{1}{4\pi} \int_{\infty} d^3\mathbf{r} \frac{1}{|\mathbf{r}''-\mathbf{r}|} u_{inc}^{(j)}\left(\mathbf{r}, t - \frac{|\mathbf{r}''-\mathbf{r}|}{c}\right) V(\mathbf{r}) \\ &= -\frac{1}{4\pi} \exp(-2\pi i\nu_0 t) \int_{\infty} d^3\mathbf{r} \frac{\exp(ik_0|\mathbf{r}''-\mathbf{r}|)}{|\mathbf{r}''-\mathbf{r}|} m\left(t - \frac{|\mathbf{r}-\mathbf{r}_{0j}|}{c} - \frac{|\mathbf{r}''-\mathbf{r}|}{c}\right) h_j(\mathbf{r}) V(\mathbf{r}). \end{aligned} \quad (18.299)$$

Now the total delay of the envelope is the propagation time from the center of the transducer to the scattering point \mathbf{r} to the observation point \mathbf{r}'' .

The received signal When the scattered wave returns to the transducer, the reciprocity principle tells us that it undergoes the same weighting as on transmission; it is multiplied by a factor $s_j(\mathbf{r})$, and the resultant weighted amplitude is integrated across the transducer face (the sensitive area of the plane $z = 0$). The output signal is thus

$$g_j(t) = C \int d^3\mathbf{r}'' s_j(\mathbf{r}'') u_{sc}^{(j)}(\mathbf{r}'', t) \quad (18.300)$$

where C is a constant related to the responsivity of the transducer. With (18.299), we find

$$\begin{aligned} g_j(t) &= -\frac{C}{4\pi} \exp(-2\pi i\nu_0 t) \int_{\infty} d^3\mathbf{r} h_j(\mathbf{r}) V(\mathbf{r}) \\ &\times \int d^3\mathbf{r}'' s_j(\mathbf{r}'') \frac{\exp(ik_0|\mathbf{r}''-\mathbf{r}|)}{|\mathbf{r}''-\mathbf{r}|} m\left(t - \frac{|\mathbf{r}-\mathbf{r}_{0j}|}{c} - \frac{|\mathbf{r}''-\mathbf{r}|}{c}\right). \end{aligned} \quad (18.301)$$

Since the same transducer is used for receiving as for transmitting in a monostatic system, we can use the same approximation as in (18.297), approximating $|\mathbf{r}'' - \mathbf{r}|$ by $|\mathbf{r}_{0j} - \mathbf{r}|$ in the argument of $m(\cdot)$. We then obtain

$$g_j(t) = C \exp(-2\pi i \nu_0 t) \int_{\infty} d^3 \mathbf{r} [h_j(\mathbf{r})]^2 m \left(t - 2 \frac{|\mathbf{r} - \mathbf{r}_{0j}|}{c} \right) V(\mathbf{r}). \quad (18.302)$$

We can write this result as

$$g_j(t) = \int d^3 \mathbf{r} L_j(t, \mathbf{r}) V(\mathbf{r}) \quad \text{or} \quad \mathbf{g} = \mathcal{L} \mathbf{V}. \quad (18.303)$$

Thus the desired kernel for the linear operator \mathcal{L} is

$$L_j(t, \mathbf{r}) = C \exp(-2\pi i \nu_0 t) [h_j(\mathbf{r})]^2 m \left(t - 2 \frac{|\mathbf{r} - \mathbf{r}_{0j}|}{c} \right). \quad (18.304)$$

Note that the monochromatic diffraction pattern of the transducer, $h_j(\mathbf{r})$, appears as a square (not squared modulus) in the kernel. Any phase distortions in the transducer plane (deliberate or otherwise) get doubled because we go through the same transducer twice. Similarly, the time delay of the envelope is doubled since a round trip is required to get back to the transducer.

Electronic filtering There is almost always some electronic filtering applied to the transducer output. At the least, there is a bandpass filter to suppress noise outside the signal bandwidth, and if chirps or other coded pulses are used, the pulse compression or decoding is performed with an electrical filter. The filters are usually linear and shift invariant, so we can write the filter output as

$$\tilde{g}_j(t) = \int_{-\infty}^{\infty} dt' g_j(t') q(t - t') \quad \text{or} \quad \tilde{\mathbf{g}} = \mathcal{Q} \mathbf{g}. \quad (18.305)$$

The overall mapping from \mathbf{V} to the filter output is then given by

$$\tilde{\mathbf{g}} = \mathcal{Q} \mathcal{L} \mathbf{V}, \quad (18.306)$$

where the kernel of $\mathcal{Q} \mathcal{L}$ is given by

$$[\mathcal{Q} \mathcal{L}]_j(t, \mathbf{r}) = \int_{-\infty}^{\infty} dt' L_j(t', \mathbf{r}) q(t - t'). \quad (18.307)$$

With the help of (18.304), we obtain

$$[\mathcal{Q} \mathcal{L}]_j(t, \mathbf{r}) = C [h_j(\mathbf{r})]^2 \int_{-\infty}^{\infty} dt' \exp(-2\pi i \nu_0 t') m [t' - \tau_j(\mathbf{r})] q(t - t'), \quad (18.308)$$

where $\tau_j(\mathbf{r}) \equiv 2|\mathbf{r} - \mathbf{r}_{0j}|/c$.

Pulse compression To illustrate the behavior of the kernel of $\mathcal{Q} \mathcal{L}$, let us suppose that the modulation is a chirp, so that

$$m(t) = A \exp(-i\pi\beta t^2) \text{rect} \left(\frac{t}{T} \right). \quad (18.309)$$

From (18.295), the source term in the wave equation is

$$s_j(\mathbf{r}, t) = A \exp(-2\pi i\nu_0 t - i\pi\beta t^2) \operatorname{rect}\left(\frac{t}{T}\right) s_j(\mathbf{r}). \quad (18.310)$$

This signal extends over $-\frac{1}{2}T < t < \frac{1}{2}T$. The corresponding local frequency is obtained by differentiating the phase as in (5.27);¹⁷ the result is

$$\nu(t) = -\frac{1}{2\pi} \frac{\partial}{\partial t} (-2\pi\nu_0 t - \pi\beta t^2) = \nu_0 + \beta t. \quad (18.311)$$

Thus the signal spectrum extends over $\nu_0 - \frac{1}{2}\beta T < \nu(t) < \nu_0 + \frac{1}{2}\beta T$. The bandwidth of the chirp is βT and the time-bandwidth product is βT^2 .

Now suppose that the filter impulse response is the same as the transmitted signal except that β is changed to $-\beta$, which has the effect of converting an up-chirp (frequency increasing with time) to a down-chirp:

$$q(t) = \exp(-2\pi i\nu_0 t + i\pi\beta t^2) \operatorname{rect}\left(\frac{t}{T}\right) \equiv q_0(t) \exp(-2\pi i\nu_0 t), \quad (18.312)$$

where the exponential factor tells us that an impulse applied to the filter will generate a bandpass signal centered on ν_0 , and the factor $q_0(t)$ is the phase modulation of that signal. This impulse response can be realized by a dispersive delay line with a delay that varies linearly with frequency as in Fig. 18.8.

With (18.308)–(18.310) and some algebra, the kernel of \mathcal{QL} becomes

$$\begin{aligned} [\mathcal{QL}]_j(t, \mathbf{r}) &= AC [h_j(\mathbf{r})]^2 \exp\{-2\pi i\nu_0[t - \tau_j(\mathbf{r})]\} \exp\{i\pi\beta[t - \tau_j(\mathbf{r})]^2\} \\ &\times \int_{-\infty}^{\infty} dt'' \exp\{-2\pi i\beta[t - \tau_j(\mathbf{r})]t''\} \operatorname{rect}\left(\frac{t''}{T}\right) \operatorname{rect}\left[\frac{t - \tau_j(\mathbf{r}) - t''}{T}\right], \end{aligned} \quad (18.313)$$

where $t'' = t' - \tau_j(\mathbf{r})$. The important point is that the quadratic phase factors inside the integral have cancelled. The integral is now just the Fourier transform of the product of the two rects, which is another rect of width $T' = T - |t - \tau_j(\mathbf{r})|$. The “frequency variable” in this Fourier transform is $\beta[t - \tau_j(\mathbf{r})]$, and the transform is small if $\beta|t - \tau_j(\mathbf{r})|T' \gg 1$. If the time-bandwidth product βT^2 is large compared to 1, we must have $|t - \tau_j(\mathbf{r})| \ll T$, and hence

$$\begin{aligned} [\mathcal{QL}]_j(t, \mathbf{r}) &\approx AC [h_j(\mathbf{r})]^2 \exp\{-2\pi i\nu_0[t - \tau_j(\mathbf{r})]\} T \operatorname{sinc}\{\beta T[t - \tau_j(\mathbf{r})]\}, \\ &(\tau_j(\mathbf{r}) \equiv 2|\mathbf{r} - \mathbf{r}_{0j}|/c). \end{aligned} \quad (18.314)$$

This kernel is just what we would have obtained by transmitting a pulse with $m(t) = AT \operatorname{sinc}(\beta T t)$ and doing no filtering. The actual transmitted pulse has been compressed from its initial width of T to a processed width of $1/(\beta T)$. The compression ratio CR is thus

$$CR \equiv \frac{\text{initial width}}{\text{width after processing}} = \frac{T}{(\beta T)^{-1}} = \beta T^2 = \text{time-bandwidth product}. \quad (18.315)$$

The factor of T in (18.314) will become important when we discuss noise. As the pulse is compressed, it is increased in amplitude, potentially aiding in the detection of signals buried in noise.

¹⁷There is a minus sign in (18.311) not seen in (5.27). The sign difference arises because we chose in Chap. 9 to use different sign conventions on spatial and temporal Fourier transforms in order to make the Fourier kernel $\exp[i(\mathbf{k} \cdot \mathbf{r} - \omega t)]$ represent a plane wave travelling parallel to \mathbf{k} .

18.6.3 Statistical analysis

When we turn to the statistical aspects of coherent ranging systems, the key question concerns the nature of randomness and the role of probability. If we say, as we did in Sec. 18.6.2, that the object is the scattering potential \mathbf{V} , and if we neglect measurement noise, then the conditional density $\text{pr}(\mathbf{g}|\mathbf{V})$ is merely $\delta(\mathbf{g} - \mathcal{L}\mathbf{V})$ and any discussion of statistics is moot. On the other hand, we seldom know the details or fine structure of the scattering potential, and we might not be interested in them anyway. Statistical descriptions are a way of overcoming this lack of information, but it is incumbent on us to say what part of the scattering potential we think of as the object of interest and what part we regard as uninteresting and hence relegate to statistical summaries.

We avoided this issue in Sec. 18.2, where we considered free-space propagation of light from a ground glass, by saying that the ground glass was one realization of a random process. In that case all we were interested in was the statistical description of the diffracted light, and the implicit statistical ensemble was a set of ground glasses from which the one currently in the laser beam was drawn.

The problem became more acute in Sec. 18.3 when we added a lens to form an imaging system. We formulated the problem there by considering the object to be a photographic transparency \mathbf{t}_{obj} placed over a coherently illuminated ground glass. We imagined a set of experiments where the ground glass was varied but the object transparency was not; thus $\text{pr}(\mathbf{g}|\mathbf{t}_{obj})$ was no longer a delta function in this interpretation, and we could regard \mathbf{t}_{obj} or $|\mathbf{t}_{obj}|^2$ as the object.

Additional ways of defining an object were suggested in Sec. 18.5, where we considered distributions of point scatterers. One approach, evident in (18.226), was to regard the object $f(\mathbf{r})$ as the average density of point scatterers, where the average is over positions of the individual points but does not involve the phases. Another approach was to treat the object as an average energy reflectance, given by the density of scatterers times the average of the square of the scattering amplitude a_n .

These definitions can be extended to the 3D problems considered here, but they are not without their difficulties. When we want to perform a specific task, such as deciding whether a given speckle pattern was produced by an object from class 1 or class 2, it may be precisely the fine structure that is most important in the discrimination. In those cases we would not want to regard the fine structure as noise and lump it into $\text{pr}(\mathbf{g}|\mathbf{f})$, but instead would like to include it in $\text{pr}(\mathbf{f}|H_j)$, which is how we distinguish the classes in the first place. As we know from Chap. 13, the discrimination is ideally based on $\text{pr}(\mathbf{g}|H_j) = \int d\mathbf{f} \text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}|H_j)$. Thus we would be better advised to use $\text{pr}(\mathbf{g}|\mathbf{f})$ to account for measurement noise and to reserve the speckle statistics for $\text{pr}(\mathbf{f}|H_j)$.

As a practical matter, however, this ideal-observer approach is beyond the current state of the art in object modeling. In practice, tissue characterization in ultrasound or identification of regions in SAR images of terrain is based on estimates of statistical parameters under assumptions of quasistationarity rather than a full consideration of $\text{pr}(\mathbf{f}|H_j)$. The estimates are treated as features, and the classifier is formulated in feature space rather than data space.

Dealing with reality As we formulated the coherent ranging problem in Sec. 18.6.2, the data consisted of a set of complex functions $\{g_j(t)\}$. Recall, however, that we are using the convention — virtually universal in wave propagation — that the real

part of all complex quantities is understood. Thus the data are actually the set of real functions, $\{\text{Re}[g_j(t)]\}$. The functions that appear in the argument of the characteristic functional for the data are also real, and we denote them by $\{\xi_j(t)\}$, with the corresponding Hilbert-space vector denoted $\boldsymbol{\xi}$.

We define the characteristic functional for the real data as

$$\Psi_{\mathbf{g}}(\boldsymbol{\xi}) = \left\langle \exp \left\{ -2\pi i \boldsymbol{\xi}^\dagger \text{Re}[\mathbf{g}] \right\} \right\rangle = \left\langle \exp \left\{ -\pi i \boldsymbol{\xi}^\dagger [\mathbf{g} + \mathbf{g}^*] \right\} \right\rangle, \quad (18.316)$$

where, to be specific,

$$\boldsymbol{\xi}^\dagger \mathbf{g} \equiv \sum_{j=1}^J \int_{-\infty}^{\infty} dt \xi_j(t) g_j(t), \quad \boldsymbol{\xi}^\dagger \mathbf{g}^* \equiv \sum_{j=1}^J \int_{-\infty}^{\infty} dt \xi_j(t) g_j^*(t), \quad (18.317)$$

with J being the total number of transducer configurations.

Since $\mathbf{g} = \mathcal{L}\mathbf{V}$, we can also write

$$\boldsymbol{\xi}^\dagger \text{Re}[\mathbf{g}] = \frac{1}{2} \sum_{j=1}^J \int_{-\infty}^{\infty} dt \xi_j(t) \{ [\mathcal{L}\mathbf{V}]_j(t) + [\mathcal{L}\mathbf{V}]_j^*(t) \}. \quad (18.318)$$

The adjoint operator for this mixed CC-CD problem is defined by combining (1.43) and (1.45), yielding

$$[\mathcal{L}^\dagger \boldsymbol{\xi}](\mathbf{r}) = \sum_{j=1}^J \int_{-\infty}^{\infty} dt \xi_j(t) L_j^*(t, \mathbf{r}), \quad [\mathcal{L}^\dagger \boldsymbol{\xi}]^*(\mathbf{r}) = \sum_{j=1}^J \int_{-\infty}^{\infty} dt \xi_j(t) L_j(t, \mathbf{r}). \quad (18.319)$$

Thus

$$\boldsymbol{\xi}^\dagger \text{Re}[\mathbf{g}] = \frac{1}{2} \int d^3\mathbf{r} \{ [\mathcal{L}^\dagger \boldsymbol{\xi}]^*(\mathbf{r}) V(\mathbf{r}) + V^*(\mathbf{r}) [\mathcal{L}^\dagger \boldsymbol{\xi}](\mathbf{r}) \} = \frac{1}{2} \{ [\mathcal{L}^\dagger \boldsymbol{\xi}]^\dagger \mathbf{V} + \mathbf{V}^\dagger [\mathcal{L}^\dagger \boldsymbol{\xi}] \}. \quad (18.320)$$

As usual, we define the characteristic functional of the complex scattering potential by

$$\Psi_{\mathbf{V}}(\boldsymbol{\zeta}) = \left\langle \exp \left[-i\pi \left(\boldsymbol{\zeta}^\dagger \mathbf{V} + \mathbf{V}^\dagger \boldsymbol{\zeta} \right) \right] \right\rangle, \quad (18.321)$$

where $\boldsymbol{\zeta}$ corresponds to the set of *complex* functions $\{\zeta_j(\mathbf{r})\}$, so that

$$\boldsymbol{\zeta}^\dagger \mathbf{V} \equiv \int d^3\mathbf{r} \boldsymbol{\zeta}^*(\mathbf{r}) V(\mathbf{r}). \quad (18.322)$$

But note from (18.320) that

$$\Psi_{\mathbf{g}}(\boldsymbol{\xi}) = \left\langle \exp \left\{ -2\pi i \boldsymbol{\xi}^\dagger \text{Re}[\mathbf{g}] \right\} \right\rangle = \left\langle \exp \left\{ -i\pi \left([\mathcal{L}^\dagger \boldsymbol{\xi}]^\dagger \mathbf{V} + \mathbf{V}^\dagger [\mathcal{L}^\dagger \boldsymbol{\xi}] \right) \right\} \right\rangle, \quad (18.323)$$

or, by comparison with (18.321),

$$\Psi_{\mathbf{g}}(\boldsymbol{\xi}) = \Psi_{\mathbf{V}}(\mathcal{L}^\dagger \boldsymbol{\xi}). \quad (18.324)$$

Thus the usual complex transformation rule works if we merely take $\boldsymbol{\xi}$ real, even though $\mathcal{L}^\dagger \boldsymbol{\xi}$ is complex.

The Gaussian case For one time t and one detector configuration j , the data value is a weighted sum of contributions from object points in a *focal volume* defined by the kernel $L_j(t, \mathbf{r})$ defined in (18.304). As we discussed qualitatively in Sec. 18.6.1, the size of this volume is determined by both the duration of the modulation pulse $m(t)$ and by λ_0/D , where D is the diameter of the transducer and λ_0 is the free-space wavelength associated with the carrier frequency.

If the scattering potential in this focal volume can be divided into many statistically independent subvolumes, then it follows from the central-limit theorem that the received signal is Gaussian. Moreover, if we can argue that the phase of the reflected wave from each point in the volume is uniformly distributed over $(-\pi, \pi)$, then the statistics of the received signal are circular Gaussian. As we saw in (18.225), the phase of this wave arises at least in part from the random location of the scattering point in the illuminating beam. Thus a large focal volume leads us to the circular Gaussian model for two reasons: the volume contains more independent regions as it gets larger, and the phases vary more because the variations in round-trip propagation times to the transducer are greater.

If circular Gaussian statistics apply, all statistical properties of the received signal are determined by the autocovariance function of the scattering potential (which is also the autocorrelation function since circular Gaussians necessarily have zero mean). It follows from (8.147) that the autocovariance operator for \mathbf{g} is related to that for \mathbf{V} by

$$\mathcal{K}_{\mathbf{g}} = \mathcal{L}\mathcal{K}_{\mathbf{V}}\mathcal{L}^\dagger, \quad (18.325)$$

and the characteristic functional for the data becomes

$$\Psi_{\mathbf{g}}(\boldsymbol{\xi}) = \exp(-\pi^2 \boldsymbol{\xi}^\dagger \mathcal{L}\mathcal{K}_{\mathbf{V}}\mathcal{L}^\dagger \boldsymbol{\xi}). \quad (18.326)$$

We can go a step further if the correlations of the scattering potential have very short range compared to the extent of the focal volume in all three dimensions. In that case we can approximate the autocovariance function (the kernel of $\mathcal{K}_{\mathbf{V}}$) by

$$K_{\mathbf{V}}(\mathbf{r}, \mathbf{r}') = f(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'). \quad (18.327)$$

A physical interpretation of $f(\mathbf{r})$ will be given below.

With (18.327), (18.325) and (18.304), the autocovariance function for the data becomes

$$\begin{aligned} [\mathcal{K}_{\mathbf{g}}]_{jj'}(t, t') &= \int d^3\mathbf{r} \int d^3\mathbf{r}' L_j(t, \mathbf{r}) f(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') L_{j'}^*(t', \mathbf{r}') = C^2 \exp[-2\pi i \nu_0(t - t')] \\ &\times \int d^3\mathbf{r} f(\mathbf{r}) [h_j(\mathbf{r})]^2 [h_{j'}^*(\mathbf{r})]^2 m\left(t - 2\frac{|\mathbf{r} - \mathbf{r}_{0j}|}{c}\right) m^*\left(t' - 2\frac{|\mathbf{r} - \mathbf{r}_{0j'}|}{c}\right). \end{aligned} \quad (18.328)$$

This expression shows that the data are correlated in time by an amount determined by the duration of the transmitted pulse; if $j = j'$ and $m(t)$ has duration T , then the integrand vanishes if $|t - t'| > T$. Signals from two different transducer configurations, $j \neq j'$, are correlated only if the two beams overlap.

Random point scatterers As in Sec. 18.5, it is often useful to think of the scattering in coherent ranging as coming from a collection of point objects at random locations. In this model the scattering potential is written

$$V(\mathbf{r}) = \sum_{n=1}^N a_n \exp(i\phi_n) \delta(\mathbf{r} - \mathbf{r}_n). \quad (18.329)$$

A very similar expression, (18.223), appeared in Sec. 18.5 when we analyzed 2D coherent imaging, but the interpretation here is quite different; (18.223) could represent both the scatterers themselves and the scattered field since the illumination was just a plane wave. Here the illumination is a complicated spatio-temporal field.

Nevertheless, we can make good use of results from Sec. 18.5. If we assume that the phases ϕ_n are completely random and that the random positions \mathbf{r}_n are statistically independent but with a nonrandom density (per unit volume) $b(\mathbf{r})$, then the derivation leading to (18.242) is still valid (for the scattering potential, not the field), and we see that

$$\Psi_{\mathbf{V}}(\zeta) = \exp \left[-\bar{N} + \int_{\mathbf{S}} d^3\mathbf{r}_n b(\mathbf{r}_n) \langle J_0[2\pi a_n |\zeta(\mathbf{r}_n)|] \rangle_{a_n} \right]. \quad (18.330)$$

From this characteristic functional the reader can show [hint: use (18.248)] that the autocovariance function of \mathbf{V} is given by

$$K_{\mathbf{V}}(\mathbf{r}, \mathbf{r}') = b(\mathbf{r}) \langle a_n^2 \rangle \delta(\mathbf{r} - \mathbf{r}'). \quad (18.331)$$

Comparison with (18.327) then shows that

$$f(\mathbf{r}) = b(\mathbf{r}) \langle a_n^2 \rangle. \quad (18.332)$$

If we think of a_n as the square root of a backscattering cross section, then $f(\mathbf{r})$ is the number of scatterers per unit volume times the average scattering cross section. Thus $f(\mathbf{r})$ has dimensions of 1/length; since the delta function has dimension 1/length³, $K_{\mathbf{V}}$ has dimensions 1/length⁴, as it must since \mathbf{V} has dimensions of 1/length² by (18.292).

We can also use (18.330) to analyze the statistics of the data. Application of (18.324) to (18.330) gives us immediately

$$\Psi_{\mathbf{g}}(\xi) = \exp \left\{ -\bar{N} + \int_{\mathbf{S}} d^3\mathbf{r}_n b(\mathbf{r}_n) \langle J_0[2\pi a_n |[\mathcal{L}^\dagger \xi](\mathbf{r}_n)|] \rangle_{a_n} \right\}. \quad (18.333)$$

When used with the definition of \mathcal{L}^\dagger from (18.319), this expression contains the complete statistical description of the data for the point-scattering model, provided the only noise present is speckle.

Electronic noise Radar and ultrasound signals are often quite weak, and post-detection electronic noise cannot be neglected. Poisson noise, on the other hand, does not arise since the energy of microwave photons and acoustic phonons is too low to liberate photoelectrons.

When electronic noise is included, the overall mapping from scattering potential to data is given by

$$\mathbf{g} = \mathcal{L}\mathbf{V} + \mathbf{n}, \quad (18.334)$$

where $\mathbf{n} \Rightarrow n_j(t)$. The real part is still understood on $\mathcal{L}\mathbf{V}$, but \mathbf{n} is assumed real.

Since electronic noise is independent of signal level, \mathbf{V} and \mathbf{n} are statistically independent, and (18.324) becomes

$$\Psi_{\mathbf{g}}(\xi) = \Psi_{\mathbf{n}}(\xi) \Psi_{\mathbf{V}}(\mathcal{L}^\dagger \xi). \quad (18.335)$$

As discussed in detail in Chap. 12, electronic noise is usually well modeled as a zero-mean Gaussian random process, and for simplicity we assume that its bandwidth is

very large so we can take it as white noise with a constant power spectral density S_n . We assume also that the noise in different transducer configurations is uncorrelated, so the noise autocovariance function is

$$[\mathcal{K}_n]_{jj'}(t, t') = S_n \delta_{jj'} \delta(t - t'), \quad \mathcal{K}_n = S_n \mathcal{I}, \quad (18.336)$$

where \mathcal{I} is the unit operator in data space. With these assumptions, the noise characteristic functional is

$$\Psi_n(\xi) = \exp[-2\pi^2 S_n \xi^\dagger \xi] = \exp \left[-2\pi^2 S_n \sum_{j=1}^J \int_{-\infty}^{\infty} dt |\xi_j(t)|^2 \right]. \quad (18.337)$$

By Parseval's theorem, an equivalent expression is

$$\Psi_n(\xi) = \exp \left[-2\pi^2 S_n \sum_{j=1}^J \int_{-\infty}^{\infty} d\nu |\Xi_j(\nu)|^2 \right], \quad (18.338)$$

where $\Xi_j(\nu) \equiv \mathcal{F}_1\{\xi_j(t)\}$.

Filtering If we also include an electronic filtering step as in (18.305), the characteristic functional for the filter output is

$$\Psi_{\tilde{\mathbf{g}}}(\xi) = \Psi_n(\mathcal{Q}^\dagger \xi) \Psi_{\mathbf{V}}(\mathcal{L}^\dagger \mathcal{Q}^\dagger \xi). \quad (18.339)$$

This characteristic functional is the complete statistical description of the noise in all of the coherent ranging systems we are considering in this section. It will form the basis for our discussion of task performance below.

For the case of white Gaussian noise, as in (18.337), the noise characteristic functional on the filter output becomes

$$\Psi_n(\mathcal{Q}^\dagger \xi) = \exp[-2\pi^2 S_n \xi^\dagger \mathcal{Q} \mathcal{Q}^\dagger \xi]. \quad (18.340)$$

In the Fourier domain [cf. (18.338)],

$$\Psi_n(\mathcal{Q}^\dagger \xi) = \exp \left[-2\pi^2 S_n \sum_{j=1}^J \int_{-\infty}^{\infty} d\nu |Q(\nu) \Xi_j(\nu)|^2 \right], \quad (18.341)$$

where $Q(\nu)$ is the transfer function of the filter, $Q(\nu) \equiv \mathcal{F}_1\{q(t)\}$. The temporal autocovariance function on the filter output is thus [cf. (8.156)]

$$K_{\tilde{\mathbf{n}}}(t, t') = S_n [\mathcal{Q} \mathcal{Q}^\dagger](t, t') = S_n \int_{-\infty}^{\infty} d\nu |Q(\nu)|^2 \exp[-2\pi i \nu (t - t')]. \quad (18.342)$$

18.6.4 Task performance

The original task of radar is implicit in the word: radio detection and ranging. In early radar, spatial resolution was poor, and all targets could be considered to be points. The only thing that could be asked of the signal was whether a target was

present and how far away it was. In the language of Sec. 13.3.9, this is a hybrid detection/estimation task.

As radar systems improved, it became feasible to distinguish one kind of target from another on the basis of the received signal; different aircraft, for example, had different *radar signatures*, so the task became classification instead of just detection. In addition, as Doppler capabilities were added (see Sec. 18.6.1), it became possible to estimate the speed of the target in the beam direction as well as the range, so the estimation part of the task became more complicated also.

Synthetic aperture radar and medical ultrasound add new possibilities in terms of task specification since they produce high-resolution images of objects regarded as functions of continuous variables, not just as point targets. From these images we can perform all of the same tasks that we would with any image: detection, classification, estimation of integrals of the object, mensuration, etc.

In this section we shall examine both detection and estimation tasks in coherent ranging systems. Both ideal and practical strategies for task performance will be discussed, and extensive use will be made of results from Chaps. 13 and 14.

Signal-detection tasks: What do we mean by “signal”? There are two distinct ways of defining the signal to be detected in 3D coherent ranging systems. One is simply to define the object in terms of the scattering potential $V(\mathbf{r})$ as we did in Sec. 18.6.2. We can then decompose the object into a background part $V_b(\mathbf{r})$ and a signal part $V_s(\mathbf{r})$ (see Sec. 18.5.3). The signal, the background or both can be regarded as random, depending on the detailed task specification. Even if we model $V_b(\mathbf{r})$ as a circular Gaussian, the data do not have zero mean under the signal-present hypothesis because $V_s(\mathbf{r})$ is not zero mean.

The other viewpoint is to think of the object as the density of scatterers, possibly weighted by the average of the square of the scattering amplitude as in (18.332). In this case a signal can be defined as a localized change in the density of scatterers, and the data do have zero mean if the phases are completely random.

SKE detection of a point target in free space We begin our discussion of signal detection in coherent ranging with the simplest of signals: a point object at a known location in free space. In terms of the scattering potential, the object is specified by

$$V_s(\mathbf{r}) = a_s \delta(\mathbf{r} - \mathbf{r}_0). \quad (18.343)$$

Since we are considering free space, $V_b(\mathbf{r}) = 0$, and the mean data under the signal-present hypothesis are given by

$$\bar{g}_j(t) = [\mathcal{L}\mathbf{V}_s]_j(t) = a_s L_j(t, \mathbf{r}_0) = C a_s \exp(-2\pi i \nu_0 t) [h_j(\mathbf{r}_0)]^2 m \left(t - 2 \frac{|\mathbf{r}_0 - \mathbf{r}_{0j}|}{c} \right), \quad (18.344)$$

where $L_j(t, \mathbf{r})$ is the kernel of \mathcal{L} , and the last step has used (18.304).

Since the background is zero (hence nonrandom), the only noise is the Gaussian electronic noise. We know a lot about SKE detection in Gaussian noise from Chap. 13, and the only thing new here is that the data have both continuous (t) and discrete (j) indices. We expect the ideal observer to be a linear discriminant, but it is not obvious how to find the discriminant function in this mixed-data setting.

To find the ideal discriminant function, we use a result from Sec. 13.2.12. From (13.244) we know that the log-likelihood ratio $\lambda(\mathbf{g})$ is equivalent to a linear

discriminant if and only if there exists a data-space vector \mathbf{w} such that¹⁸

$$\Psi_{\mathbf{g}|H_2}(\boldsymbol{\xi}) \propto \Psi_{\mathbf{g}|H_1}\left(\boldsymbol{\xi} + \frac{i}{2\pi}\mathbf{w}\right). \quad (18.345)$$

Thus, in order for the log-likelihood ratio to be a linear discriminant, $\Psi_{\mathbf{g}|H_2}(\boldsymbol{\xi})$ must be proportional to $\Psi_{\mathbf{g}|H_1}(\boldsymbol{\xi})$ with each component shifted along the imaginary axis; the vector \mathbf{w} is the ideal-observer discriminant function.

We apply this result here to the filtered data $\tilde{\mathbf{g}}$ rather than the raw transducer output \mathbf{g} . The signal-present characteristic functional for a nonrandom \mathbf{V}_s in free space is

$$\Psi_{\tilde{\mathbf{g}}|H_2}(\boldsymbol{\xi}) = \langle \exp[-2\pi i(\mathbf{Q}\mathcal{L}\mathbf{V}_s + \mathbf{Q}\mathbf{n})^\dagger \boldsymbol{\xi}] \rangle_{\mathbf{n}} = \exp[-2\pi i(\mathbf{Q}\mathcal{L}\mathbf{V}_s)^\dagger \boldsymbol{\xi}] \Psi_{\mathbf{n}}(\mathbf{Q}^\dagger \boldsymbol{\xi}). \quad (18.346)$$

If we consider white Gaussian noise on the transducer output and use (18.340), we can write

$$\Psi_{\tilde{\mathbf{g}}|H_2}(\boldsymbol{\xi}) = \exp[-2\pi i(\mathbf{Q}\mathcal{L}\mathbf{V}_s)^\dagger \boldsymbol{\xi}] \exp[-2\pi^2 S_n \boldsymbol{\xi}^\dagger \mathbf{Q}\mathbf{Q}^\dagger \boldsymbol{\xi}]. \quad (18.347)$$

The shifted version of the no-signal characteristic functional is

$$\Psi_{\tilde{\mathbf{g}}|H_1}\left(\boldsymbol{\xi} + \frac{i}{2\pi}\mathbf{w}\right) = \exp\left[-2\pi^2 S_n \left(\boldsymbol{\xi} + \frac{i}{2\pi}\mathbf{w}\right)^\dagger \mathbf{Q}\mathbf{Q}^\dagger \left(\boldsymbol{\xi} + \frac{i}{2\pi}\mathbf{w}\right)\right]. \quad (18.348)$$

Recalling that $\tilde{\mathbf{g}}$, $\boldsymbol{\xi}$ and \mathbf{w} are all real since the actual data are real, and that $\mathbf{Q}\mathcal{L}\mathbf{V}_s$ is real by the convention that the real part is understood, we find that $\Psi_{\tilde{\mathbf{g}}|H_2}(\boldsymbol{\xi}) \propto \Psi_{\tilde{\mathbf{g}}|H_1}\left(\boldsymbol{\xi} + \frac{i}{2\pi}\mathbf{w}\right)$ if

$$S_n \mathbf{Q}\mathbf{Q}^\dagger \mathbf{w} = \mathbf{Q}\mathcal{L}\mathbf{V}_s. \quad (18.349)$$

A formal solution to this equation is given by [cf. (1.194) and (1.199)]

$$\mathbf{w} = \frac{1}{S_n} [\mathbf{Q}\mathbf{Q}^\dagger]^\dagger \mathbf{Q}\mathcal{L}\mathbf{V}_s = \frac{1}{S_n} \mathbf{Q}^{\dagger\dagger} \mathcal{L}\mathbf{V}_s, \quad (18.350)$$

where the second step follows from (1.151). Other solutions exist, but they differ from this one by null functions of \mathbf{Q}^\dagger , which correspond to frequency components outside the filter passband and do not affect the detectability.

An explicit form for the discriminant function can be found by using the fact that \mathbf{Q} and $\mathbf{Q}\mathbf{Q}^\dagger$ are 1D and shift-invariant. [Recall from Sec. 7.2.3 that the adjoint of convolution with $q(t)$ is correlation with $q^*(t)$.] With judicious insertion of 1D (temporal) Fourier operators, (18.350) becomes

$$\mathcal{F}_1 \mathbf{w} = \frac{1}{S_n} \mathcal{F}_1 \mathbf{Q}^{\dagger\dagger} \mathcal{F}_1^{-1} \mathcal{F}_1 \mathcal{L}\mathbf{V}_s. \quad (18.351)$$

¹⁸The derivation leading to (13.244) assumed a finite-dimensional data space, and $\Psi(\cdot)$ denoted a characteristic function rather than functional in that chapter, but the result is independent of the dimension of the data and therefore extends in the limit to continuous data and characteristic functionals.

If we write $q(t) = q_0(t) \exp(-2\pi i\nu_0 t)$ and $w_j(t) = w_{j0}(t) \exp(-2\pi i\nu_0 t)$, do the transforms and drop some irrelevant constants, (18.351) becomes

$$W_{j0}(\nu) \equiv \mathcal{F}_1\{w_{j0}(t)\} \propto [h_j(\mathbf{r}_0)]^2 \exp[-2\pi i\nu\tau_j(\mathbf{r}_0)] \frac{M(\nu)}{Q_0^*(\nu)}, \quad (\nu \text{ in filter passband}), \quad (18.352)$$

where capital letters denote Fourier transforms as usual, and $\tau_j(\mathbf{r}_0) \equiv 2|\mathbf{r}_0 - \mathbf{r}_{0j}|/c$. The 0 subscripts on W_{j0} and Q_0 indicate that the functions are translated back to zero frequency (*baseband* in radar parlance) before calculating the test statistic. In practice, this is done by homodyne detection in which a signal centered at frequency ν_0 is mixed with a local oscillator described in complex terms by $\exp(-2\pi i\nu_0 t)$ and only the low-frequency terms are retained.

The ideal-observer test statistic (an affine transformation of the log-likelihood ratio) is the scalar product in the mixed data space of \mathbf{w} and $\tilde{\mathbf{g}}$; by Parseval's theorem, it can be written as

$$t_{ideal}(\tilde{\mathbf{g}}) = \mathbf{w}^\dagger \tilde{\mathbf{g}} \propto \sum_{j=1}^J \int_{-\infty}^{\infty} d\nu W_{j0}^*(\nu) \tilde{G}_{j0}(\nu) \\ \propto \sum_{j=1}^J [h_j^*(\mathbf{r}_0)]^2 \int_{-\nu_{max}}^{\nu_{max}} d\nu \frac{\tilde{G}_{j0}(\nu) M^*(\nu)}{Q_0(\nu)} \exp[2\pi i\nu\tau_j(\mathbf{r}_0)], \quad (18.353)$$

where the filter passband is $\nu_0 - \nu_{max} < \nu < \nu_0 + \nu_{max}$.

The second line in (18.353) tells us that the ideal observer will first undo the electrical filter by applying an inverse filter (thereby prewhitening the data temporally), then do a temporal matched filter on the signal with its original modulation. The phase factor in the integrand tells us that the observer is looking specifically for a signal delayed by the known amount $\tau_j(\mathbf{r}_0)$ in each of the received signals. The weighting with $[h_j^*(\mathbf{r}_0)]^2$ and the sum over j constitute a matched filter with respect to the discrete transducer configurations; no prewhitening is needed in this step since we assume [see (18.336)] that signals with different j are uncorrelated.

Point-target detectability and the radar equation Since the data are Gaussian and the discriminant function is linear, the ideal-observer test statistic obeys Gaussian statistics also. Thus the SNR of the test statistic as defined in (13.19) is identical to the detectability index d_A from (13.21), and either can be used to specify the performance. The reader can fill in the details, but it follows from (13.178) that SNR^2 for an ideal observer and a point target at $\mathbf{r} = \mathbf{r}_0$ is given by

$$\text{SNR}_{ideal}^2(\mathbf{r}_0) = \frac{1}{S_n} \mathbf{V}_s^\dagger \mathcal{L}^\dagger \mathcal{Q}^\dagger \mathcal{Q}^{\dagger+} \mathcal{L} \mathbf{V}_s = \frac{C^2 |a_s|^2 \mathcal{E}_t}{S_n} \sum_{j=1}^J |h_j(\mathbf{r}_0)|^4, \quad (18.354)$$

where \mathcal{E}_t is the total energy in the transmitted signal, given by

$$\mathcal{E}_t \equiv \int_{-\nu_{max}}^{\nu_{max}} d\nu |M(\nu)|^2. \quad (18.355)$$

Each of the factors in (18.354) has a straightforward physical interpretation. We see that SNR^2 is inversely proportional to the power spectral density of the white

noise going into the filter, but it is directly proportional to the signal strength as expressed by the cross section $|a_s|^2$. The transducer conversion factor C comes in quadratically since the noise is introduced after the transducer; thus an inefficient transducer reduces the signal but not the noise. The sum over j indicates that additional transducer configurations (or “looks” at the target) are beneficial to the degree that the target remains in the beam, as specified by the factor $|h_j(\mathbf{r})|^4$. The form of the transmitted signal comes into the SNR only as the total energy \mathcal{E}_t ; the details of the modulation are irrelevant for detectability [cf. (13.120)]. In particular, note that the linear phase factor $\exp[2\pi i\nu\tau_j(\mathbf{r}_0)]$ seen in (18.353) has disappeared since the temporal matched filtering is a correlation, and the autocorrelation of $m(t - \tau)$ is the same as the autocorrelation of $m(t)$, namely a function peaked at $t = 0$. (By contrast, the autoconvolution of $m(t - \tau)$ is peaked at $t = 2\tau$.)

Since $h_j(\mathbf{r})$ is the amplitude in the diffraction pattern of the transducer, it falls off as $1/|\mathbf{r}_{0j} - \mathbf{r}_0|$ in the Fraunhofer region. Thus, for a monostatic system where all of the \mathbf{r}_{0j} are the same,

$$\text{SNR}_{ideal}^2(\mathbf{r}_0) \propto \frac{C^2 |a_s|^2 \mathcal{E}_t}{S_n} \frac{1}{|\mathbf{r}_{0j} - \mathbf{r}_0|^4}. \quad (18.356)$$

This expression is known as the *radar equation*. It shows that the point-target detectability falls off as the inverse fourth power of distance but that it can be increased by increasing either the energy of the transmitted signal or the transducer conversion efficiency. The latter option gets considerable attention in medical ultrasound.

SKE detection of extended targets in free space Much of what we learned above about ideal-observer detection for a point target in free space is readily extended to more complicated nonrandom targets, so long as we assume that the first Born approximation is valid. In particular, if there is no scattering background, so that $V_b(\mathbf{r}) = 0$ and the only noise is electronic, then the characteristic functionals of the filtered data under H_1 and H_2 are still given by (18.340) and (18.346), respectively. The ideal-observer test statistic is still linear, and the discriminant function is still given formally by (18.350).

To get a useful operational form for the test statistic, we use (18.303) – (18.305) to write [cf. (18.353)]

$$t_{ideal}(\tilde{\mathbf{g}}) \propto \sum_{j=1}^J \int d^3\mathbf{r} [h_j^*(\mathbf{r})]^2 V_s(\mathbf{r}) \int_{-\nu_{max}}^{\nu_{max}} d\nu \frac{\tilde{G}_{j0}(\nu) M^*(\nu)}{Q_0(\nu)} \exp[2\pi i\nu\tau_j(\mathbf{r})]. \quad (18.357)$$

As with point targets, the electrical filter is useless to the ideal observer, so the first step is to get rid of it by inverse-filtering (and hence temporally prewhitening) each received signal. Then the j^{th} prewhitened signal is converted to a spatial function by setting $t = \tau_j(\mathbf{r})$, and this spatial signal is matched-filtered against the expected signal; no spatial prewhitening is required by dint of (18.336).

An expression for the detectability for an extended target will be given below when we allow both electronic noise and speckle.

SKE detection in speckle So far in this section, we have considered only targets in free space, but many problems in coherent ranging also involve a diffuse scattering background, so we have speckle as well as electronic noise. As we discussed

in Sec. 18.6.3, the speckle may be well described by circular Gaussian statistics in some cases, but if the number of scatterers in a focal volume is small, non-Gaussian statistics may also arise.

In the Gaussian case, the data statistics are fully specified by the autocovariance operator, given by

$$\mathcal{K}_{\tilde{\mathbf{g}}} = \mathcal{Q}\mathcal{K}_{\mathbf{n}}\mathcal{Q}^\dagger + \mathcal{Q}\mathcal{L}\mathcal{K}_{\mathbf{V}}\mathcal{L}^\dagger\mathcal{Q}^\dagger. \quad (18.358)$$

An explicit form for the first term is given in (18.342), and one for the second term can be obtained from (18.328) by replacing $m(t)$ with $[q * m](t)$.

Since the noise is signal-independent and Gaussian, the ideal observer is a linear discriminant, and the discriminant function must satisfy [cf. (18.349)]

$$[S_n\mathcal{Q}\mathcal{Q}^\dagger + \mathcal{Q}\mathcal{L}\mathcal{K}_{\mathbf{V}}\mathcal{L}^\dagger\mathcal{Q}^\dagger]\mathbf{w} = \mathcal{Q}\mathcal{L}\mathbf{V}_s. \quad (18.359)$$

Without the speckle term in the covariance, we were able to get an explicit operational form for the discriminant, (18.352), by performing a temporal Fourier transform; because the electronic noise was stationary, Fourier transformation diagonalized the covariance operator. The speckle, on the other hand is not temporally stationary, so it is not obvious that a temporal Fourier transform will be useful in the present problem.

In similar situations in earlier chapters, we appealed to quasistationarity and assumed that the noise was locally stationary in the vicinity of the signal. For a signal centered at $\mathbf{r} = \mathbf{r}_0$, the essential approximation is to rewrite (18.327) as

$$K_{\mathbf{V}}(\mathbf{r}, \mathbf{r}') = f_b(\mathbf{r})\delta(\mathbf{r} - \mathbf{r}') \approx f_b(\mathbf{r}_0)\delta(\mathbf{r} - \mathbf{r}'), \quad (18.360)$$

where $f_b(\mathbf{r})$ is the background object, defined as in (18.332) by the mean density of scatterers times the mean scattering cross section. The assumption of spatial stationarity does not, however, immediately translate to temporal stationarity in the received signal; the covariance on \mathbf{g} is given by [cf. (18.328)]

$$\begin{aligned} & [\mathcal{K}_{\mathbf{g}}]_{jj'}(t, t') \\ & \approx C^2 f_b(\mathbf{r}_0) \exp[-2\pi i\nu_0(t - t')] \int d^3\mathbf{r} [h_j(\mathbf{r})]^2 [h_{j'}^*(\mathbf{r})]^2 m[t - \tau_j(\mathbf{r})] m^*[t' - \tau_{j'}(\mathbf{r})], \end{aligned} \quad (18.361)$$

which is not just a function of $t - t'$. Some additional approximations are needed.

Since the transducers are assumed to lie in the plane $z = 0$, it is convenient to describe the response functions in terms of the 2D vector $\mathbf{r} = (x, y)$, so that $h_j(\mathbf{r}) \equiv h_j(\mathbf{r}, z)$. In keeping with the quasistationary approximation (18.360), we can replace z with the signal coordinate z_0 in the response functions. The one place where we do not want to make this approximation, however, is in the argument of $m(\cdot)$; the modulation function determines the longitudinal resolution of the system, and we cannot assume that it is constant over the region of the signal. For propagation approximately parallel to the z axis, $\tau_j(\mathbf{r}) \approx 2z/c$ (conveniently independent of j), so

$$[\mathcal{K}_{\mathbf{g}}]_{jj'}(t, t') \approx f_b(\mathbf{r}_0) A_{jj'} \exp[-2\pi i\nu_0(t - t')] \int dz m\left(t - \frac{2z}{c}\right) m^*\left(t' - \frac{2z}{c}\right), \quad (18.362)$$

where $A_{jj'}$ is a measure of the overlap of the beams from different transducer configurations:

$$A_{jj'} \equiv C^2 \int d^2r [h_j(\mathbf{r}, z_0)]^2 [h_{j'}^*(\mathbf{r}, z_0)]^2. \quad (18.363)$$

A change of variables $z' = z - ct/2$ yields

$$\int dz m\left(t - \frac{2z}{c}\right) m^*\left(t' - \frac{2z}{c}\right) = \int dz' m\left(-\frac{2z'}{c}\right) m^*\left(t' - t - \frac{2z'}{c}\right), \quad (18.364)$$

showing that the covariance is now a function of only the time difference $t - t'$.

The remainder of the calculation proceeds by analogy with the case of SKE detection of a target in free space. By inserting Fourier operators appropriately, the reader can show that (18.359) is equivalent to

$$S_n |Q_0(\nu)|^2 W_{j0}(\nu) + \frac{c}{2} f_b(\mathbf{r}_0) |M(\nu)|^2 |Q_0(\nu)|^2 \sum_{j'=1}^J A_{jj'} W_{j'0}(\nu) = S_{j0}(\nu), \quad (18.365)$$

where $S_{j0}(\nu)$ is the signal transformed to the data domain by applying the operator \mathcal{QL} , Fourier-transforming, and shifting the frequency to baseband:

$$S_{j0}(\nu) \equiv [\mathcal{F}_1 \mathcal{QL} \mathbf{V}_s]_j(\nu - \nu_0) = CM(\nu) Q_0(\nu) \int d^3\mathbf{r} [h_j(\mathbf{r})]^2 V_s(\mathbf{r}) \exp[2\pi i \nu \tau_j(\mathbf{r})]. \quad (18.366)$$

The solution of (18.365) can be written as

$$W_{j0}(\nu) = \frac{1}{S_n |Q_0(\nu)|^2} \sum_{j'=1}^J \left[\left(\mathbf{I} + \frac{c}{2S_n} f_b(\mathbf{r}_0) |M(\nu)|^2 \mathbf{A} \right)^{-1} \right]_{jj'} S_{j'0}(\nu), \quad (18.367)$$

where \mathbf{A} is the $J \times J$ matrix with components $A_{jj'}$, and \mathbf{I} is the $J \times J$ unit matrix.

Numerical evaluation of the inverse is not difficult since \mathbf{A} is banded around the diagonal in practice; any reasonable scanning strategy will move the beam by an amount comparable to its width for each change in j since to move it in smaller increments would be to collect redundant data, while larger increments would risk missing the target altogether. Thus a small target will be seen by the system for only a few transducer configurations, and methods developed in Sec. 14.3.2 for dealing with nearly diagonal covariances, especially (14.39), are applicable here.

From (13.209), the ideal-observer detectability in this problem is

$$\begin{aligned} \text{SNR}_{ideal}^2 &= \sum_{j=1}^J \int_{-\nu_{max}}^{\nu_{max}} d\nu S_{j0}^*(\nu) W_{j0}(\nu) \\ &= \sum_{j=1}^J \sum_{j'=1}^J \int_{-\nu_{max}}^{\nu_{max}} d\nu \frac{1}{S_n |Q_0(\nu)|^2} S_{j0}^*(\nu) \left[\left(\mathbf{I} + \frac{c}{2S_n} f_b(\mathbf{r}_0) |M(\nu)|^2 \mathbf{A} \right)^{-1} \right]_{jj'} S_{j'0}(\nu). \end{aligned} \quad (18.368)$$

Note that the characteristics of the electrical filter do not affect SNR_{ideal}^2 (provided only that it doesn't cut off any signal frequencies) since $S_{j0}^*(\nu) S_{j'0}(\nu) \propto |Q_0(\nu)|^2$.

If $f_b(\mathbf{r}_0) \rightarrow 0$ (so there is no speckle) and we consider a point target, (18.368) reproduces (18.354). In the opposite case where $S_n \rightarrow 0$ and there is no electronic noise, we find

$$\text{SNR}_{ideal}^2 = \frac{2}{cf_b(\mathbf{r}_0)} \sum_{j=1}^J \sum_{j'=1}^J \int_{-\nu_{max}}^{\nu_{max}} d\nu \frac{1}{|M(\nu)|^2 |Q_0(\nu)|^2} S_{j_0}^*(\nu) [\mathbf{A}^{-1}]_{jj'} S_{j'_0}(\nu). \quad (18.369)$$

The detectability in this limit is independent of both the electrical filter and the details of the modulation since $S_{j_0}^*(\nu) S_{j'_0}(\nu) \propto C^2 |M(\nu)|^2 |Q_0(\nu)|^2$. It is even independent of the strength of the received wave since both the signal and the speckle scale the same way with the amplitude of the incident wave (contained in $|M(\nu)|^2$) and the transducer efficiency C^2 (contained in \mathbf{A}). The detectability does, however, depend on the details of the beam profile and the scanning strategy.

The SNR expressions in (18.368) and (18.369) simplify considerably if \mathbf{A} is nearly diagonal, which can happen if the beam is translated by approximately its width on each step. When \mathbf{A} is diagonal, (18.369) becomes¹⁹

$$\text{SNR}_{ideal}^2 = \frac{2}{cf_b(\mathbf{r}_0)} \sum_{j=1}^J \frac{\int_{-\nu_{max}}^{\nu_{max}} d\nu \left| \int d^3\mathbf{r} [h_j(\mathbf{r})]^2 V_s(\mathbf{r}) \exp[2\pi i\nu\tau_j(\mathbf{r})] \right|^2}{\int d^2r |h_j(\mathbf{r}, z_0)|^4}. \quad (18.370)$$

Since $\tau_j(\mathbf{r}) = 2z/c$ for propagation approximately parallel to the z axis, the numerator in (18.370) can be written

$$\begin{aligned} & \int_{-\nu_{max}}^{\nu_{max}} d\nu \int d^2r \int dz \int d^2r' \int dz' [h_j^*(\mathbf{r}, z)]^2 V_s^*(\mathbf{r}, z) [h_j(\mathbf{r}', z')]^2 V_s(\mathbf{r}', z') \\ & \quad \times \exp \left[4\pi i\nu \frac{z' - z}{c} \right] \\ & = 2\nu_{max} \int d^2r \int dz \int d^2r' \int dz' [h_j^*(\mathbf{r}, z)]^2 V_s^*(\mathbf{r}, z) [h_j(\mathbf{r}', z')]^2 V_s(\mathbf{r}', z') \\ & \quad \times \text{sinc} \left[\frac{4}{c} \nu_{max} (z' - z) \right]. \end{aligned} \quad (18.371)$$

We can go further if we assume that the signal to be detected is large and slowly varying in all three dimensions. First, if $V_s(\mathbf{r}, z)$ is slowly varying in the z direction compared to $\text{sinc} \left[\frac{4}{c} \nu_{max} (z' - z) \right]$, we can write

$$2\nu_{max} \text{sinc} \left[\frac{4}{c} \nu_{max} (z' - z) \right] \approx \frac{c}{2} \delta(z - z'), \quad (18.372)$$

and we can use this delta function to do the integral over z' . Similarly, if $V_s(\mathbf{r}, z)$ is slowly varying in x and y compared to the width of the beam, and the transducer is scanned laterally to successive positions \mathbf{r}_j , we can write

$$h_j^2(\mathbf{r}, z) = h_0^2(\mathbf{r} - \mathbf{r}_j, z) \approx \left[\int d^2r h_0^2(\mathbf{r}, z) \right] \delta(\mathbf{r} - \mathbf{r}_j), \quad (18.373)$$

¹⁹Since the matrix \mathbf{A}^{-1} arises from performing a prewhitening operation in j , neglecting the off-diagonal elements is justified even with beam overlap if we say we are using a non-prewhitening observer.

where $h_0(\mathbf{r}, z)$ is the response function for a transducer centered at $\mathbf{r}_j = \mathbf{0}$. Finally, we assume that the beam profile is nearly constant over the signal region, so $h_0(\mathbf{r}, z) \approx h_0(\mathbf{r}, z_0)$.

With all of these assumptions, the detectability takes the simple form,

$$\text{SNR}_{ideal}^2 \approx \frac{1}{f_b(\mathbf{r}_0)} \frac{|\int d^2r h_0^2(\mathbf{r}, z_0)|^2}{\int d^2r |h_0(\mathbf{r}, z_0)|^4} \sum_j \int dz |V_s(\mathbf{r}_j, z)|^2. \quad (18.374)$$

We reiterate that this expression is for SKE detection of a broad, structureless signal described by the first Born approximation when there is no electronic noise and the background scattering that leads to speckle is spatially quasistationary. We also had to assume that the beam profiles do not change appreciably with z in the signal region, that the beams propagate approximately parallel to the z axis, and that the beam steps in x and y are approximately equal to the beam width so overlap can be neglected. If electronic noise is present or the assumptions about the beam profile are not valid, we have to use the more general expression given in (18.368), and probably evaluate it numerically.

SKE detection of increases in density of scatterers So far in this section we have considered the signal to be a known, nonrandom scattering potential $V_s(\mathbf{r})$. In many applications, however, we are interested in detecting an increased density of random scatterers. In medical ultrasound, for example, some tumors are evidenced by an increased backscattering or *echogenicity*, while cysts produce markedly weaker echo signals. Early work on detectability in this situation was carried out by Smith *et al.* (1983) and Wagner *et al.* (1983, 1986, 1987). More recent work on the subject was presented by Abbey *et al.* (2003) and Zemp *et al.* (2003).

A reasonable model for this problem is to treat the scattering potential as a zero-mean random process with different autocovariances under the two hypotheses (Abbey *et al.*, 2003). If we assume that the correlation length of the random process is small compared to the system resolution, then we can follow (18.327) and write

$$K_{\mathbf{V}_1}(\mathbf{r}, \mathbf{r}') = f_b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}'), \quad K_{\mathbf{V}_2}(\mathbf{r}, \mathbf{r}') = [f_b(\mathbf{r}) + f_s(\mathbf{r})] \delta(\mathbf{r} - \mathbf{r}'), \quad (18.375)$$

where $K_{\mathbf{V}_i}(\mathbf{r}, \mathbf{r}')$ is the autocovariance function under hypothesis H_i ($i = 1, 2$), and $f_b(\mathbf{r})$ and $f_s(\mathbf{r})$ are defined similarly to (18.332) as the density of scatterers times the average cross section for background and signal, respectively. The corresponding autocovariance operators in the data domain are given by

$$\mathcal{K}_{\mathbf{g}_i} = \mathcal{K}_n + \mathcal{L} \mathcal{K}_{\mathbf{V}_i} \mathcal{L}^\dagger. \quad (18.376)$$

If the mean number of scatterers in a resolution cell is large, then Gaussian statistics apply and the characteristic functionals for the data are given by (18.326). If the number of scatterers is small (but not too small), then the characteristic functional of (18.333) is applicable, but we shall address only the Gaussian case here.

In Sec. 13.2.10, we considered the problem of discrimination between signals in Gaussian noise with unequal covariance matrices. That analysis was for finite-dimensional random vectors, but the results extend readily to random processes; from (13.163), the log-likelihood ratio is the quadratic discriminant function,

$$\lambda(\mathbf{g}) = \frac{1}{2} \mathbf{g}^\dagger [\mathcal{K}_{\mathbf{g}_1}^{-1} - \mathcal{K}_{\mathbf{g}_2}^{-1}] \mathbf{g}. \quad (18.377)$$

The inverses exist because \mathbf{K}_n is a full-rank operator with our noise model, (18.336).

If we let $\Delta\mathbf{K}_V \equiv \mathbf{K}_{V2} - \mathbf{K}_{V1}$ and make use of (18.376), we can write the operator in (18.377) as

$$\mathbf{K}_{g1}^{-1} - (\mathbf{K}_{g1} + \mathcal{L}\Delta\mathbf{K}_V\mathcal{L}^\dagger)^{-1} = \mathbf{K}_{g1}^{-1} - (\mathcal{I} + \mathbf{K}_{g1}^{-1}\mathcal{L}\Delta\mathbf{K}_V\mathcal{L}^\dagger)^{-1}\mathbf{K}_{g1}^{-1}. \quad (18.378)$$

Following a suggestion by Abbey *et al.* (2003), we use the Neumann series (A.59) to obtain

$$\lambda(\mathbf{g}) = \frac{1}{2}\mathbf{g}^\dagger\mathbf{K}_{g1}^{-1}\mathcal{L}\Delta\mathbf{K}_V\mathcal{L}^\dagger\mathbf{K}_{g1}^{-1}\mathbf{g} + \dots \quad (18.379)$$

The omitted terms are negligible if $\Delta\mathbf{K}_V$ is small enough, so the truncated expansion should suffice if the signal contrast $f_s(\mathbf{r})/f_b(\mathbf{r})$ is very low. In the limit where the electronic noise goes to zero, we can also write

$$\lambda(\mathbf{g}) = \frac{1}{2}\mathbf{g}^\dagger [\mathcal{L}\mathbf{K}_{V1}\mathcal{L}^\dagger]^+ \mathcal{L}\Delta\mathbf{K}_V\mathcal{L}^\dagger [\mathcal{L}\mathbf{K}_{V1}\mathcal{L}^\dagger]^+ \mathbf{g} + \dots, \quad (18.380)$$

where $[\mathcal{L}\mathbf{K}_{V1}\mathcal{L}^\dagger]^+$ is a Moore-Penrose pseudoinverse, defined according to (1.141) as²⁰

$$[\mathcal{L}\mathbf{K}_{V1}\mathcal{L}^\dagger]^+ = \lim_{S_n \rightarrow 0} [S_n\mathcal{I} + \mathcal{L}\mathbf{K}_{V1}\mathcal{L}^\dagger]^{-1}, \quad (18.381)$$

where S_n is the power spectral density of the white electronic noise (see (18.336)).

Various simplified forms of the log-likelihood ratio can be obtained by assuming quasistationarity ($f_b \approx \text{constant}$) and assuming that the beam propagates approximately parallel to z with little change in lateral profile over the signal region. The calculations are similar to those presented above for detection of a nonrandom scattering potential and will not be detailed here.

Figures of merit for the ideal observer in this problem can be derived from likelihood-generating function $G(\beta)$ introduced in Sec. 13.2.7. We know from the discussion in that section that all properties of the likelihood ratio and its logarithm under both hypotheses are fully determined by $G(\beta)$. Moreover, the single number $G(0)$ is a very useful approximation to the SNR for the log-likelihood ratio (Clarkson and Barrett, 2000), and it can be used to set bounds on the ideal-observer AUC (Barrett *et al.*, 1998a, b; Shapiro, 1999; Clarkson, 2002).

One way of defining $G(0)$ is in terms of the Bhattacharyya distance; for a general M -dimensional random vector \mathbf{g} , we know from (13.97) that for a general

$$G(0) = -4 \log \left\{ \int d^M g [\text{pr}(\mathbf{g}|H_1) \text{pr}(\mathbf{g}|H_2)]^{\frac{1}{2}} \right\}. \quad (18.382)$$

In the present problem, the data vector is an infinite-dimensional random process, but we can use (18.382) as if \mathbf{g} were finite-dimensional and then let $M \rightarrow \infty$.

For a circular-Gaussian random vector, we know from (8.245) that

$$\text{pr}(\mathbf{g}|H_i) = \frac{1}{\pi^N \det(\mathbf{K}_{g_i})} \exp(-\mathbf{g}^\dagger \mathbf{K}_{g_i}^{-1} \mathbf{g}). \quad (18.383)$$

²⁰As written, (1.141) applies to an operator \mathcal{H} that maps from one space to another. Here the operator $\mathcal{L}\mathbf{K}_{V1}\mathcal{L}^\dagger$ is Hermitian and maps data space to itself, and (13.181) is an equivalent form in that case. The reader who doubts the validity of (13.181) is invited to check the Penrose equations.

Thus

$$\begin{aligned}
G(0) &= -4 \log \left\{ \frac{1}{\pi^N \sqrt{\det(\mathbf{K}_{\mathbf{g}_1}) \det(\mathbf{K}_{\mathbf{g}_2})}} \int d^M g \exp \left[-\frac{1}{2} \mathbf{g}^\dagger (\mathbf{K}_{\mathbf{g}_1}^{-1} + \mathbf{K}_{\mathbf{g}_2}^{-1}) \mathbf{g} \right] \right\} \\
&= 4 \log \left\{ \det \left(\mathbf{K}_{\mathbf{g}_1}^{\frac{1}{2}} \right) \det \left(\mathbf{K}_{\mathbf{g}_2}^{\frac{1}{2}} \right) \det \left(\frac{1}{2} \mathbf{K}_{\mathbf{g}_1}^{-1} + \frac{1}{2} \mathbf{K}_{\mathbf{g}_2}^{-1} \right) \right\}, \quad (18.384)
\end{aligned}$$

where in the second line we have used the normalization of $\text{pr}(\mathbf{g}|H_i)$ along with some properties of determinants from Sec. A.5; the square-root matrix is defined in Sec. A.8.3.

Now we define $\Delta \mathbf{K} \equiv \mathbf{K}_{\mathbf{g}_2} - \mathbf{K}_{\mathbf{g}_1}$ and use the following expansions:

$$\det \left[(\mathbf{K}_{\mathbf{g}_1} + \Delta \mathbf{K})^{\frac{1}{2}} \right] = \det \left[\mathbf{K}_{\mathbf{g}_1}^{\frac{1}{2}} \left(\mathbf{I} + \frac{1}{2} \mathbf{K}_{\mathbf{g}_1}^{-1} \Delta \mathbf{K} - \frac{1}{8} \mathbf{K}_{\mathbf{g}_1}^{-1} \Delta \mathbf{K} \mathbf{K}_{\mathbf{g}_1}^{-1} \Delta \mathbf{K} + \dots \right) \right]; \quad (18.385)$$

$$\det \left[(\mathbf{K}_{\mathbf{g}_1} + \Delta \mathbf{K})^{-1} \right] = \det \left[\mathbf{K}_{\mathbf{g}_1}^{-1} \left(\mathbf{I} - \mathbf{K}_{\mathbf{g}_1}^{-1} \Delta \mathbf{K} + \mathbf{K}_{\mathbf{g}_1}^{-1} \Delta \mathbf{K} \mathbf{K}_{\mathbf{g}_1}^{-1} \Delta \mathbf{K} + \dots \right) \right]. \quad (18.386)$$

To second order in $\Delta \mathbf{K}$, $G(0)$ is given by

$$G(0) \approx 4 \log \left\{ \det \left(\mathbf{I} + \frac{1}{8} \mathbf{K}_{\mathbf{g}_1}^{-1} \Delta \mathbf{K} \mathbf{K}_{\mathbf{g}_1}^{-1} \Delta \mathbf{K} \right) \right\} \approx \text{tr} \left[\mathbf{K}_{\mathbf{g}_1}^{-1} \Delta \mathbf{K} \mathbf{K}_{\mathbf{g}_1}^{-1} \Delta \mathbf{K} \right], \quad (18.387)$$

where the last step uses the series expansion (A.114) or (18.67), again terminated at second order in $\Delta \mathbf{K}$. The limit $M \rightarrow \infty$ is accomplished merely by replacing \mathbf{K} with \mathcal{K} . The SNR on the log-likelihood ratio is then given by (13.96) as

$$\text{SNR}_\lambda^2 \approx 2G(0) \approx \text{tr} \left[\mathcal{K}_{\mathbf{g}_1}^{-1} \Delta \mathcal{K} \mathcal{K}_{\mathbf{g}_1}^{-1} \Delta \mathcal{K} \right]. \quad (18.388)$$

This expression is guaranteed to be real and nonnegative since it is equal to the sum of the squares of the eigenvalues of the Hermitian operator $\mathcal{K}_{\mathbf{g}_1}^{-1} \Delta \mathcal{K}$.

Limits and special cases of this general result remain to be explored, and its relation to earlier work such as Wagner *et al.* (1983, 1986, 1987), Abbey *et al.* (2003) and Zemp *et al.* (2003) needs to be elucidated.

Known signals at unknown locations The SKE detection paradigm is unrealistic in radar and ultrasound because we never know in advance where the target is located. There are two ways we can consider incorporating this uncertainty into our analysis of detectability. The first is to consider a pure detection problem with random signal locations, and the second is to consider a joint detection-estimation problem. The difference is really in how we keep score. If the observer is given credit for a correct detection even it thinks the signal is at an incorrect location, then the problem is pure detection. In the joint detection-estimation problem, on the other hand, errors in position estimation are penalized. In the former case, figures of merit are related to the ROC curve, while in the latter case an LROC, FROC or AFROC curve can be used (see Sec. 14.2.3 and Figs. 14.4 and 14.5).

The likelihood ratio for an ideal observer attempting to detect a known signal at an unknown location in Gaussian noise was derived in Sec. 13.2.10. We saw in (13.161) that the optimal strategy in this case is to prewhiten the data, form the scalar product of the prewhitened data with the known signal, exponentiate the result and average over all possible signal locations; all information about signal

location is lost in this averaging step. This strategy optimizes the area under the ROC curve with no penalty for incorrect signal location.

A common suboptimal strategy is the scanning matched filter or cross-correlator, where the noisy data are correlated with the known signal, essentially forming the scalar product for all possible shifts in a continuous fashion and omitting the exponentiation step. The final decision on signal-absent vs. signal-present is then made by choosing the shift for which the cross-correlator output is maximum and comparing the result to a threshold. For Gaussian noise, this strategy is equivalent to using the generalized likelihood ratio defined in (13.401). Various workers, including Nolte and Jaarsma (1967), Pelli (1985) and Wagner *et al.*, (1990b) have shown that this approach gives performance predictions very close to those of the optimal observer in the SNR ranges of experimental interest.

The joint detection-estimation problem was discussed in Sec. 13.3.9, where we formulated the problem as one of minimizing a cost function that involved both the detection and estimation aspects. With assumptions about the costs stated in that section, the optimal strategy is to first do the pure detection problem optimally by averaging the likelihood ratio over locations and then do MAP estimation if a signal-present decision is made.

In spite of the importance of joint detection-estimation problems in radar, ultrasound and many other areas, much further work is needed. In general terms, it is not yet clear how decisions about optimization of imaging systems might change depending on whether the task is formulated as pure detection or hybrid detection-estimation, and in the latter case how they might depend on the nature of the parameters to be estimated and their assumed probability densities. With particular reference to coherent imaging, it is not clear how the detectability is degraded by envelope detection and how it is affected by non-Gaussian statistics. It is also not yet known how to perform joint detection-estimation tasks optimally in non-Gaussian speckle.

19

Imaging in Fourier space

Imaging is fundamentally a way of obtaining information about the spatial distribution of some object characteristic, such as its transmittance, reflectance or radiant exitance. A direct-imaging system measures that distribution by sampling it over local, point-like spatial regions. Indirect imaging systems may start with nonlocal measurements but again the goal is to sample the spatial distribution in some sense.

In some indirect imaging systems, the initial measurements are essentially samples of the Fourier transform of the object distribution, rather than the desired distribution itself. Then the reconstruction step is some sort of inverse Fourier transform. Another way of thinking about such systems is that they are CD mappings in which the detector sensitivity functions approximate kernels of the Fourier transform; by contrast, direct imaging systems use sensitivity functions that approximate delta functions.

Fourier imaging systems are widespread. Magnetic resonance imaging (MRI) measures Fourier components of the induced magnetization in a patient's body, and some forms of synthetic-aperture radar sample the Fourier transform of the microwave reflectance of the terrain. Radioastronomy is basically the measurement of selected Fourier components of celestial sources of radio waves.

The whole field of Fourier optics (Goodman, 1968) is concerned with systems that use coherent light to study the Fourier transforms of object transmittances. In particular, certain kinds of holography yield measurements of the complex Fourier transforms of complex amplitude distributions.

Even tomographic systems such as SPECT (see Chap. 17) fit at least partially into the rubric of Fourier imaging; they measure line-integral projections of the object, but the central-slice theorem (Sec. 4.4.2) tells us that 1D Fourier transforms of the projections give us the 2D Fourier transform of the object.

In this chapter we shall illustrate the principles of Fourier imaging by considering two classes of measurement systems that directly acquire information about the object Fourier transform. The first class, called Fourier modulators and discussed in Sec. 19.1, consists of systems that use a sequence of masks that are related in a

simple way to the Fourier kernel. The second class, covered in Sec. 19.2, consists of a variety of interferometers used mainly in astronomy. Our goal is to show how the tools developed in this book can be used to analyze and evaluate systems in both classes.

19.1 FOURIER MODULATORS

A Fourier modulator is a system that implements the Fourier integral literally. Computation of the Fourier transform of a function consists of two steps: modulating the function by multiplication with the Fourier kernel and integration of the result. Each step—modulation and integration—can be implemented in many different ways, depending on the physical nature of the object and the kind of radiation detector used. Here we consider mainly systems that measure the radiant exitance of some self-luminous object, though we shall also briefly discuss reflecting objects. Modulation will be by means of a series of masks placed directly over the object or over an intermediate image of the object.

The kinds of masks that can be used and the nature of the information they convey is surveyed in Sec. 19.1.1. Noise is included in the formalism in Sec. 19.1.2, and reconstruction of an object from a set of noisy samples of its Fourier transform is treated in Sec. 19.1.3. The key issue of image quality is discussed in Sec. 19.1.4.

19.1.1 Data acquisition

To pick a trivial starting point, the 2D Fourier transform is defined by

$$F(\boldsymbol{\rho}) = \int_{\infty} d^2r f(\mathbf{r}) \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \quad (19.1)$$

Suppose that we want to apply this definition to compute not the entire 2D distribution in the Fourier plane but rather its value at a single point, $\boldsymbol{\rho} = \boldsymbol{\rho}_0$. If we could synthesize a mask with the complex transmittance $\exp(-2\pi i \boldsymbol{\rho}_0 \cdot \mathbf{r})$, lay it over the object and integrate the resulting product, we would have the desired complex value, $F(\boldsymbol{\rho}_0)$.

There are several obvious problems with this approach. We may not know how to construct a complex mask, there may not be a good way of doing the complex integration, and even if we solve those problems, all that we have obtained is one point in the Fourier transform; to scan the entire Fourier plane we have to repeat the process with many different masks with different magnitudes and orientations of the spatial frequency vector $\boldsymbol{\rho}$. Undaunted, let us consider each of these problems in turn.

Complex masks Since $\exp(-2\pi i \boldsymbol{\rho}_0 \cdot \mathbf{r}) = \cos(2\pi \boldsymbol{\rho}_0 \cdot \mathbf{r}) - i \sin(2\pi \boldsymbol{\rho}_0 \cdot \mathbf{r})$, we can rewrite the definition of the Fourier transform as

$$F(\boldsymbol{\rho}_0) = \int_{\infty} d^2r f(\mathbf{r}) \cos(2\pi \boldsymbol{\rho}_0 \cdot \mathbf{r}) - i \int_{\infty} d^2r f(\mathbf{r}) \sin(2\pi \boldsymbol{\rho}_0 \cdot \mathbf{r}). \quad (19.2)$$

Now we need two real masks instead of one complex one. Moreover, if $f(\mathbf{r})$ is real, we do not have to do a complex integration. Laying the cosine mask over the object and integrating the product gives the first integral in (19.2), and using the sine

mask similarly gives the second integral; both integrals are real, and each yields one number. If we record the two real numbers separately in our lab notebook (or computer), we have the real and imaginary parts of $F(\boldsymbol{\rho}_0)$ for one particular $\boldsymbol{\rho}_0$.

Nonnegativity In many applications, $f(\mathbf{r})$ represents a radiant exitance, reflectance or other quantity that cannot go negative, and the relevant transmittance is a nonnegative real quantity between 0 and 1. We cannot synthesize a mask with transmittance $\cos(2\pi\boldsymbol{\rho}_0 \cdot \mathbf{r})$ but we can synthesize one with transmittance $\frac{1}{2}[1 \pm \cos(2\pi\boldsymbol{\rho}_0 \cdot \mathbf{r})]$. Thus it is advantageous to rewrite the definition of the Fourier transform once more as

$$F(\boldsymbol{\rho}_0) = \int_{\infty} d^2r f(\mathbf{r}) \frac{1}{2}[1 + \cos(2\pi\boldsymbol{\rho}_0 \cdot \mathbf{r})] - \int_{\infty} d^2r f(\mathbf{r}) \frac{1}{2}[1 - \cos(2\pi\boldsymbol{\rho}_0 \cdot \mathbf{r})] \\ - i \int_{\infty} d^2r f(\mathbf{r}) \frac{1}{2}[1 + \sin(2\pi\boldsymbol{\rho}_0 \cdot \mathbf{r})] + i \int_{\infty} d^2r f(\mathbf{r}) \frac{1}{2}[1 - \sin(2\pi\boldsymbol{\rho}_0 \cdot \mathbf{r})]. \quad (19.3)$$

Now we have decomposed the complex integral into four real integrals, each of which has a nonnegative integrand. Each integral is obtained by laying the appropriate mask over the object and collecting all of the emerging light with a nonimaging detector. For each $\boldsymbol{\rho}_0$, we must measure four nonnegative real numbers in this way, but at least it is beginning to appear that there are no physical impediments to the measurement.

Reducing the number of masks The form of (19.3) is a bit misleading since it seems to imply that we need four masks for each spatial frequency. Suppose, however, that we have one mask with transmittance $\frac{1}{2}[1 + \cos(2\pi\boldsymbol{\rho}_0 \cdot \mathbf{r})]$. We can shift this mask to four positions, producing the other three required transmittances; for example, $\frac{1}{2}[1 + \sin(2\pi\boldsymbol{\rho}_0 \cdot \mathbf{r})]$ is obtained by shifting the original mask, $\frac{1}{2}[1 + \cos(2\pi\boldsymbol{\rho}_0 \cdot \mathbf{r})]$ a quarter period in the direction $\boldsymbol{\rho}_0$. Thus one physical mask serves for all four measurements required at one frequency $\boldsymbol{\rho}_0$.

Moreover, the same mask can be rotated to yield all of the spatial frequencies with the same magnitude as $\boldsymbol{\rho}_0$ but different orientations. Thus if we choose to scan the 2D Fourier plane in polar coordinates, one real, nonnegative mask will suffice for all of the complex measurements on a circle of radius ρ_0 . Different masks will be needed for different radii in Fourier space.

Note also that it is not necessary to lay the mask directly on the object. It suffices to relay the object to an intermediate image plane and locate the mask there. If this relay system has variable magnification, one mask can serve for a range of scales of ρ .

Moiré masks One way to synthesize the needed masks is by the moiré effect.¹ Suppose we have two very fine masks, each of transmittance $\frac{1}{2}[1 + \cos(2\pi\rho_c \cdot \mathbf{r})]$, where subscript c denotes *carrier frequency*. We shall assume that ρ_c is large compared to any spatial frequency present in the object. If we overlay the two masks, we get a low-frequency moiré pattern as shown in Fig. 19.1, and the two overlapping high-frequency masks serve as one of the low-frequency masks needed in the method

¹The word moiré, referring to “watered silk,” comes from the English *mohair*, which was apparently borrowed into French and then returned to English with the accent.

described above. The relative rotation angle between the two masks varies the magnitude of the spatial frequency of the pattern, and rotating both masks together varies its direction. Moreover, the phase of the moiré pattern can be shifted by shifting either mask laterally. The reader is invited to verify these contentions by making two copies of Fig. 19.1a on transparency paper and overlaying them, say on a light box or overhead projector.

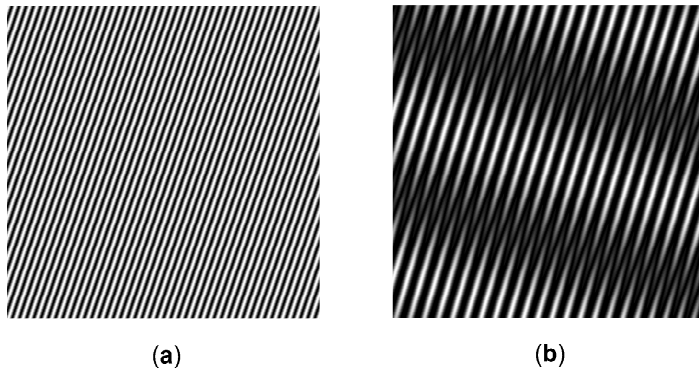

Fig. 19.1 Illustration of the moiré pattern produced by overlaying two cosinusoidal patterns. (a) Single cosinusoidal pattern; (b) product of two identical patterns slightly rotated with respect to each other.

To explain the moiré effect mathematically, let us use a 2D rotation operator $\mathbf{R}(\theta)$ and write the transmittance of the overlaid masks as

$$T(\mathbf{r}; \theta_1, \theta_2) = \frac{1}{2} \{1 + \cos[2\pi \boldsymbol{\rho}_c \cdot \mathbf{R}(\theta_1) \mathbf{r}]\} \frac{1}{2} \{1 + \cos[2\pi \boldsymbol{\rho}_c \cdot \mathbf{R}(\theta_2) \mathbf{r}]\}. \quad (19.4)$$

Since the rotation operator is unitary, $\mathbf{R}^\dagger(\theta) = \mathbf{R}^{-1}(\theta) = \mathbf{R}(-\theta)$, and we can use the definition of the adjoint to write

$$\begin{aligned} T(\mathbf{r}; \theta_1, \theta_2) &= \frac{1}{2} \{1 + \cos[2\pi \mathbf{R}(-\theta_1) \boldsymbol{\rho}_c \cdot \mathbf{r}]\} \frac{1}{2} \{1 + \cos[2\pi \mathbf{R}(-\theta_2) \boldsymbol{\rho}_c \cdot \mathbf{r}]\} \\ &= \frac{1}{4} \{1 + \cos[2\pi \boldsymbol{\rho}_{1,2} \cdot \mathbf{r}]\} + \text{high-frequency terms}, \end{aligned} \quad (19.5)$$

where

$$\boldsymbol{\rho}_{1,2} \equiv \mathbf{R}(-\theta_1) \boldsymbol{\rho}_c - \mathbf{R}(-\theta_2) \boldsymbol{\rho}_c. \quad (19.6)$$

As shown in Fig. 19.2, $\boldsymbol{\rho}_{1,2}$ is simply the vector difference of the two rotated spatial-frequency vectors.

Fig. 19.2 Vector diagram illustrating the sum- and difference-frequency terms seen in the moiré pattern of Fig. 19.1b.

The high-frequency terms in (19.5) all have $\rho \geq \rho_c$ and can be neglected if the object Fourier transform is negligible at these frequencies. By the same argument, we could use square-wave patterns, and the harmonics of the carrier frequency can be neglected. Harmonics of the difference frequency, however, still remain.

The interesting difference-frequency term in (19.5) can be scanned over a portion of the Fourier plane by varying the two angles, θ_1 and θ_2 . Specifically, if we allow θ_1 and θ_2 to cover $(0, 2\pi)$ but restrict $|\theta_1 - \theta_2| \leq \Delta\theta_{max}$, then we can reach any frequency that satisfies $\rho \leq 2\rho_c \sin \frac{1}{2}\Delta\theta_{max}$.

A possible moiré-Fourier imaging system takes the form shown in Fig. 19.3, where the moiré mask is placed in close proximity to the object, and the object is either self-luminous or a transparency placed over a diffuse light source. A single-element nonimaging detector collects some fraction of the emerging light. If we assume that the fraction of the light collected is the same for all points in the object plane, the mean detector output is given by

$$\bar{V}_{out} \propto \int_{\infty} d^2r f(\mathbf{r}) T(\mathbf{r}; \theta_1, \theta_2). \quad (19.7)$$

By shifting either mask laterally to get four terms as in (19.3) and by scanning the difference frequency by varying the two angles, we can sample the desired portion of the Fourier plane.

The configuration shown in Fig. 19.3 was first suggested by Mertz (1956). It can be used for any kind of radiation, and in fact it was used for gamma rays by Chou and Barrett (1978). In that case the masks were made of lead.

Fig. 19.3 Simple system for measuring Fourier components of a planar object. The object and the two masks are shown separated for clarity, but would actually be in close proximity to each other, with the nonimaging detector a larger distance away. Rotation of the two masks varies the spatial frequency of the moiré pattern and hence the Fourier component being measured.

Projecting fringe patterns If the object is reflecting rather than self-luminous or transmitting, we cannot place the mask in close proximity to it since it would then obscure the illumination. We could relay the object to an intermediate image plane and place the mask there, but we can also implement the mask by structuring the illumination itself.

Suppose $f(\mathbf{r})$ represents a reflectance, and let $I(\mathbf{r})$ be the illuminating irradiance. If we can arrange to make $I(\mathbf{r}) \propto \frac{1}{2}[1 + \cos(2\pi\rho_0 \cdot \mathbf{r} + \phi)]$, then the total reflected light is given by one of the integrals in (19.3), with the phase ϕ specifying which one.

An easy way to get the desired irradiance profile is to interfere two plane waves. Suppose we produce two plane waves in a 3D space, with the complex amplitudes given by $u_1(\mathbf{r}) = A \exp(i\mathbf{k}_1 \cdot \mathbf{r})$ and $u_2(\mathbf{r}) = A \exp(i\mathbf{k}_2 \cdot \mathbf{r})$. If we let the two waves overlap on the plane $z = 0$, the resulting irradiance is²

$$\begin{aligned} I(\mathbf{r}) &= |u_1(\mathbf{r}) + u_2(\mathbf{r})|_{z=0}^2 = 2|A|^2 \{1 + \cos[(\mathbf{k}_1 - \mathbf{k}_2) \cdot \mathbf{r}]\}_{z=0} \\ &= 2|A|^2 [1 + \cos(2\pi \boldsymbol{\rho}_0 \cdot \mathbf{r})], \end{aligned} \quad (19.8)$$

where

$$\boldsymbol{\rho}_0 = \left(\frac{k_{1x} - k_{2x}}{2\pi}, \frac{k_{1y} - k_{2y}}{2\pi} \right). \quad (19.9)$$

Thus the 2D spatial frequency can be tuned by varying the \mathbf{k} vectors of the two interfering plane waves.

Zone-plate moiré A Fresnel zone plate is a pattern of concentric annular zones, alternately clear and opaque, as illustrated in Fig. 19.4. Mathematically, a zone plate has a transmittance given by

$$T_{zp}(\mathbf{r}) = \frac{1}{2} \{1 + \text{sgn}[\sin(\alpha r^2)]\} S(\mathbf{r}), \quad (19.10)$$

where $\text{sgn}[\cdot]$ is the signum function defined in Sec. 2.3.2, and $S(\mathbf{r})$ is a support function specifying the overall area of the zone plate. If $S(\mathbf{r})$ is a cylinder function [defined in (3.257)] centered on the origin, we refer to the zone plate as *on-axis*, but if it is a cylinder function displaced from the origin the zone plate is said to be *off-axis*. The transitions between clear and opaque zones occur at the zeros of the sine, or when $\alpha r_n^2 = n\pi$, ($n = 1, 2, 3, \dots$). Thus $r_1 = \sqrt{\pi/\alpha}$, and $r_n = r_1 \sqrt{n}$. It follows that all zones of an on-axis zone plate have the same area, namely πr_1^2 .

Fig. 19.4 Fresnel zone plates. (a) On-axis; (b) off-axis.

²We employ the same convention for spatial vectors here as in earlier chapters. The gothic \mathbf{r} is a 3D vector and the Times Roman \mathbf{r} is 2D, but they refer to the same physical point. Thus, if the point is on the plane $z = 0$, $\mathbf{r} = (x, y)$ and $\mathbf{r} = (x, y, 0)$.

Overlaying two Fresnel zone plates yields straight-line moiré fringe patterns, as shown in Fig. 19.5. Different moiré spatial frequencies are generated by shifting one zone plate relative to the other, rather than by rotating the patterns as with the cosine masks discussed above. The reader may play with the zone-plate moiré effect by making two transparencies of Fig. 19.4.

Fig. 19.5 Moiré patterns produced by overlapping two identical zone plates with a slight relative shift. (a) On-axis zone plates; (b) off-axis zone plates.

The visual appearance of the moiré fringes in Fig. 19.5 is similar to that seen for cosine grating patterns in Fig. 19.1, but the math is quite different. Expanding $\text{sgn}[\sin(\alpha r^2)]$ in a Fourier series in the variable r^2 , we can write (Shulman, 1970; Barrett and Swindell, 1981, 1996)

$$T_{zp}(\mathbf{r}) = \left[\frac{1}{2} + \frac{1}{\pi i} \sum_{\substack{k=-\infty \\ (k \text{ odd})}}^{\infty} \frac{1}{k} \exp(-i\alpha k r^2) \right] S(\mathbf{r}). \quad (19.11)$$

The net transmittance of two overlapping zone plates, one shifted by \mathbf{r}_0 , is

$$\begin{aligned} & T_{zp}(\mathbf{r}) T_{zp}(\mathbf{r} - \mathbf{r}_0) \\ &= \left[\frac{1}{2} + \frac{1}{\pi i} \sum_{\substack{k=-\infty \\ (k \text{ odd})}}^{\infty} \frac{1}{k} \exp(-i\alpha k r^2) \right] \left[\frac{1}{2} + \frac{1}{\pi i} \sum_{\substack{k'=-\infty \\ (k' \text{ odd})}}^{\infty} \frac{1}{k'} \exp(-i\alpha k' |\mathbf{r} - \mathbf{r}_0|^2) \right] S(\mathbf{r}, \mathbf{r}_0), \end{aligned} \quad (19.12)$$

where $S(\mathbf{r}, \mathbf{r}_0) \equiv S(\mathbf{r}) S(\mathbf{r} - \mathbf{r}_0)$. The straight-line moiré fringes arise from terms with $k = -k'$. Focusing on $k = \pm 1$, we can write

$$\begin{aligned} & T_{zp}(\mathbf{r}) T_{zp}(\mathbf{r} - \mathbf{r}_0) \\ &= \left\{ \frac{1}{4} + \frac{1}{\pi^2} [\exp(-i\alpha r^2) \exp(i\alpha |\mathbf{r} - \mathbf{r}_0|^2) + \exp(i\alpha r^2) \exp(-i\alpha |\mathbf{r} - \mathbf{r}_0|^2)] \right\} S(\mathbf{r}, \mathbf{r}_0) \\ & \quad + \text{other terms}, \end{aligned} \quad (19.13a)$$

which simplifies to

$$T_{zp}(\mathbf{r}) T_{zp}(\mathbf{r} - \mathbf{r}_0) = \left[\frac{1}{4} + \frac{2}{\pi^2} \cos(2\alpha \mathbf{r} \cdot \mathbf{r}_0 - \alpha r_0^2) \right] S(\mathbf{r}, \mathbf{r}_0) + \text{other terms}. \quad (19.13b)$$

Thus the fringes have a spatial frequency of $\alpha\mathbf{r}_0/\pi$ and a phase of αr_0^2 . By varying the shift \mathbf{r}_0 , we can generate a sequence of positive and negative sine and cosine moiré masks of varying frequency. The reader will appreciate this result more by actually observing the effect with transparencies made from Fig. 19.4.

Another way to understand (19.13) — and to make some statements about the neglected terms — is to use the concept of local spatial frequency, introduced in Sec. 5.1.3. We know from (5.35) that a pure phase function $f(\mathbf{r}) = \exp[i\Phi(\mathbf{r})]$ has a local frequency at point \mathbf{r} given by $\boldsymbol{\rho}_{loc}(\mathbf{r}) = (2\pi)^{-1} \nabla\Phi(\mathbf{r})$. For Fresnel zone plates, each term in the expansion (19.11) is a pure phase function, and $\boldsymbol{\rho}_{loc}(\mathbf{r})$ for the k^{th} term is given by $-(\alpha k/\pi)\mathbf{r}$ [cf. (5.37)]. When we overlap two zone plates as in (19.12), the moiré or difference-frequency term for $k = -k' = \pm 1$ is $\boldsymbol{\rho}_{loc}(\mathbf{r}) = \pm(\alpha/\pi)[\mathbf{r} - (\mathbf{r} - \mathbf{r}_0)] = \pm(\alpha/\pi)\mathbf{r}_0$. For $k = -k' \neq \pm 1$, we find $\boldsymbol{\rho}_{loc}(\mathbf{r}) = \pm(\alpha k/\pi)\mathbf{r}_0$, so these terms correspond to odd harmonics of the fundamental frequency $(\alpha/\pi)\mathbf{r}_0$; the moiré fringes are not pure cosines or sines for binary zone plates. Should we wish to eliminate the harmonic terms, we could use sinusoidal zone plates rather than binary ones. The reader is invited to retrace the analysis for this case.

Terms with $k \neq -k'$ are potentially more worrisome. Even with sinusoidal zone plates, we have the terms with $k = k' = \pm 1$, for which $\boldsymbol{\rho}_{loc}(\mathbf{r}) = \pm(\alpha/\pi)[\mathbf{r} + (\mathbf{r} - \mathbf{r}_0)] = \pm(\alpha/\pi)[2\mathbf{r} - \mathbf{r}_0]$. This sum-frequency term has a local frequency that depends linearly on \mathbf{r} , so it corresponds to a chirp in the moiré pattern [cf. (5.37)]. With this term present, we measure a linear combination of the Fourier and the Fresnel transform of the object (see Sec. 4.3.2).

To eliminate nettlesome sum-frequency terms, we can use off-axis zone plates. Suppose the support function $S(\mathbf{r})$ is given by $\text{cyl}[(\mathbf{r} - \mathbf{r}_c)/D]$, which describes an aperture of diameter D centered at $\mathbf{r} = \mathbf{r}_c$. For the k^{th} term in the expansion, the local frequency at the center of the aperture is $(\alpha k/\pi)\mathbf{r}_c$. Thus, for $k = k' = \pm 1$ and for $r_0 \ll r_c$, the relevant local frequency is in the vicinity of $\pm(\alpha/\pi)2\mathbf{r}_c$; if this frequency is large compared to any spatial frequency in the object, the sum-frequency term is not important. This approximation is essentially the same as ignoring the carrier-frequency terms in (19.5), but with zone plates frequency is coupled to position by the local-frequency relation.

We shall return to the issue of neglected terms in Sec. 19.1.3 when we discuss reconstruction from Fourier samples.

Parallel data acquisition So far we have discussed systems that sample one Fourier component of the object at a time; getting another component requires replacing masks or performing some other mechanical motion. It would be desirable to have some way of measuring many different Fourier components simultaneously without mechanical motion.

With zone-plate moiré, the different masks are obtained by shifts of one zone plate with respect to the other, and the shifts can be accomplished by parallax rather than mechanically. Consider the system shown in Fig. 19.6. The object, assumed to be either self-luminous or an illuminated transparency, is in contact with the first zone plate. The second zone plate, half the scale of the first, is placed midway between the masked object and an observation plane. If we neglect diffraction,³ light emerging from the first zone plate at point \mathbf{r} and arriving at point

³This is the first mention of diffraction in this chapter; if the object and one or more masks are all in contact, diffraction is irrelevant.

\mathbf{r}_d on the observation plane must have passed through the middle zone plate at the point $\mathbf{r}' = \frac{1}{2}(\mathbf{r}_d + \mathbf{r})$. (Note that \mathbf{r} , \mathbf{r}' and \mathbf{r}_d are 2D vectors in different planes.) If we denote the transmittance of the first zone plate by $T_{zp}(\mathbf{r})$, and that of the second (half-scale) zone plate by $T_{zp}(2\mathbf{r}')$, then the irradiance at point \mathbf{r}_d is given by

$$I(\mathbf{r}_d) \propto \int_{\infty} d^2r f(\mathbf{r}) T_{zp}(\mathbf{r}) T_{zp}(\mathbf{r}_d + \mathbf{r}). \quad (19.14)$$

From this point on, we have exactly the same mathematics as in (19.12) and (19.13), but we see that the variable mechanical shift \mathbf{r}_0 has been replaced by the variable observation point \mathbf{r}_d . A detector array placed in the observation plane will sample many different shifts simultaneously. Since a shift \mathbf{r}_d corresponds to a spatial frequency of $\alpha\mathbf{r}_d/\pi$ and a phase of αr_d^2 in the moiré pattern, a single readout of the detector array yields measurements of many different sine and cosine Fourier components.

Fig. 19.6 Configuration for implementing the shift between two zone plates by parallax. Note the relative shift of the projections of the two zone plates from points A and B in the viewing plane.

Mertz Fresnel sandwich There is one minor problem with the configuration of Fig. 19.6. If we consider only the terms with $k = -k' = 1$, then

$$\begin{aligned} I(\mathbf{r}_d) &\propto \int_{\infty} d^2r f(\mathbf{r}) \exp(i\alpha r^2) \exp(-i\alpha|\mathbf{r}_d + \mathbf{r}|^2) + \text{dull terms} \\ &= \exp(-i\alpha r_d^2) \int_{\infty} d^2r f(\mathbf{r}) \exp(-2i\alpha\mathbf{r}_d \cdot \mathbf{r}) + \text{dull terms}. \end{aligned} \quad (19.15)$$

This expression is the desired Fourier transform multiplied by a quadratic phase factor.

We could simply ignore the quadratic phase factor, since it is just a constant independent of \mathbf{r} (hence outside the integral), but we can also cancel it out by adding one more zone plate as shown in Fig. 19.7. This third zone plate has the same scale as the first one, so it is described by the transmittance $T_{zp}(\mathbf{r}_d)$. The math gets very messy if we use the full expansion (19.11), but the essential point is that $T_{zp}(\mathbf{r}_d)$ contains a term in $\exp(+i\alpha r_d^2)$, which will serve to cancel the $\exp(-i\alpha r_d^2)$ in (19.15). Other terms are present as well, but we can argue that they are not so important

if we use off-axis zone plates with sufficiently high center frequencies.

Fig. 19.7 Fresnel sandwich, obtained from the configuration of Fig. 19.6 by placing an additional zone plate in the output plane. (a) Layout. (b) schematic.

The three-zone-plate configuration was first presented in a delightful little book entitled *Transformations in Optics*, by Larry Mertz (1965). Mertz referred to Fig. 19.7 as a *Fresnel sandwich*, and he showed how it led to practical imaging applications as well as insightful analogies.

We have actually already met the Fresnel sandwich in earlier chapters. Recall from Sec. 4.3.3 that we can compute the Fourier transform of a function in a roundabout way if we multiply it by a chirp, convolve with the conjugate chirp, and multiply again by the original chirp. With judicious selection of terms, that is precisely what we are doing with the configuration of Fig. 19.7.

Another context in which we have met the same mathematics is in discussing coherent optical Fourier transformers in Sec. 9.7.2. We know from that section that the system shown in Fig. 19.8a performs a Fourier transformation on the electric field at its input. This system involves a section of free-space propagation, multiplication by the amplitude transmittance of a lens, and then another section of free-space propagation. In the Fresnel approximation, free-space propagation amounts to convolution with a chirp [see (9.94)], and transmission through a lens is equivalent to multiplication by a chirp [see (9.159)], so the system of Fig. 19.8a implements the convolve-multiply-convolve or CMC chirp-Fourier transform algorithm of Sec. 4.3.3. The Fresnel sandwich, on the other hand, implements the MCM (multiply-convolve-multiply) chirp-Fourier transform algorithm. A coherent optical system that also implements MCM is shown in Fig. 19.8b.

Fig. 19.8 Two coherent optical Fourier-transform systems. (a) System that implements the CMC chirp-Fourier transform algorithm; (b) system that implements the MCM algorithm, analogously to the Fresnel sandwich.

19.1.2 Noise

So far our analysis of Fourier imaging has neglected noise and treated the problem as CC. In reality we collect only a finite amount of noisy data, so a better description of a Fourier imaging system, as with any digital imaging system, is as a CD mapping. As detailed in Chap. 12, measurement noise can usually be modeled as either Gaussian or Poisson. In this section we shall discuss the effects of this noise on the discrete raw data and on estimates of the Fourier transform values derived from these data.

The data It will prove useful to denote each discrete measurement with two indices, one for the spatial frequency and one for the phase of the Fourier kernel. Thus we write

$$g_{mj} = C \int_{\infty} d^2r f(\mathbf{r}) T_{mj}(\mathbf{r}) + n_{mj}, \quad (19.16)$$

where C is a radiometric constant and $T_{mj}(\mathbf{r})$ is the transmittance of one of the mask structures discussed in Sec. 19.1. For example, to describe the set of four integrals in (19.3), we take

$$T_{mj}(\mathbf{r}) = \frac{1}{2}[1 + \cos(2\pi\boldsymbol{\rho}_m \cdot \mathbf{r} + \phi_j)] S(\mathbf{r}), \quad \phi_j = (j-1)\frac{\pi}{2}, \quad j = 0, 1, 2, 3. \quad (19.17)$$

Thus (19.16) fits our usual CD mapping, $\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}$, with the kernel given by

$$h_{mj}(\mathbf{r}) = \frac{1}{2}C[1 + \cos(2\pi\boldsymbol{\rho}_m \cdot \mathbf{r} + \phi_j)] S(\mathbf{r}). \quad (19.18)$$

For both Gaussian and Poisson noise, the integral in (19.16) is the mean of g_{mj} , so $\langle n_{mj} \rangle = 0$ by definition.

Modified data: Points in the Fourier transform As a first step toward image reconstruction, we may choose to form an estimate of the complex Fourier transform value $F(\boldsymbol{\rho}_m)$. For the data described by (19.16)–(19.18), we can define these estimates in a natural way as

$$\hat{F}(\boldsymbol{\rho}_m) \equiv \frac{1}{C} [g_{m0} - g_{m2} - ig_{m1} + ig_{m3}]. \quad (19.19)$$

It can be verified that $\hat{F}(\boldsymbol{\rho}_m)$ is an unbiased estimate of $F(\boldsymbol{\rho}_m)$ and that it is the maximum-likelihood estimate in the case of i.i.d. Gaussian noise.

We can put (19.19) in matrix form by writing

$$\hat{F}(\boldsymbol{\rho}_m) = \sum_{m'j'} A_{mm'j'} g_{m'j'}. \quad (19.20)$$

By comparison with (19.19), we see that

$$A_{mm'j'} = \frac{1}{C} \delta_{mm'} [\delta_{j'0} - \delta_{j'2} - i\delta_{j'1} + i\delta_{j'3}]. \quad (19.21)$$

In operator form,

$$\hat{\mathbf{F}} = \mathbf{A}\mathbf{g} = \mathbf{A}\mathcal{H}\mathbf{f} + \mathbf{n}. \quad (19.22)$$

For some reconstruction algorithms, we may take $\hat{\mathbf{F}}$ as the data instead of \mathbf{g} .

Gaussian noise Consider the simple system of Fig. 19.3, and suppose the detector is afflicted with i.i.d. Gaussian noise such that each measurement has variance σ^2 . Then the noise covariance matrix is given by

$$\mathbf{K}_n = \sigma^2 \mathbf{I}. \quad (19.23)$$

If we use four masks at each of M spatial frequencies, then \mathbf{I} is the $4M \times 4M$ unit matrix.

If we consider only a single object, the noise covariance \mathbf{K}_n is the same thing as the data covariance \mathbf{K}_g . We shall discuss the effect of object variability below,

but for now consider only a single object.

For Gaussian noise and nonrandom objects, $\hat{F}(\boldsymbol{\rho}_m)$ is a linear combination of zero-mean Gaussian random variables, so it is itself a zero-mean Gaussian random variable. Since $\hat{F}(\boldsymbol{\rho}_m)$ is complex, however, we have to be careful in specifying its variance and covariance (see Sec. 8.3.6). The covariance matrix is defined by

$$[\mathbf{K}_{\hat{\mathbf{F}}}]_{mm'} \equiv \left\langle \Delta \hat{F}(\boldsymbol{\rho}_m) \Delta \hat{F}^*(\boldsymbol{\rho}_{m'}) \right\rangle, \quad (19.24)$$

where $\Delta \hat{F}(\boldsymbol{\rho}_m) \equiv \hat{F}(\boldsymbol{\rho}_m) - F(\boldsymbol{\rho}_m)$.

To evaluate this covariance matrix, note first that the real and imaginary parts of $\hat{F}(\boldsymbol{\rho}_m)$ are uncorrelated (and hence statistically independent since they are Gaussian). Moreover, $\hat{F}(\boldsymbol{\rho}_m)$ and $\hat{F}(\boldsymbol{\rho}_{m'})$ are uncorrelated (and independent) for $m \neq m'$. Thus

$$[\mathbf{K}_{\hat{\mathbf{F}}}]_{mm'} = \left\langle |\Delta \hat{F}(\boldsymbol{\rho}_m)|^2 \right\rangle \delta_{mm'} = \left\langle \left[\Delta \hat{F}_r(\boldsymbol{\rho}_m) \right]^2 + \left[\Delta \hat{F}_i(\boldsymbol{\rho}_m) \right]^2 \right\rangle \delta_{mm'}, \quad (19.25)$$

where subscripts r and i denote real and imaginary parts, respectively. Since the real and imaginary parts are i.i.d., we have, finally,

$$[\mathbf{K}_{\hat{\mathbf{F}}}]_{mm'} = \frac{4\sigma^2}{C^2} \delta_{mm'}, \quad (19.26)$$

or simply,

$$\mathbf{K}_{\hat{\mathbf{F}}} = \frac{4\sigma^2}{C^2} \mathbf{I}, \quad (19.27)$$

where now \mathbf{I} is the $M \times M$ unit matrix.

Poisson noise If photon noise dominates and the objects are nonrandom, then each measurement is a Poisson random variable, and we can write the noise covariance matrix as [cf. (11.41)]

$$[\mathbf{K}_{\mathbf{n}}]_{mm'} = \bar{g}_m \delta_{mm'}. \quad (19.28)$$

The covariance on $\Delta \hat{F}(\boldsymbol{\rho}_m)$ in this case is found to be

$$[\mathbf{K}_{\hat{\mathbf{F}}}]_{mm'} = \frac{1}{C^2} [\bar{g}_{0m} + \bar{g}_{1m} + \bar{g}_{2m} + \bar{g}_{3m}] \delta_{mm'}. \quad (19.29)$$

Note that \hat{F} is a linear combination of Poisson random variables but not itself Poisson.

Temporal noise issues Up to now we have regarded the measurement system as static; a mask is inserted, a measurement is taken, and then a new mask is inserted. It may, however, be more practical to use some continuous scanning mechanism. Then the required discrete measurements can be obtained by sampling the dynamic detector output at appropriate times.

When we consider such dynamic measurements, the noise must be treated as a temporal random process, and consideration must be given to the bandwidth of the electronics. Suppose, for simplicity, that the detector noise is a stationary, white, Gaussian random process, with power spectral density $S_n(\nu) = S_n = \text{constant}$. If we denote the temporal impulse response of the electronics by $p(t)$ and the corresponding transfer function by $P(\nu)$, then the power spectral density on the voltage

at the output of the electronics is $S_V(\nu) = |P(\nu)|^2 S_n$ [see (8.156)]. Since the noise is stationary and the system is shift-invariant, all measurements have the same variance, namely [cf. (12.16)]

$$\sigma^2 = \int_{-\infty}^{\infty} d\nu S_V(\nu) = S_n \int_{-\infty}^{\infty} d\nu |P(\nu)|^2 = 2S_n |P(0)|^2 B, \quad (19.30)$$

where B is the *effective noise bandwidth* as defined in (12.18).

It is evident from (19.30) that we can reduce the noise variance by reducing the bandwidth, but doing so will also distort the desired signal⁴ information. Suppose, for example, that we scan the interfering plane waves in such a way that the spatial frequency of the fringe pattern varies linearly with time,

$$\boldsymbol{\rho}(t) = \mathbf{a} + \mathbf{b}t. \quad (19.31)$$

If we assume for simplicity that the spatial phase of the fringe pattern is fixed at $\phi = \phi_j$, then the mean measurement \bar{g}_{mj} is given by

$$\bar{g}_{mj} = C \int_{-\infty}^{\infty} dt p(t_m - t) \int_{\infty} d^2r \frac{1}{2} \{1 + \cos[2\pi(\mathbf{a} + \mathbf{b}t) \cdot \mathbf{r} + \phi_j]\} f(\mathbf{r}). \quad (19.32)$$

The reader may show that

$$\bar{g}_{mj} = CP(0) \int_{\infty} d^2r \frac{1}{2} \left\{ 1 + \frac{|P(\mathbf{b} \cdot \mathbf{r})|}{P(0)} \cos[2\pi(\mathbf{a} + \mathbf{b}t_m) \cdot \mathbf{r} + \phi_j + \Psi_p(\mathbf{b} \cdot \mathbf{r})] \right\} f(\mathbf{r}), \quad (19.33)$$

where $P(\nu) \equiv |P(\nu)| \exp[i\Psi_P(\nu)]$.

Two deleterious effects are seen in (19.33): the amplitude of the cosine modulation is reduced by the MTF of the electrical filter, and, perhaps more importantly, the phase of the modulation is shifted. Depending on the scan rate and the filter design, the phase shift could even convert the cosine to a sine, leading to an entirely erroneous estimate of the Fourier transform value. One might try to design the electrical filter so that $\Psi_P(\nu)$ is small at all relevant frequencies, but it cannot in principle be made zero; causal filters for which $p(t) = 0$ when $t < 0$ necessarily introduce phase shifts. For a simple RC filter, as discussed in Sec. 12.1.1, a $\pi/4$ phase shift occurs at the frequency for which $|P(\nu)|/P(0) = \frac{1}{2}$, and the limiting phase shift as $\nu \rightarrow \infty$ is $\pi/2$; more complicated filters can have larger phase shifts.

We are thus faced with a tradeoff: we want to choose the bandwidth of the filter small so as to reduce the noise, but not so small that it distorts the desired signal. Two general principles guide us in making this tradeoff. First, whatever distortion is incurred in the measurement should also be modeled in the reconstruction process; we should not blindly estimate Fourier transform values by (19.23) if (19.16) does not accurately describe the forward problem. Second, we should choose the bandwidth to optimize task performance. If the task depends on high spatial frequencies in the object, it may be better to use a larger bandwidth and accept more noise.

⁴We use the word "signal" here to mean "that which we are trying to measure," not "that which we are trying to discern in a detection task."

Object randomness So far we have discussed the contribution of measurement noise to the randomness in the data, but we know from previous chapters that object variability is also important in many cases. The two sources of randomness—measurement noise and object variability—make the data doubly stochastic, and there are two terms in the covariance matrix. The relevant theory is developed in Sec. 8.5.3, and we shall now apply it to the special case of imaging in Fourier space.

The general formulas we need are (8.347) and (8.348):

$$\mathbf{K}_{\mathbf{g}} = \overline{\mathbf{K}}_{\mathbf{n}} + \mathbf{K}_{\overline{\mathbf{g}}}, \quad \mathbf{K}_{\overline{\mathbf{g}}} = \mathcal{H}\mathcal{K}_{\mathbf{f}}\mathcal{H}^\dagger, \quad (19.34)$$

where $\overline{\mathbf{K}}_{\mathbf{n}}$ means the same thing as $\mathbf{K}_{\mathbf{n}}$ for object-independent noise, but for Poisson noise it is given by (19.28) averaged over some ensemble of objects. The object randomness is described by $\mathbf{K}_{\overline{\mathbf{g}}}$, which is the autocovariance operator of the object, $\mathcal{K}_{\mathbf{f}}$, reflected into the data domain in the absence of measurement noise.

For the masks defined in (19.17) and real objects, we find

$$\begin{aligned} [\mathbf{K}_{\overline{\mathbf{g}}}]_{mj,m'j'} &= \frac{1}{4}C^2 \int_{\mathbf{S}} d^2r \int_{\mathbf{S}} d^2r' \langle \Delta f(\mathbf{r}) \Delta f(\mathbf{r}') \rangle [1 + \cos(2\pi \boldsymbol{\rho}_m \cdot \mathbf{r} + \phi_j)] \\ &\quad \times [1 + \cos(2\pi \boldsymbol{\rho}_{m'} \cdot \mathbf{r}' + \phi_{j'})], \end{aligned} \quad (19.35)$$

where $\Delta f(\mathbf{r}) \equiv f(\mathbf{r}) - \langle f(\mathbf{r}) \rangle$. The integrals here are over the support of the masks, but since portions of the object outside of the masks never make any contribution to the data, we may as well think of \mathbf{S} as the support of the objects. The expectation $\langle \Delta f(\mathbf{r}) \Delta f(\mathbf{r}') \rangle$ is the autocovariance function of the object (*i.e.*, the kernel of $\mathcal{K}_{\mathbf{f}}$), which we denote $K_{\mathbf{f}}(\mathbf{r}, \mathbf{r}')$.

With a little algebra, we find that the covariance matrix for the estimated Fourier samples is

$$[\mathbf{K}_{\hat{\mathbf{f}}}]_{mm'} = \frac{4\sigma^2}{C^2} \delta_{mm'} + \int_{\mathbf{S}} d^2r \int_{\mathbf{S}} d^2r' K_{\mathbf{f}}(\mathbf{r}, \mathbf{r}') \exp[-2\pi i (\boldsymbol{\rho}_m \cdot \mathbf{r} - \boldsymbol{\rho}_{m'} \cdot \mathbf{r}')]. \quad (19.36)$$

Thus the object-variability part of the covariance matrix for the estimated Fourier samples is just a Fourier-transformed and sampled version of the autocovariance function of the object. One might be tempted to assume stationarity and simplify this expression further, but that impulse should be resisted in general. One situation in which at least quasistationarity can be justified is discussed in Sec. 19.1.4.

19.1.3 Reconstruction

Having collected a set of noisy measurements and characterized the noise, it remains to reconstruct an image of the object. We could simply refer back to Chap. 15 and say that all of the reconstruction algorithms introduced there are applicable, but this would ignore the fact that the data are related to the object by a well-understood transform, the Fourier transform. At the opposite extreme, we could reconstruct simply by applying an inverse Fourier transform (necessarily the inverse DFT since the data are discrete), but this would ignore many complications in the data-acquisition process.

Regular sampling in Fourier space We begin the discussion of image reconstruction by assuming that the sampled spatial frequencies (of a mask or projected fringe

pattern) form a square grid of spacing $\Delta\rho$. In this case it is convenient to denote the spatial frequency as $\boldsymbol{\rho}_{\mathbf{k}} \equiv \mathbf{k}\Delta\rho$, where \mathbf{k} is a 2D multi-index, $\mathbf{k} = (k_x, k_y)$, with integer components. Both components of \mathbf{k} will be assumed to run from $-K$ to K , so the total number of sampled frequencies is $M = (2K + 1)^2$.

We shall also assume that the sampled frequencies satisfy the Nyquist condition for sampling in frequency space, as discussed in Sec. 3.5.4. Specifically, if $f(\mathbf{r})$ vanishes outside of a square of side L , we require that $\Delta\rho \leq 1/L$. Note that there is no requirement that $f(\mathbf{r})$ be bandlimited. We shall use the term *exact Nyquist sampling* to mean $\Delta\rho = 1/L$ and hence $\boldsymbol{\rho}_{\mathbf{k}} = \mathbf{k}/L$.

Backprojection In many inverse problems of the form $\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}$, it is useful to apply the adjoint or backprojection operator \mathcal{H}^\dagger to the data as a first step toward reconstruction. Consider data described by (19.16)–(19.18) with sampling on a regular grid. With the multi-index notation, backprojection is the superposition of mask functions weighted by the data values [cf. (1.45)]:

$$[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) = C \sum_{\mathbf{k}=-K}^K \sum_{j=0}^3 g_{\mathbf{k}j} \frac{1}{2} [1 + \cos(2\pi \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r} + \phi_j)], \quad (19.37)$$

where the limits on the first sum imply that both components of \mathbf{k} run over the specified range. Making use of (19.16) and (19.17), we find

$$\begin{aligned} [\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) &= C^2 \sum_{\mathbf{k}=-K}^K \sum_{j=0}^3 \int_{\mathbf{S}} d^2 r' f(\mathbf{r}') \frac{1}{2} [1 + \cos(2\pi \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}' + \phi_j)] \frac{1}{2} [1 + \cos(2\pi \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r} + \phi_j)] \\ &\quad + C \sum_{\mathbf{k}=-K}^K \sum_{j=0}^3 n_{\mathbf{k}j} \frac{1}{2} [1 + \cos(2\pi \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r} + \phi_j)]. \end{aligned} \quad (19.38)$$

Interchanging the j sum and the integral and doing a bit of algebra yields⁵

$$\begin{aligned} &[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) \\ &= C^2 \sum_{\mathbf{k}=-K}^K \left\{ \int_{\mathbf{S}} d^2 r' f(\mathbf{r}') + \frac{1}{4} \int_{\mathbf{S}} d^2 r' f(\mathbf{r}') \exp[2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot (\mathbf{r} - \mathbf{r}')] \right. \\ &\quad \left. + \frac{1}{4} \int_{\mathbf{S}} d^2 r' f(\mathbf{r}') \exp[-2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot (\mathbf{r} - \mathbf{r}')] \right\} \\ &\quad + C \sum_{\mathbf{k}=-K}^K \sum_{j=0}^3 n_{\mathbf{k}j} \frac{1}{2} [1 + \cos(2\pi \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r} + \phi_j)]. \end{aligned} \quad (19.39)$$

For exact Nyquist sampling, where $\boldsymbol{\rho}_{\mathbf{k}} = \mathbf{k}/L$, the integrals above are proportional to Fourier-series coefficients of the object, denoted $F_{\mathbf{k}}$ and defined by

$$F_{\mathbf{k}} \equiv \frac{1}{L^2} \int_{\mathbf{S}} d^2 r' f(\mathbf{r}') \exp(-2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}') = \frac{1}{L^2} F(\boldsymbol{\rho}_{\mathbf{k}}), \quad (19.40)$$

⁵For those wishing to check the algebra, note that there are 4 terms in the sum over j and that $\sum_j \exp(\pm i\phi_j)$ and $\sum_j \exp(\pm 2i\phi_j)$ vanish.

where $F(\boldsymbol{\rho})$ is the ordinary 2D Fourier transform of the object (assumed to have support \mathbf{S}).

Making use of the symmetry $F_{\mathbf{k}} = F_{-\mathbf{k}}^*$, we find

$$\begin{aligned} [\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) &= C^2 L^2 (2K+1)^2 F_0 + \frac{1}{2} C^2 L^2 \sum_{\mathbf{k}=-K}^K F_{\mathbf{k}} \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}) \\ &+ C \sum_{\mathbf{k}=-K}^K \sum_{j=0}^3 n_{\mathbf{k}j} \frac{1}{2} [1 + \cos(2\pi \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r} + \phi_j)]. \end{aligned} \quad (19.41)$$

The third term in this equation is the noise in the data transformed by \mathcal{H}^\dagger . Note that this transformation creates a continuous function of \mathbf{r} , so the transformed noise is a random process. The reader is invited to compute the autocovariance function of this random process.

The first term in (19.41) is not a function of \mathbf{r} , but it is object dependent since it is proportional to F_0 , which is the average object value across the field of view. Moreover, the term can be very large because of the factor $(2K+1)^2$, which is the total number of sampled frequencies. The object is unknown, so we do not know the value of F_0 , but we can estimate it from the data and subtract off the estimate; one way of doing so is presented below, but for now we shall just refer to the first term in (19.41), or any spatially constant term, as a DC term. Basically, the DC term in the backprojection comes from the DC term in the mask transmittances.

The second term in (19.41) is the desired reconstruction. We therefore define

$$\hat{f}(\mathbf{r}) \equiv \frac{1}{\frac{1}{2} C^2 L^2} [\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) = \sum_{\mathbf{k}=-K}^K F_{\mathbf{k}} \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}) + \text{DC term} + \text{noise}. \quad (19.42)$$

If the sum here ran over the infinite 2D grid of Fourier frequencies, it would equal the actual object $f(\mathbf{r})$. Instead it includes only the frequencies for which $-K \leq k_x, k_y \leq K$. Since the masks contain only these spatial frequencies, the functions $\{L^{-1} \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r})\}$ form a basis for the measurement space (no matter what set of frequencies is used). If $\boldsymbol{\rho}_{\mathbf{k}} = \mathbf{k}/L$ for some set of integer-valued multi-indices $\{\mathbf{k}\}$, this basis is orthonormal and the sum in (19.42) is exactly the measurement component of the object [cf. (1.165)]. Then we can write

$$\sum_{\mathbf{k}=-K}^K F_{\mathbf{k}} \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}) = f_{meas}(\mathbf{r}) = [\mathcal{P}_{meas} \mathbf{f}](\mathbf{r}), \quad (19.43)$$

where \mathcal{P}_{meas} is the projector onto measurement space. Thus

$$\hat{f}(\mathbf{r}) = f_{meas}(\mathbf{r}) + \text{DC term} + \text{noise}. \quad (19.44)$$

The conclusion is that simple backprojection recovers the measurement component of the object except for noise and the DC term. This conclusion is, however, quite specific to the assumptions we made about the data. The masks had to be exactly described by (19.16)–(19.18), with pure sinusoidal variations and no higher-order terms, and we had to assume exact Nyquist sampling on the same grid as used to define the Fourier series.

Backprojection from the Fourier domain Suppose we start not with the raw data \mathbf{g} but rather with the estimated Fourier transform values $\hat{\mathbf{F}}$ as defined by (19.19) or (19.22). Backprojection in this case means applying the adjoint of the operator $\mathbf{A}\mathcal{H}$:

$$\hat{f}(\mathbf{r}) \equiv [\mathbf{A}\mathcal{H}]^\dagger \hat{\mathbf{F}} = [\mathbf{A}\mathcal{H}]^\dagger \mathbf{A}\mathbf{g} = \mathcal{H}^\dagger \mathbf{A}^\dagger \mathbf{A}\mathbf{g}. \quad (19.45)$$

As the reader may show,

$$\begin{aligned} [(\mathbf{A}\mathcal{H})^\dagger \mathbf{A}\mathbf{g}](\mathbf{r}) &= \frac{1}{C} \sum_{\mathbf{k}} \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}) (g_{\mathbf{k}0} - g_{\mathbf{k}2} - i g_{\mathbf{k}1} + i g_{\mathbf{k}3}) \\ &= \sum_{\mathbf{k}} \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}) \hat{F}(\boldsymbol{\rho}_{\mathbf{k}}). \end{aligned} \quad (19.46)$$

Thus backprojection from the Fourier estimates amounts to superposition of the complex conjugates of the Fourier kernels [see (1.45)] weighted by the estimates.

Since $\hat{F}(\boldsymbol{\rho}_{\mathbf{k}})$ is an unbiased estimator of $F(\boldsymbol{\rho}_{\mathbf{k}})$, we can write

$$\hat{f}(\mathbf{r}) = \sum_{\mathbf{k}} \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}) F(\boldsymbol{\rho}_{\mathbf{k}}) + \text{noise} = f_{meas}(\mathbf{r}) + \text{noise}. \quad (19.47)$$

There is no longer a DC term since we subtracted off the DC part of the mask transmittances in forming $\hat{F}(\boldsymbol{\rho}_{\mathbf{k}})$.

Irregular grids and pseudoinversion The sum in (19.42) or (19.47) can be identified with $f_{meas}(\mathbf{r})$ only if the Fourier basis functions are orthonormal, which is the case for sampling on a regular grid where $\boldsymbol{\rho}_{\mathbf{k}} = \mathbf{k}/L$.⁶ For sampling on irregular grids, however, we do not recover the measurement component by simple backprojection. What is required is a pseudoinverse of \mathcal{H} (or $\mathbf{A}\mathcal{H}$ when we start from the Fourier estimates), not just its adjoint; fortunately we know from Sec. 15.2.3 how to compute this pseudoinverse.

The basic trick used in Sec. 15.2.3 is broadly applicable. It amounts to using the identity (1.149) or (15.80):

$$\mathcal{H}^+ = \mathcal{H}^\dagger (\mathcal{H}\mathcal{H}^\dagger)^+. \quad (19.48)$$

In any CD problem, the operator $\mathcal{H}\mathcal{H}^\dagger$ is an $M \times M$ matrix (where M is the number of measurements). Its pseudoinverse can be found by standard methods if M is not too large, or the identity can be used as a starting point to develop iterative algorithms. Moreover, for Fourier samplers, $\mathcal{H}\mathcal{H}^\dagger$ is simply related by (15.79) to the Fourier transform of the support function.

Thus there is no great difficulty in dealing with irregular grids in Fourier samplers. We need to keep in mind, however, that simple backprojection does not recover the measurement component of the object in these cases.

⁶Strictly speaking, orthonormality also requires that the support function be square, but we can get around this problem with circular masks by considering a square that contains the circle. The circular support is then associated with the object rather than the basis function.

Discretization The reconstruction methods discussed so far in this section yield functions $\hat{f}(\mathbf{r})$, but of course any computer-implemented algorithm will produce only discrete vectors. We could simply sample the formulas above on a discrete grid to get $\hat{f}(\mathbf{r}_n)$, but we can also adopt some approximate discrete representation for $f(\mathbf{r})$ at the outset and attempt to estimate the coefficients.

Following (7.24) or (15.6) we can write the approximate object representation as

$$f_a(\mathbf{r}) = \sum_{n=1}^N \theta_n \phi_n(\mathbf{r}), \quad (19.49)$$

where $\{\phi_n(\mathbf{r})\}$ is any convenient set of expansion functions such as pixels. In operator notation, (19.49) becomes

$$\mathbf{f}_a = \mathcal{D}_\phi^\dagger \boldsymbol{\theta}, \quad (19.50)$$

where \mathcal{D}_ϕ is a CD discretization operator and \mathcal{D}_ϕ^\dagger is its adjoint (hence a DC operator). The data can be written as [cf. (15.10)–(15.14)]

$$\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n} = \mathbf{H}\boldsymbol{\theta} + \boldsymbol{\epsilon}, \quad (19.51)$$

where $\boldsymbol{\epsilon}$ includes both modeling error and noise, and the matrix \mathbf{H} is given by

$$\mathbf{H} = \mathcal{H}\mathcal{D}_\phi^\dagger, \quad H_{mn} = \int_{\mathbf{S}} d^q r h_m(\mathbf{r}) \phi_n(\mathbf{r}). \quad (19.52)$$

To apply this formalism to the present problem, we add a second data index j as in (19.16). If we take

$$\phi_n(\mathbf{r}) = \text{rect} \left[\frac{\mathbf{r} - \mathbf{r}_n}{\epsilon} \right] \quad (19.53)$$

and use the system kernel given in (19.18), then we find

$$H_{mjn} = \frac{\epsilon^2 C}{2} [1 + \cos(2\pi \boldsymbol{\rho}_m \cdot \mathbf{r}_n + \phi_j) \text{sinc}(\epsilon \boldsymbol{\rho}_m)]. \quad (19.54)$$

This matrix can now be used in any of the discrete reconstruction algorithms discussed in Chap. 15.

Use of the FFT Unlike many \mathbf{H} matrices, the one given in (19.54) is not sparse; its elements are nonzero for almost any combination of m , j and n , so $4MN$ multiplies will be required to compute $\mathbf{H}\boldsymbol{\theta}$ at any step in an iterative reconstruction algorithm. If, however, we choose the frequencies $\{\boldsymbol{\rho}_m\}$ and the spatial points $\{\mathbf{r}_n\}$ to lie on regular grids of the same size, we can formulate the problem in terms of the DFT and take advantage of the FFT algorithm.

Reverting to multi-index notation, we let $\mathbf{r}_n = \mathbf{n}\epsilon$, where $\epsilon = L/N$ and $0 \leq n_x, n_y \leq N - 1$, so an $N \times N$ grid is used for the object representation. To be able to use the same grid in the Fourier domain, we assume that measurements are taken for frequencies $\boldsymbol{\rho}_k = \mathbf{k}\Delta\rho$, where $\Delta\rho = 1/L$ and $0 \leq k_x, k_y \leq N - 1$; the use of only nonnegative integer indices causes no difficulty for real objects because of the symmetry relation (3.322).

With these grids, the matrix defined by (19.54) applied to an arbitrary $\boldsymbol{\theta}$ yields

$$[\mathbf{H}\boldsymbol{\theta}]_{kj} = \frac{\epsilon^2 C}{2} \Theta_0 + \frac{\epsilon^2 C}{4} [\Theta_{\mathbf{k}} \exp(-i\phi_j) + \Theta_{\mathbf{k}}^* \exp(i\phi_j)], \quad (19.55)$$

where Θ is the 2D DFT of θ , defined by

$$\Theta_{\mathbf{k}} = \sum_{\mathbf{n}=0}^{N-1} \exp\left(-2\pi i \frac{\mathbf{k} \cdot \mathbf{n}}{N}\right) \theta_{\mathbf{n}}. \quad (19.56)$$

Thus the data vector associated with θ is expressed in terms of DFTs and can be efficiently computed by means of the FFT algorithm. The reader may derive a similar expression for \mathbf{H}^{\dagger} applied to an arbitrary \mathbf{g} . It is also of interest to consider what happens if we take an inverse DFT of the estimated Fourier components.

Iterative algorithms There are two problems with the reconstruction algorithms described so far: they are all based on the idealized system description of (19.16)-(19.18), and all of them can yield unphysical negative values. These difficulties can be circumvented by using an iterative algorithm with a positivity constraint, such as the EM algorithm described in Sec. 15.4.6.

Virtually any departure from the ideal system behavior can be incorporated into an iterative algorithm, provided only that the effect can be adequately modeled. For example, if the Fourier samples are obtained by one of the moiré methods described in Sec. 19.1, there is no need to neglect any of the higher-order terms; they can readily be incorporated into the \mathbf{H} matrix, and the iterative algorithm will automatically compensate for them. Similarly, if there are phase shifts arising from the temporal response of the filter in a scanning system, they can be modeled as in (19.33) and again compensated by the algorithm.

The problem of negative values is inherent in the use of a finite set of spatial frequencies. If we represent a nonnegative function by a Fourier series and delete terms, the result will virtually always have negative values. Most iterative algorithms enforce a positivity constraint at each iteration and thereby correct this problem. With the EM algorithm, for example, the initial estimate is chosen to be nonnegative, and the multiplicative correction factor for the next estimate involves this estimate, the \mathbf{H} matrix and the data [see (15.297)], all of which are nonnegative. Thus the second estimate is nonnegative, and by the same argument all subsequent estimates are nonnegative.

19.1.4 Image quality

The principles of task-based evaluation and optimization of imaging systems were enunciated in Chaps. 13 and 14. In this section we shall discuss the application of these principles to systems that measure Fourier components of an object, with particular attention to choice of the set of sampled frequencies $\{\rho_n\}$.

SKE/BKE detection tasks We begin with SKE/BKE (signal known exactly, background known exactly) detection tasks. As we shall see, this task can lead to misleading conclusions about system optimization.

To be specific, consider the case of i.i.d. Gaussian noise and suppose that the data used for the detection task consist of Fourier components estimated according to (19.19). We know from (19.27) that the variance of each of these estimates is $4\sigma^2/C^2$, and it follows from (13.120) that the SNR for the ideal observer on an

SKE/BKE detection task is

$$\text{SNR}_\lambda^2 = \frac{C^2}{4\sigma^2} \sum_{m=1}^M |S(\boldsymbol{\rho}_m)|^2, \quad (19.57)$$

where $S(\boldsymbol{\rho})$ is the Fourier transform of the signal to be detected.

For most signals of interest, $|S(\boldsymbol{\rho})|$ is maximal at $\boldsymbol{\rho} = 0$, so the sum in (19.57) is maximized (for a fixed number of measurements) by choosing all $\boldsymbol{\rho}_m$ to be zero! In other words, we can do no better than measure the total integral of the object. Since the background is presumed to be known in all details, including its total integral, any increase in the integral of the object is an indication of the presence of a signal. In practice, however, we would never have this degree of prior information about the object, so we must choose a more realistic task for system optimization.

SKE/BKE discrimination tasks One way to avoid the incorrect conclusion that only the zero-frequency components are of interest is to consider discrimination between two different signals that have the same integral or DC value. This so-called *Rayleigh task* was discussed in Sec. 16.2.5. The ideal-observer SNR is still given by (13.120), but now the difference signal must be used in place of the signal in a detection task; (19.57) becomes

$$\text{SNR}_\lambda^2 = \frac{C^2}{4\sigma^2} \sum_{m=1}^M |\Delta S(\boldsymbol{\rho}_m)|^2. \quad (19.58)$$

There is some frequency $\boldsymbol{\rho}_0$ where $|\Delta S(\boldsymbol{\rho}_m)|$ is maximal, and (19.57) tells us that all samples should be taken at precisely that frequency. Again, this conclusion presumes an unrealistic amount of prior information and should not be taken seriously.

Random signals and backgrounds The best way to avoid the trap of assuming unrealistic prior information is to formulate the problem realistically in the first place, with unknown random signals and backgrounds. When we do so it becomes difficult to compute the ideal-observer SNR (see Sec. 14.3.3), and we must often revert to the Hotelling observer. Even that observer is complicated in the present problem, however, since it requires inversion of the covariance matrix given in (19.36). Methods for performing (or avoiding!) the inversion are discussed in Sec. 14.3.2, but an analytical solution would offer more insights.

We can make some headway analytically if we assume that we are interested in detecting a spatially localized signal with nonzero values only in the neighborhood of some point \mathbf{r}_0 and that the background statistics in this neighborhood are quasistationary (see Secs. 8.4.4 and 13.2.13). As in (13.259), the quasistationarity is best expressed in sum and difference coordinates; we define

$$K_{\mathbf{f}}(\mathbf{r}, \mathbf{r}') = K_{\mathbf{f}}(\bar{\mathbf{r}} + \frac{1}{2}\Delta\mathbf{r}, \bar{\mathbf{r}} - \frac{1}{2}\Delta\mathbf{r}) \equiv \tilde{K}_{\mathbf{f}}(\bar{\mathbf{r}}, \Delta\mathbf{r}), \quad (19.59)$$

where

$$\mathbf{r} \equiv \bar{\mathbf{r}} + \frac{1}{2}\Delta\mathbf{r}, \quad \mathbf{r}' \equiv \bar{\mathbf{r}} - \frac{1}{2}\Delta\mathbf{r}. \quad (19.60)$$

For a signal localized near \mathbf{r}_0 , only background variations in some neighborhood of $\bar{\mathbf{r}} = \mathbf{r}_0$ influence the detectability. If the background statistics in this neighborhood

are quasistationary, it may be valid to approximate $\tilde{K}_f(\bar{\mathbf{r}}, \Delta\mathbf{r})$ by $\tilde{K}_f(\mathbf{r}_0, \Delta\mathbf{r})$. Moreover, it might be valid to assume that the background correlations are short range, so that $\tilde{K}_f(\mathbf{r}_0, \Delta\mathbf{r})$ drops to zero over a distance $|\Delta\mathbf{r}|$ small compared to the object support. With these assumptions, (19.36) becomes

$$[\mathbf{K}_{\bar{\mathbf{F}}}]_{mm'} = \frac{4\sigma^2}{C^2} \delta_{mm'} + \int_{\mathbf{S}} d^2\bar{\mathbf{r}} \exp[-2\pi i (\boldsymbol{\rho}_m - \boldsymbol{\rho}_{m'}) \cdot \bar{\mathbf{r}}] \int_{\infty} d^2\Delta\mathbf{r} \tilde{K}_f(\mathbf{r}_0, \Delta\mathbf{r}) \exp[-\pi i (\boldsymbol{\rho}_m + \boldsymbol{\rho}_{m'}) \cdot \Delta\mathbf{r}]. \quad (19.61)$$

In many cases of interest, the integral over $\bar{\mathbf{r}}$ is either approximately or exactly zero unless $m = m'$. For exact Nyquist sampling, that integral is exactly $L^2\delta_{mm'}$. For sampling on a sparser grid, the integral is small compared to L^2 if $|\boldsymbol{\rho}_m - \boldsymbol{\rho}_{m'}|L \gg 1$, where L is the width of the object support. Thus we can write

$$[\mathbf{K}_{\bar{\mathbf{F}}}]_{mm'} = \left[\frac{4\sigma^2}{C^2} + L^2 \int_{\infty} d^2\Delta\mathbf{r} \tilde{K}_f(\mathbf{r}_0, \Delta\mathbf{r}) \exp(-2\pi i \boldsymbol{\rho}_m \cdot \Delta\mathbf{r}) \right] \delta_{mm'}. \quad (19.62)$$

The remaining integral is recognized as the stochastic Wigner distribution function [cf. (8.140) and (13.261)] for the zero-mean process $\Delta f(\mathbf{r})$, evaluated at $\mathbf{r} = \mathbf{r}_0$ and $\boldsymbol{\rho} = \boldsymbol{\rho}_m$. Denoting this Wigner distribution as $W_{\Delta f}(\mathbf{r}, \boldsymbol{\rho})$, we have

$$[\mathbf{K}_{\bar{\mathbf{F}}}^{-1}]_{mm'} = \left[\frac{4\sigma^2}{C^2} + L^2 W_{\Delta f}(\mathbf{r}_0, \boldsymbol{\rho}_m) \right]^{-1} \delta_{mm'}. \quad (19.63)$$

Thus the assumption of quasistationary noise leads to a diagonal (and therefore easily invertible) covariance matrix in this problem even though the system is far from shift-invariant.

With this inverse covariance, the Hotelling detectability satisfies

$$\text{SNR}_{Hot}^2(\mathbf{r}_0) = \sum_{m=1}^M \frac{|S(\boldsymbol{\rho}_m)|^2}{\frac{4\sigma^2}{C^2} + L^2 W_{\Delta f}(\mathbf{r}_0, \boldsymbol{\rho}_m)}. \quad (19.64)$$

This expression reduces to (19.57) if there is no background variability. When there is background variability, it has a form similar to expressions derived in Chap. 13 [e.g., (13.252) and (13.266)], but only within the validity of the quasistationary model.

One qualitative conclusion from (19.64) is that higher spatial frequencies are more useful with background variability than they are with a BKE task since the object Wigner distribution $W_{\Delta f}(\mathbf{r}_0, \boldsymbol{\rho})$ will tend to decrease with increasing frequency. The signal $|S(\boldsymbol{\rho})|^2$ also decreases with frequency in many problems, but if the spatial extent of the signal is smaller than the correlation length of the background, the ratio $|S(\boldsymbol{\rho})|^2/W_{\Delta f}(\mathbf{r}_0, \boldsymbol{\rho})$ increases with frequency, so higher frequencies provide more discrimination between signal and background. On the other hand, higher frequencies yield a smaller ratio of $|S(\boldsymbol{\rho})|^2$ to the frequency-independent measurement noise $4\sigma^2/C^2$. Numerical evaluation of (19.64) must be performed for quantitative comparisons of different sampling schemes, but no matrix inverses are needed because of the quasistationarity assumption.

The reader might be tempted to say, as we did in discussing (19.57) and (19.58), that there is some frequency $\boldsymbol{\rho}_0$ where the summand in (19.64) is maximal, so all samples should be taken at that one frequency. Recall, however, that we assumed in going from (19.61) to (19.62) that $\boldsymbol{\rho}_m \neq \boldsymbol{\rho}_{m'}$ if $m \neq m'$, and this assumption is certainly not true if all frequencies are the same.

Estimation tasks If an estimation task is to be performed, quantitative accuracy of the reconstruction is paramount. This accuracy depends on the choice of spatial frequencies, noise level and reconstruction algorithm, but in many cases the most important factor is the modeling of the forward problem. If, for example, we neglect higher-order terms in a moiré system, then we should assess their effect on estimates of the parameters of interest. If the noise level in the data is high, inaccurate modeling may make a small contribution to the mean-square error (MSE) in parameter estimates, but eventually, as exposure time is increased and the noise is reduced, modeling error will dominate.

We must remember, however, that MSE is applicable (at least in a non-Bayesian sense) only to estimable parameters (see Secs. 14.3.4 and 15.1.3). In the present problem, our basic measurements are unbiased estimates of the Fourier transform values $\{F(\boldsymbol{\rho}_n)\}$, so any linear combination of these values is estimable. If we wish to estimate the integral of the object over some region of interest (ROI), the template defining this region must be well approximated by a series of the form

$$t(\mathbf{r}) \approx \sum_n T_n \exp(2\pi i \boldsymbol{\rho}_n \cdot \mathbf{r}) \quad (19.65)$$

in order for the integral to be estimable. If this condition is not satisfied, different objects can give the same mean data but different true values for the ROI integral, and we would not know which object to select as defining the true value of the parameter. Some readers might opt for choosing a particular object, such as a uniform field, and defining an MSE with respect to this object, but in our view that would give a misleading picture of the estimation performance of the system. We recommend using estimable parameters for evaluating estimation performance whenever possible. For systems that measure Fourier samples, we should take enough samples for the approximation in (19.65) to be valid.

When we cannot satisfy approximation (19.65), the best we can do is use the ensemble mean-square error (EMSE) as defined in (13.288) in place of the MSE corresponding to a particular true value. To compute the EMSE exactly, we would need a PDF on the objects, but we can estimate it with a finite number of realistic simulated objects (see Sec. 14.3.4).

19.2 INTERFEROMETERS

Though often taught in elementary courses as distinct entities, interferometers and imaging systems are in fact virtually indistinguishable. All interferometers are imaging systems, and all imaging systems using coherent or partially coherent radiation involve interference.

Consider a common application of interferometry, testing the figure of a mirror during fabrication. The mirror under test is placed in one arm of an interferometer, and a reference surface such as a high-quality spherical mirror is placed in the other

arm. The interferometer serves to overlap the two reflected waves, and a fringe pattern is formed on some detector. The key point for the present discussion, however, is that the reflected waves do not simply propagate to the detector; instead, they are imaged through some optical system (if only the human eye) so that the waves arriving at the detector are replicas of the waves emerging from the two mirrors. Then the fringe pattern is an image of the cosine of the phase difference between the waves.

In this example, the imaging system is direct, but there are also important indirect-imaging applications of interferometry. As a consequence of the van Cittert-Zernike theorem, data collected in interference experiments can be used to reconstruct an image of the illuminating source.

In this section we shall explore a variety of systems that can be viewed as either interferometers or imaging systems. In keeping with the spirit of the chapter, we use these systems to illustrate various mathematical points introduced earlier in the book.

We begin in Sec. 19.2.1 by discussing the classical double-slit experiment of Thomas Young as a way of introducing interferometers that use pairs of apertures. This section illustrates the concept of partial coherence and the van Cittert-Zernike theorem, and it shows how these principles can be adapted to imaging.

In Sec. 19.2.2 we give some now-familiar mathematical descriptions for noise in the raw data, and then we discuss the transition from noisy data to estimates of Fourier coefficients in interferometers.

Section 19.2.3 is a detailed treatment of a two-aperture interferometer of great historical and pedagogical significance, the Michelson stellar interferometer. Included is a discussion of how one goes from interferometric measurements to estimation of stellar diameters. Section 19.2.4 is a broad-brush look at some modern multiple-telescope systems that can operated as interferometers.

19.2.1 Young's double-slit experiment

Thomas Young (1773–1829) was an English physicist and physician who contributed an astonishing number of key concepts to modern science. He was the first to establish clearly the wave nature of light (thereby earning the animosity of English scientists devoted to Newton's corpuscular theory). He also showed that light consisted of transverse oscillations and laid the groundwork for the theory of polarization. He gave the first modern interpretation of energy, and he made key discoveries in elasticity and surface tension. In visual perception, he observed how the lens of the eye changes shape to focus at different distances, and he proposed that color vision involved only three color receptors. As if these physiological and physical contributions were not enough, he also translated the Rosetta stone and laid the foundation for modern Egyptology.

To an optics audience, Young's name is most familiar from the double-slit experiment illustrated in Fig. 19.9. There are several crucial deductions about the nature of light that can be made with this apparatus. First, when only one slit is open, a broad Fraunhofer diffraction pattern is seen, but when both slits are open simultaneously, a pattern of fine fringes appears. There are dark regions where less light is seen with both slits open. This observation demonstrates that light is a wave, capable of interference.

Fig. 19.9 Young's double-slit experiment.

Second, if we place polarizers over the slits, we find that the fringes disappear when the polarizations are orthogonal. This observation establishes the vector nature of the wave; the electric fields do not interfere if their dot product is zero.

Third, we can use the double-slit apparatus with modern position-sensitive, photon-counting detectors to better understand the quantum-mechanical nature of light and light-matter interactions. If we use a very weak light source, so that only one photon at a time is moving from the source to the detector plane, then each photon will impinge on the detector and be recorded at a single point. Nevertheless, after many photons have been recorded, the same fringe pattern is seen if both slits are open. If one slit is blocked, the fringes disappear, indicating that the picture of photons as localized particles is not adequate for describing this experiment.

This observation can be explained via quantum electrodynamics, where a probability amplitude is assigned to the path through each slit. The total probability for finding the photon at some point on the detector plane is the square of the sum of the probability amplitudes; since the amplitudes are complex, they can interfere, possibly making the total probability lower than it would be with only one slit open.

Alternatively, the observation can be explained by the semiclassical approach discussed in Sec. 10.1.4 where the field is treated classically but the atoms in the detector are treated quantum-mechanically. In this view, the interference is between the classical wave amplitudes emerging from the two slits; the irradiance on the detector plane, which is proportional to the square of the sum of the amplitudes, exhibits a classical fringe pattern. This irradiance then causes photoelectric interactions at random points on the detector surface. The observed pattern is a nonstationary Poisson random process where the probability density function on the positions of photoelectric interactions is proportional to the optical fluence (energy per unit area). Since fluence is irradiance times exposure time, it does not matter whether we use a weak light source (small irradiance) and long exposure time or a strong source and short time; we are not regarding the field as composed of photons, so there is no issue of how many photons are traversing the system simultaneously.

The experimental observation that is most important for the imaging applications of Young's double slit and other interferometers is that the visibility of the fringes is greatest for a quasimonochromatic point source, generally decreasing as the source size is increased. We know from Sec. 9.7 that the dependence of visibility on source distribution is a consequence of the spatial coherence of the field at the slit plane as described by the van Cittert-Zernike theorem. In fact, in that section we used a double-pinhole arrangement, Fig. 9.19, as a way of illustrating the concept of spatial coherence. The van Cittert-Zernike theorem was used as a description of

the forward problem: given the source, compute the mutual coherence function and hence the fringe visibility. Here we shall discuss the inverse problem: given a set of fringe measurements taken with a double-pinhole or double-slit system, deduce properties of the source. As preliminaries, however, we shall discuss the fringes produced by point sources and extended sources, and we shall take another look at the meaning of the van Cittert-Zernike theorem and give a new and perhaps more intuitive derivation of it.

Monochromatic point source Consider first a monochromatic point source at 2D position \mathbf{r}_s (where subscript s indicates *source*) in the plane $z = -z_0$. Two small pinholes are at 2D positions $\mathbf{r} = \mathbf{r}_1$ and $\mathbf{r} = \mathbf{r}_2$ in the plane $z = 0$, and the fringe pattern is observed in the plane $z = z_0$. The source emits a spherical wave that propagates to the pinhole plane, and each pinhole in turn emits a spherical wave that propagates to the observation plane. The interference of these two secondary spherical waves produces a straight-line fringe pattern.

We can analyze the fringe pattern by Fresnel diffraction theory as developed in Sec. 9.4.6. Within the Fresnel approximation, the field at the j^{th} pinhole ($j = 1, 2$) is given by [cf. (9.94)]

$$u_0(\mathbf{r}_j) \propto \exp \left[i \frac{\pi}{\lambda z_0} |\mathbf{r}_j - \mathbf{r}_s|^2 \right]. \quad (19.66)$$

If the pinholes are small compared to a wavelength, then a spherical wave from each propagates to the observation plane, and the field at point \mathbf{r} is given by

$$u_{z_0}(\mathbf{r}) \propto \exp \left[i \frac{\pi}{\lambda z_0} \left(|\mathbf{r}_1 - \mathbf{r}_s|^2 + |\mathbf{r}_1 - \mathbf{r}|^2 \right) \right] + \exp \left[i \frac{\pi}{\lambda z_0} \left(|\mathbf{r}_2 - \mathbf{r}_s|^2 + |\mathbf{r}_2 - \mathbf{r}|^2 \right) \right]. \quad (19.67)$$

With a little algebra,⁷ we find that the irradiance at point \mathbf{r} in the observation plane is given by

$$I_{z_0}(\mathbf{r}) \propto |u_{z_0}(\mathbf{r})|^2 \propto 1 + \cos \left[\frac{2\pi}{\lambda z_0} (\mathbf{r}_2 - \mathbf{r}_1) \cdot (\mathbf{r}_s + \mathbf{r}) \right]. \quad (19.68)$$

For fixed pinhole locations \mathbf{r}_1 and \mathbf{r}_2 , this function describes the fringe pattern as a function of position \mathbf{r} in the observation plane. Note that a maximum irradiance is seen at $\mathbf{r} = -\mathbf{r}_s$; the path length from the source through pinhole 1 to this point equals that through pinhole 2, so constructive interference occurs. We can say that the fringe pattern is centered at $\mathbf{r} = -\mathbf{r}_s$. Thus the lateral displacement or phase of the fringes is determined by the position \mathbf{r}_s of the source point, and the fringe frequency ρ_f is determined by the pinhole spacing as

$$\rho_f = \frac{1}{\lambda z_0} (\mathbf{r}_2 - \mathbf{r}_1). \quad (19.69)$$

The fringe visibility is 100% for a point source.

The relationship between (19.68) and (19.13) should not be overlooked. We know from (19.11) that a Fresnel zone plate is a sum of quadratic phase factors,

⁷We assume here that the origin of coordinates is halfway between the two pinholes, so that $r_1^2 = r_2^2$

just as spherical waves have complex amplitudes given by quadratic phase factors. When we take the product of two zone-plate transmittances as in (19.13), we get terms where the quadratic phases cancel, leaving phases that depend linearly on position, *i.e.*, straight-line moiré fringes. Similarly, when we interfere two spherical waves and compute the irradiance, we again get cancellation of quadratic phase terms so that straight-line interference fringes remain. The physics is very different in the two problems, but the math is quite similar.

Extended source: van Cittert-Zernike revisited Now consider a quasimonochromatic but spatially incoherent extended source. As discussed in Sec. 9.7.4, spatial incoherence means that the spatial autocorrelation function of the source is well approximated by a Dirac delta function, so there can be no interference between waves emanating from different source points. Instead, each point on the source produces its own fringe pattern, described by (19.68), and the total irradiance at point \mathbf{r} is the sum (integral) of the irradiances from individual source points. If the radiant exitance of the source at point \mathbf{r}_s is denoted $f(\mathbf{r}_s)$, we can write

$$I_{z_0}(\mathbf{r}) = C \int_{\infty} d^2r_s f(\mathbf{r}_s) \{1 + \cos[2\pi\boldsymbol{\rho}_f \cdot (\mathbf{r}_s + \mathbf{r})]\}, \tag{19.70}$$

where C is a constant containing geometric factors such as the distance z_0 and the pinhole diameters.

To put (19.70) into a more familiar form, we can define a dimensionless complex number γ by

$$\gamma \equiv \frac{\int_{\infty} d^2r_s f(\mathbf{r}_s) \exp[-2\pi i\boldsymbol{\rho}_f \cdot \mathbf{r}_s]}{\int_{\infty} d^2r_s f(\mathbf{r}_s)} = \frac{F(\boldsymbol{\rho}_f)}{F(0)}, \tag{19.71}$$

where $F(\boldsymbol{\rho})$ is the 2D Fourier transform of $f(\mathbf{r}_s)$, and, by the central-ordinate theorem, $F(0)$ is the integral of the object. With this definition, (19.70) becomes

$$I_{z_0}(\mathbf{r}) = CF(0) [1 + |\gamma| \cos(2\pi\boldsymbol{\rho}_f \cdot \mathbf{r} - \Phi_{\gamma})], \tag{19.72}$$

where $\gamma \equiv |\gamma| \exp(i\Phi_{\gamma})$.

As with a point source, the fringe frequency is determined solely by the pinhole positions, but now the fringe visibility $|\gamma|$ and phase Φ_{γ} are determined by the source distribution through (19.71). In fact, (19.71) is just a restatement of the van Cittert-Zernike theorem (9.317) when γ is recognized as the complex degree of coherence for points \mathbf{r}_1 and \mathbf{r}_2 . By this theorem, the mutual coherence function is the Fourier transform of the source exitance, and by (9.259) the complex degree of coherence is a normalized version of the mutual coherence function.

Detector sensitivity functions To gain further insight into the meaning of the van Cittert-Zernike theorem, we can look at the sensitivity function associated with each detector element.

As with any linear CD system, we can write the mean measurement in the form

$$\bar{g}_{\mathbf{m}} = \int_{\infty} d^2r_s f(\mathbf{r}_s) h_{\mathbf{m}}(\mathbf{r}_s). \tag{19.73}$$

In the present problem, the detectors sample the continuous interference pattern, so we see from (19.68) and (19.69) that

$$h_{\mathbf{m}}(\mathbf{r}_s) \propto 1 + \cos[2\pi\boldsymbol{\rho}_f \cdot (\mathbf{r}_s + \mathbf{r}_{\mathbf{m}})]. \tag{19.74}$$

This form is familiar from Sec. 19.1.1 where we described several systems for measuring samples of the Fourier transform by modulating the object with a $(1 + \cos)$ pattern and integrating. In the double-pinhole setup, different detector elements correspond to cosine patterns all of the same frequency but with different phases. Thus the full array of measurements for one pinhole spacing can be used to estimate the complex Fourier transform for a single frequency.⁸

From pinholes to slits A practical difficulty with the system as described so far is that very small pinholes must be used in order for the waves emerging from them to be good approximations to spherical waves, as we have assumed. Small pinholes, however, collect very little light. One way to get more light is to follow the lead of Thomas Young and use slits rather than pinholes.

The analysis above is readily modified for slits. For a point source, straight-line fringes are still produced, and for a spatially incoherent source, the irradiances from different source points add linearly. Thus, for slits parallel to the y axis, (19.70) becomes

$$I_{z_0}(\mathbf{r}) = C' \int_{-\infty}^{\infty} d^2r_s f(\mathbf{r}_s) \{1 + \cos [2\pi\xi_f(x_s + x)]\}, \quad (19.75)$$

where C' is another radiometric constant (much larger than C), and the fringe frequency is given by [cf. (19.69)]

$$\xi_f = \frac{1}{\lambda z_0}(x_2 - x_1), \quad (19.76)$$

with x_1 and x_2 specifying the slit locations.

A consequence of (19.75) is that we get no information about $F(\xi, \eta)$ except for $\eta = 0$, *i.e.*, for $\boldsymbol{\rho}$ parallel to the x axis. Thus we need to rotate the object or the slits to obtain Fourier samples distributed over the 2D plane.

Another way to think about double-slit interferometry is in terms of the Radon transform and tomography (see Sec. 4.4). We know from the central-slice theorem, (4.150), that $F(\xi, 0)$ is the same as the 1D Fourier transform of the projection of the object along the y axis. If we sample ξ_f on a fine regular grid and extract the complex visibility for each sample, we can perform an inverse DFT to get an approximation to the projection $\lambda(p, \phi)$ for $\phi = 0$, and rotating the object or the slits will give other projections. Reconstruction can then proceed by any standard 2D tomographic algorithm such as filtered backprojection. Many algorithms, however, start by Fourier-transforming the projection data, and with double slits we directly collect data in Fourier space, so we may as well stay there.

19.2.2 Visibility estimation

As we have seen, a 2D fringe distribution is obtained for each pair of pinhole or slit locations, but it tells us relatively little about the object. The only useful information is contained in the visibility and phase of the fringes. If we can estimate γ from measured fringe data, we have an estimate of $F(\boldsymbol{\rho})$ for one particular $\boldsymbol{\rho}$,

⁸In fact, just four measurements would suffice if they were placed properly so that the phase $2\pi\boldsymbol{\rho}_f \cdot \mathbf{r}_m$ took on the values $0, \pi/2, \pi$ and $3\pi/2$, but it would be mechanically tricky to alter the detector locations for different pinhole spacings.

according to (19.71). To get additional Fourier components, we need additional pairs of pinhole locations.

Image reconstruction can thus be formulated as a two-step process. We can first estimate the Fourier components and then estimate the parameters in a discrete object representation. Alternatively, we can go directly from the raw data to a reconstructed image. In either case, it is necessary to characterize the noise in the data and how it affects the estimates of interest. In this section we look at visibility estimation in Gaussian and Poisson noise.

Visibility estimation — Gaussian data We assume a regular array of detectors in the observation plane. If each detector element is small compared to the period of the finest interference fringes used, the measurement by the detector at point \mathbf{r}_m (where \mathbf{m} is a 2D multi-index) is given by

$$g_m = K [1 + |\gamma| \cos(2\pi \boldsymbol{\rho}_f \cdot \mathbf{r}_m - \Phi_\gamma)] + n_m = \bar{g}_m + n_m, \quad (19.77)$$

where n_m is the noise in the measurement and K is a constant independent of \mathbf{m} but proportional to the integral of the object. For simplicity we assume that the integral of the object can be estimated accurately from the fringe data or measured independently, so K will be regarded as known. Thus the quantities to be estimated are the two real parameters $|\gamma|$ and Φ_γ .

For i.i.d. normal noise, the log-likelihood for this problem is given by

$$\ln[\text{pr}(\mathbf{g} | |\gamma|, \Phi_\gamma)] = \text{const} - \frac{1}{2\sigma^2} \sum_{\mathbf{m}} \{g_m - K[1 + |\gamma| \cos(2\pi \boldsymbol{\rho}_f \cdot \mathbf{r}_m - \Phi_\gamma)]\}^2. \quad (19.78)$$

It is convenient, however, to use γ and γ^* as the independent parameters, as discussed in Sec. A.9.4. Dropping the irrelevant constant, we can thus write the log-likelihood as

$$\begin{aligned} & \ln [\text{pr}(\mathbf{g} | \gamma, \gamma^*)] \\ &= -\frac{1}{2\sigma^2} \sum_{\mathbf{m}} [g_m - K - \frac{1}{2}K\gamma \exp(-2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_m) - \frac{1}{2}K\gamma^* \exp(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_m)]^2. \end{aligned} \quad (19.79)$$

We need to maximize this expression with respect to γ and γ^* . Differentiating with respect to γ^* according to the differentiation rules of Sec. A.9.4, we see that

$$\begin{aligned} & \frac{2\sigma^2}{K} \frac{\partial}{\partial \gamma^*} \ln [\text{pr}(\mathbf{g} | \gamma)] \\ &= \sum_{\mathbf{m}} [g_m - K - \frac{1}{2}K\gamma \exp(-2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_m) - \frac{1}{2}K\gamma^* \exp(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_m)] \exp(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_m). \end{aligned} \quad (19.80)$$

The derivative with respect to γ is just the complex conjugate of (19.80).

Equating (19.80) to zero gives

$$\sum_{\mathbf{m}} (g_m - K) \exp(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_m) = \frac{1}{2}K\gamma \sum_{\mathbf{m}} 1 + \frac{1}{2}K\gamma^* \sum_{\mathbf{m}} \exp(4\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_m). \quad (19.81)$$

We shall assume for simplicity that an integer number of fringes fit across the array, in which case the last sum is identically zero, Thus the maximum-likelihood estimate

of the complex degree of coherence is given by (Walkup and Goodman, 1973)

$$\hat{\gamma} = \frac{2}{KM^2} \sum_{\mathbf{m}} (g_{\mathbf{m}} - K) \exp(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}). \quad (19.82)$$

Computationally, $\hat{\gamma}$ is given by a discrete Fourier transform of the data, though only for a single frequency for each pair of pinhole locations. There is thus no advantage to the FFT algorithm, which is an efficient way of computing the DFT for a large set of frequencies.

Bias and variance Since M^2 is large, we can appeal to the asymptotic properties of ML estimators to argue that the estimate given by (19.82) is unbiased and efficient. It is instructive, however, to compute the bias and variance directly.

From (19.77) and (19.82), the mean of $\hat{\gamma}$ is

$$\begin{aligned} \langle \hat{\gamma} \rangle &= \frac{2}{KM^2} \sum_{\mathbf{m}} (\bar{g}_{\mathbf{m}} - K) \exp(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}) \\ &= \frac{2}{KM^2} \sum_{\mathbf{m}} \left[\frac{K}{2} \gamma \exp(-2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}) + \frac{K}{2} \gamma^* \exp(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}) \right] \exp(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}). \end{aligned} \quad (19.83)$$

From the assumption made above that an integer number of fringes fit across the array, it follows that $\sum_{\mathbf{m}} \exp(4\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}})$ is identically zero. Thus $\langle \hat{\gamma} \rangle = \gamma$, and the estimator is unbiased.

To study the variance, we write

$$\Delta \hat{\gamma} \equiv \hat{\gamma} - \gamma = \frac{2}{KM^2} \sum_{\mathbf{m}} \Delta g_{\mathbf{m}} \exp(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}), \quad (19.84)$$

where $\Delta g_{\mathbf{m}} \equiv g_{\mathbf{m}} - \bar{g}_{\mathbf{m}}$. The zero-mean complex random variable $\Delta \hat{\gamma}$ has real and imaginary parts given, respectively, by

$$\begin{aligned} \Delta \hat{\gamma}_r &= \frac{2}{KM^2} \sum_{\mathbf{m}} \Delta g_{\mathbf{m}} \cos(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}), \\ \Delta \hat{\gamma}_i &= \frac{2}{KM^2} \sum_{\mathbf{m}} \Delta g_{\mathbf{m}} \sin(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}). \end{aligned} \quad (19.85)$$

Since the data covariance is given by

$$\langle \Delta g_{\mathbf{m}} \Delta g_{\mathbf{m}'} \rangle = \sigma^2 \delta_{\mathbf{m}\mathbf{m}'}, \quad (19.86)$$

we can show that

$$\text{Var} \{ \Delta \hat{\gamma}_r \} = \text{Var} \{ \Delta \hat{\gamma}_i \} = \frac{2\sigma^2}{K^2 M^2}, \quad \langle \Delta \hat{\gamma}_r \Delta \hat{\gamma}_i \rangle = 0, \quad (19.87)$$

where we have used the fact that $\sum_{\mathbf{m}} \cos^2(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}) = \sum_{\mathbf{m}} \sin^2(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}) = \frac{1}{2} M^2$ but $\sum_{\mathbf{m}} \cos(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}) \sin(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}) = 0$ since an integer number of fringes fit across the array.

Thus $\Delta \hat{\gamma}_r$ and $\Delta \hat{\gamma}_i$ are uncorrelated and have the same variance. Moreover, each is a linear transformation of a Gaussian random variable, so they are i.i.d. Gaussian, and the complex quantity $\Delta \hat{\gamma}$ is circular Gaussian (see Sec. 8.3.6). The reader is invited to compute the Cramér-Rao bound for this problem and verify that $\hat{\gamma}$ is an efficient estimator.

Noise with photon-counting detectors So far in this section we have assumed that the interference pattern was detected by a 2D detector array in which the noise was i.i.d. normal. Now we consider photon-counting detectors.

As we showed classically in Sec. 11.3.7 and quantum-mechanically in Sec. 11.5.3, the photon statistics in the observation plane will virtually always be Poisson. All that is required is $\tau \Delta\nu \gg 1$, where $\Delta\nu$ is the spectral bandwidth of the source and τ is the observation time. We also know from Sec. 11.3 that all statistical properties of a Poisson random process are determined by the photon fluence $b(\mathbf{r})$. For narrowband radiation of mean frequency $\bar{\nu}$, photon fluence is fluence divided by the mean photon energy $h\bar{\nu}$, and fluence is irradiance times observation time, so

$$b(\mathbf{r}) = \tau \frac{I_{z_0}}{h\bar{\nu}}. \quad (19.88)$$

In spite of the term “photon fluence,” this expression does not imply that the radiation actually consists of photons; it can be treated fully classically. Nevertheless, the pattern of photoelectric interactions in the observation plane will be a Poisson random process with fluence $\eta b(\mathbf{r})$, where η is the quantum efficiency. As discussed in Sec. 11.3.4, we can integrate this Poisson random process over detector elements to get discrete Poisson data.

Though $\hat{\gamma}$ in (19.82) is the ML estimator only for i.i.d. Gaussian noise, it might be used with photon-counting detectors where the noise is Poisson. In that case we cannot be sure it is asymptotically efficient and unbiased. We need to examine the behavior of (19.82) for Poisson data when it is not ML, and we need to derive the ML estimator correctly under a Poisson model.

Using the Gaussian ML estimator with Poisson data Let us recompute the mean and variance of the Gaussian ML estimator but with Poisson data. Since the mean is the same for both Poisson and Gaussian data, it follows immediately from (19.83) that the estimator is unbiased no matter which data model is used. The definitions in (19.85) are still valid, and we just need to compute the variances and covariance of $\hat{\gamma}_r$ and $\hat{\gamma}_i$. In the Poisson case, the data covariance is given by

$$\langle \Delta g_{\mathbf{m}} \Delta g_{\mathbf{m}'} \rangle = \bar{g}_{\mathbf{m}} \delta_{\mathbf{m}\mathbf{m}'}, \quad (19.89)$$

and it follows that

$$\begin{aligned} & \text{Var} \{ \Delta \hat{\gamma}_r \} \\ &= \frac{4}{KM^4} \sum_{\mathbf{m}} \left[1 + \frac{1}{2} \gamma \exp(-2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}) + \frac{1}{2} \gamma^* \exp(2\pi i \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}) \right] \cos^2(2\pi \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}}). \end{aligned} \quad (19.90)$$

The spatial average across the array of the terms involving the complex exponentials is zero. The term varying just as $\cos^2(2\pi \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}})$ sums to $\frac{1}{2}M^2$, as does the \sin^2 term in $\text{Var} \{ \Delta \hat{\gamma}_r \}$, and we are left with

$$\text{Var} \{ \Delta \hat{\gamma}_r \} = \text{Var} \{ \Delta \hat{\gamma}_i \} = \frac{2}{KM^2}, \quad \langle \Delta \hat{\gamma}_r \Delta \hat{\gamma}_i \rangle = 0. \quad (19.91)$$

This result differs from (19.87) in that the variance is proportional to $1/K$ rather than $1/K^2$. Since K is proportional to the source brightness and the exposure time, we see that the precision of the visibility estimates improves more rapidly with these parameters in the Gaussian case than in the Poisson case.

ML estimators for Poisson data The maximum-likelihood estimate of the complex visibility from Poisson data is given by

$$\hat{\gamma} = \underset{\gamma}{\operatorname{argmax}} \{ \ln[\operatorname{pr}(\mathbf{g}|\gamma)] \} = \underset{\gamma}{\operatorname{argmax}} \left\{ \sum_{\mathbf{m}} [g_{\mathbf{m}} \ln \bar{g}_{\mathbf{m}}(\gamma) - \bar{g}_{\mathbf{m}}(\gamma)] \right\}, \quad (19.92)$$

where

$$\bar{g}_{\mathbf{m}}(\gamma) = K [1 + |\gamma| \cos(2\pi \boldsymbol{\rho}_f \cdot \mathbf{r}_{\mathbf{m}} - \Phi_{\gamma})]. \quad (19.93)$$

This equation must be solved iteratively, for example by an EM algorithm (see Sec. 15.4.6). Methods developed in Sec. 15.3.6 can be used to analyze the noise properties of the estimate.

From visibilities to image Having obtained visibility estimates, it remains to use them to reconstruct an image. Since many visibility measurements are needed, with many pairs of pinhole locations, we add an index to distinguish the different locations. For pinholes at $\mathbf{r}_1 = \mathbf{r}_{1n}$ and $\mathbf{r}_2 = \mathbf{r}_{2n}$, the fringe frequency is $\boldsymbol{\rho}_n = (\mathbf{r}_{2n} - \mathbf{r}_{1n})/(\lambda z_0)$, and the estimated object Fourier transform at this frequency is

$$\hat{F}(\boldsymbol{\rho}_n) = F(0) \hat{\gamma}(\boldsymbol{\rho}_n). \quad (19.94)$$

Recall that we are assuming that $F(0)$ is measured independently, so estimation of γ directly yields an estimate of $F(\boldsymbol{\rho})$ at the fringe frequency. Note also that the index \mathbf{m} has disappeared; even though we collect a 2D data set for each fringe frequency, we process it to extract a single complex number $\hat{F}(\boldsymbol{\rho}_n)$. The double-pinhole system is thus an alternative to the various systems treated in Sec. 19.1 for estimating values of the 2D Fourier transform of the object, and image reconstruction can be performed by any of the methods discussed in Sec. 19.1.3.

19.2.3 Michelson stellar interferometer

Albert A. Michelson (1842–1931) can rightfully be called the father of modern interferometry (though the French would nominate Fizeau, for reasons discussed in Sec. 19.2.4). A graduate of the U.S. Naval Academy, Michelson served as a science instructor there from 1875 to 1879, and during this time he began a series of measurements of the velocity of light. After a period of travel in Europe to study optics, he accepted a position in 1883 at the Case School of Applied Science in Cleveland. In collaboration with chemist Edward W. Morley, he constructed an exquisitely sensitive interferometer and used it in a famous experiment to measure the difference in the speed of light as the earth traversed the ether, the supposed medium for light propagation. In 1887 Michelson and Morley announced what has been called the most significant negative result in the history of science: they found no difference in the speed of light for propagation parallel or perpendicular to the earth's orbit. In modern language, the speed of light was independent of the reference frame. It was this critical observation that led Einstein to the special theory of relativity. In 1907 Michelson received the Nobel Prize in physics, the first awarded to an American.

Michelson's connection to imaging traces back to 1890 when he used an interferometer to study the moons of Jupiter (Michelson, 1890, 1891a), and soon thereafter he had given a clear statement of the role of fringe visibility (Michelson, 1891b). His biggest impact on astronomy, however, came in 1919 when he and Pease

fitted a large telescope with an interferometer and used it to measure the diameter of the supergiant star Betelgeuse (Alpha Orionis) (Michelson and Pease, 1921).

The Michelson and Pease experiment is of interest in this chapter since it illustrates another technique for collecting data in Fourier space, and also because it is an example of an imaging system that relies on strong prior information, namely that stars are spherical. It is of enormous interest to the astronomy community because it allows high resolution without the expense of building a huge telescope.

Comprehensive reviews of interferometric imaging in astronomy are given by Tango and Twiss (1980), Roddier (1988), Shao and Colavita (1992), Lawson (2000), Quirrenbach (2001) and Saha (2002). A good popular discussion is given by Armstrong *et al.* (1995). Textbooks that provide useful background material include Hecht (1987), Lipson *et al.* (1995) and Born and Wolf (1999). A delightful collection of essays on many topics in optics, including the Michelson stellar interferometer, is Mansuripur (2002).

Acquisition geometry As shown schematically in Fig. 19.10a, Michelson and Pease placed two periscopes on a 6 m beam mounted in front of the 100 inch (2.54 m) Hooker telescope on Mt. Wilson. Each periscope consisted of two flat folding mirrors, and the outer mirror of each pair was movable. Two small apertures were used, each collecting light from one of the two periscopes. Then the primary mirror of the telescope was used to superimpose the star images from the two apertures, and fringes were observed visually. An equivalent optical system with a lens in place of the large spherical mirror is shown in Fig. 19.10b.

The setups shown in Fig. 19.10 can be regarded as modifications of Young's double-pinhole apparatus, with movable folding mirrors and their associated apertures in place of the movable pinholes. Unlike the double-pinhole experiment, however, the apertures are not assumed to be comparable in size to a wavelength. In the analysis of double pinholes, we assumed that the waves emerging from the pinholes were diverging spherical waves; in Fig. 19.10 the waves emerging from the apertures are close to plane waves, and the primary mirror or lens converts them to converging spherical waves which are imaged to Airy diffraction patterns in the focal plane. Thus, when both apertures are open, we see an Airy pattern modulated by fringes instead of a large-area fringe pattern as in the double-pinhole case [*cf.* (19.72)].

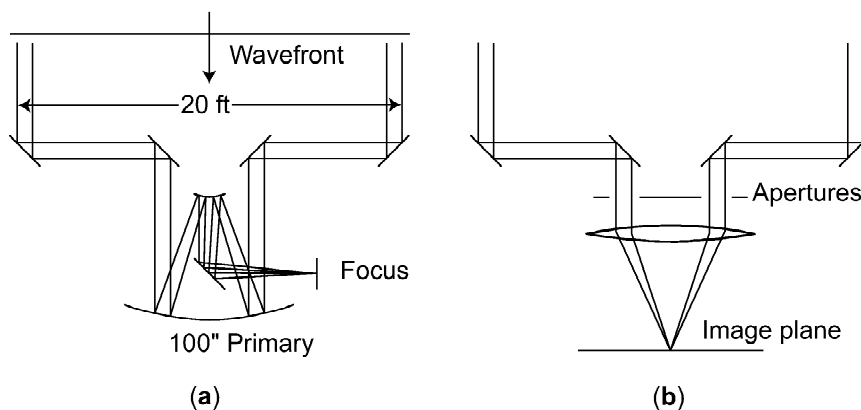

Fig. 19.10 The Michelson stellar interferometer. (a) Mirror system used by Michelson and Pease. (b) Equivalent lens system.

If the diameter of each aperture is D_{ap} , the angular size of the Airy pattern is approximately λ/D_{ap} ; in practice this number is much larger than the angular diameter of the star. For example, a 20 cm aperture has an angular resolution of 2.5 μrad at a wavelength of 0.5 μm . By comparison, Betelgeuse has a diameter of 0.044 arc sec or 0.21 μrad .⁹ One might think that Betelgeuse could be marginally resolved by using the full 100 inch aperture of the telescope, since its diffraction-limited resolution is approximately 0.2 μrad , but phase disturbances from the atmosphere limit the actual telescope resolution to about what one would get with a 20 cm aperture, around 2.5 μrad .

PSF analysis We can analyze the Michelson-Pease geometry just as we did with double pinholes, by first computing the irradiance image of a point source, then convolving it with an extended object distribution. We again assume that the object is spatially incoherent, so the image of an extended object is a linear superposition of the irradiance patterns from individual points. We shall treat the telescope as an ideal thin lens as in Fig. 19.10b, but essentially the same results apply to mirrors.

Because astronomical objects are essentially at an infinite distance from the imaging system, a monochromatic point source produces a plane wave described by $\exp(2\pi i k \hat{\mathbf{a}}_0 \cdot \mathbf{r})$, where $k = 2\pi/\lambda$, $\hat{\mathbf{a}}_0 = (\alpha_{0x}, \alpha_{0y}, \alpha_{0z})$ is a 3D unit vector directed away from the source, and $\mathbf{r} = (x, y, z)$ is a 3D position vector. In the plane $z = 0$, the wave can be written as $\exp(2\pi i \boldsymbol{\rho}_0 \cdot \mathbf{r})$, where $\mathbf{r} = (x, y)$ is a 2D position vector, and $\boldsymbol{\rho}_0 = (\alpha_{0x}/\lambda, \alpha_{0y}/\lambda)$ specifies the 2D spatial-frequency of the wave amplitude in that plane and hence the angular position of the source.

Let \mathbf{r}_1 and \mathbf{r}_2 be the 2D positions of the outer periscope mirrors in the plane $z = 0$, and let \mathbf{r}_{a1} and \mathbf{r}_{a2} be the 2D positions of the corresponding apertures (and hence also of the inner periscope mirrors). The vector distance $\mathbf{r}_1 - \mathbf{r}_2$ is called the *baseline*.

We choose the coordinate system so that the pupil lies in the plane $z = 0$, no matter how the telescope is aimed. Since the periscopes translate the fields laterally, the field in the pupil is given by

$$u_{pupil}^{(\delta)}(\mathbf{r}) \propto \exp[2\pi i \boldsymbol{\rho}_0 \cdot (\mathbf{r} + \mathbf{r}_1 - \mathbf{r}_{a1})] \text{cyl} \left[\frac{\mathbf{r} - \mathbf{r}_{a1}}{D_{ap}} \right] \\ + \exp[2\pi i \boldsymbol{\rho}_0 \cdot (\mathbf{r} + \mathbf{r}_2 - \mathbf{r}_{a2})] \text{cyl} \left[\frac{\mathbf{r} - \mathbf{r}_{a2}}{D_{ap}} \right], \quad (19.95)$$

where the cylinder function is defined by (3.257), and the superscript δ indicates that we are dealing with a point source.

In Sec. 9.6 we learned how to analyze the imaging properties of an ideal thin lens. The key was the Fresnel diffraction formula (9.98), which was used to express the field in the image plane as the Fourier transform of the field emerging from the lens times a quadratic phase factor. For an ideal lens in the Fresnel approximation, we saw in (9.159) that the lens itself introduces a quadratic phase factor that exactly cancels the quadratic phase factor in the Fresnel formula when the lens equation

⁹As a rule of thumb, 1 arc sec = 5 μrad ; a more precise number is 4.848 μrad per arc sec.

(9.169) is satisfied. For the special case of a lens focused at infinity ($q = f$), the result is that [cf. (9.170) and (9.172)]

$$u_{im}(\mathbf{r}) \propto \exp\left(i\pi \frac{r^2}{\lambda f}\right) [\mathcal{F}_2 \{u_{pupil}(\mathbf{r}')\}]_{\boldsymbol{\rho}=\mathbf{r}/\lambda f}, \quad (19.96)$$

where $u_{pupil}(\mathbf{r}')$ is the field in the pupil (before it is modified by the amplitude transmittance of the lens). Thus the field in the image plane is essentially the Fourier transform of the field in the pupil.

Using (3.237), (3.238) and (3.259), we find

$$u_{im}^{(\delta)}(\mathbf{r}) \propto \exp\left(i\pi \frac{r^2}{\lambda f}\right) \frac{\pi D_{ap}^2}{4} \text{besinc}\left(D_{ap} \left|\boldsymbol{\rho}_0 - \frac{\mathbf{r}}{\lambda f}\right|\right) \\ \times \left\{ \exp\left[2\pi i \left(\boldsymbol{\rho}_0 \cdot \mathbf{r}_1 - \frac{1}{\lambda f} \mathbf{r} \cdot \mathbf{r}_{a1}\right)\right] + \exp\left[2\pi i \left(\boldsymbol{\rho}_0 \cdot \mathbf{r}_2 - \frac{1}{\lambda f} \mathbf{r} \cdot \mathbf{r}_{a2}\right)\right] \right\}. \quad (19.97)$$

The corresponding image-plane irradiance is

$$I_{im}^{(\delta)}(\mathbf{r}) = |u_{im}^{(\delta)}(\mathbf{r})|^2 \propto 2 \left[\frac{\pi D_{ap}^2}{4} \text{besinc}\left(D_{ap} \left|\boldsymbol{\rho}_0 - \frac{\mathbf{r}}{\lambda f}\right|\right) \right]^2 \\ \times \left\{ 1 + \cos \left[2\pi \boldsymbol{\rho}_0 \cdot (\mathbf{r}_1 - \mathbf{r}_2) - \frac{2\pi}{\lambda f} \mathbf{r} \cdot (\mathbf{r}_{a1} - \mathbf{r}_{a2}) \right] \right\}. \quad (19.98)$$

The [besinc]² factor is the Airy pattern centered at $\mathbf{r} = \lambda f \boldsymbol{\rho}_0$, which is the geometric image of the point source. The $\{1 + \cos\}$ factor is the superimposed fringe pattern. The fringe frequency is determined by the aperture spacing ($\mathbf{r}_{a1} - \mathbf{r}_{a2}$); the baseline ($\mathbf{r}_1 - \mathbf{r}_2$) affects the phase but not the frequency of the fringes. The fringes have 100% visibility for a point source.

Extended objects Above we considered a point source that radiates a plane wave with 2D spatial frequency $\boldsymbol{\rho}_0$ in the plane $z = 0$. An extended source produces a distribution of plane waves, hence a distribution of spatial frequencies. In keeping with common practice in astronomy, we shall use the direction cosines of the waves rather than spatial frequencies. Thus we specify the source by $f(\boldsymbol{\alpha}_s)$, where $\boldsymbol{\alpha}_s$ (without a hat since it is not a unit vector) is the 2D vector of direction cosines of the 3D wavevector, *i.e.*, $\boldsymbol{\alpha}_s = (\alpha_{sx}, \alpha_{sy})$; the third direction cosine is unneeded since $\alpha_{sx}^2 + \alpha_{sy}^2 + \alpha_{sz}^2 = 1$. Similarly, we use the 2D direction-cosine vector $\boldsymbol{\alpha} = (\alpha_x, \alpha_y)$ to specify position in the image plane. We shall assume that $f(\boldsymbol{\alpha}_s)$ is nonzero only for a very small range of α_x and α_y so that paraxial approximations apply. Thus we can relate angles to focal-plane coordinates by $\boldsymbol{\alpha} = \mathbf{r}/f$, and we can use infinite limits in integrals over α_x and α_y .

For an extended incoherent object, the image-plane irradiance (in angular units) is found by superimposing the contributions of each source point:

$$I_{im}(\boldsymbol{\alpha}) = C \int_{\infty} d^2\alpha_s f(\boldsymbol{\alpha}_s) \text{besinc}^2\left(\frac{D_{ap}}{\lambda} |\boldsymbol{\alpha}_s - \boldsymbol{\alpha}|\right) \\ \times \left\{ 1 + \cos \left[\frac{2\pi}{\lambda} \boldsymbol{\alpha}_s \cdot (\mathbf{r}_1 - \mathbf{r}_2) - \frac{2\pi}{\lambda} \boldsymbol{\alpha} \cdot (\mathbf{r}_{a1} - \mathbf{r}_{a2}) \right] \right\}, \quad (19.99)$$

where C is a radiometric constant that includes a factor of $(\pi D_{ap}^2/4)^2$.

Some limits of this result are interesting. First, if the periscopes are omitted so that $\mathbf{r}_1 = \mathbf{r}_{a1}$ and $\mathbf{r}_2 = \mathbf{r}_{a2}$, then the integral becomes a convolution; the image irradiance is the source distribution blurred by a PSF given by the besinc² modulated with a fringe pattern. This result is expected since the coherent PSF is just the Fourier transform of the pupil function, and the incoherent PSF is the squared-modulus of the coherent one (see Sec. 9.7.6).

Another limit that leads to a similar result, even with the periscopes, is when D_{ap} is small, as it was in the Michelson and Pease experiment. Small apertures reduce problems with atmospheric fluctuations and simplify the analysis of the output; only the latter advantage will be discussed here.

When the aperture is small, the width of the besinc function in (19.99) is large. If it is much larger than the angular diameter of the source and $f(\boldsymbol{\alpha}_s)$ is concentrated near $\boldsymbol{\alpha}_s = \boldsymbol{\alpha}_{s0}$, then we can approximate (19.99) as

$$I_{im}(\boldsymbol{\alpha}) = C \text{besinc}^2\left(\frac{D_{ap}}{\lambda} |\boldsymbol{\alpha}_{s0} - \boldsymbol{\alpha}|\right) \times \int_{\infty} d^2\alpha_s f(\boldsymbol{\alpha}_s) \left\{ 1 + \cos\left[\frac{2\pi}{\lambda} \boldsymbol{\alpha}_s \cdot (\mathbf{r}_1 - \mathbf{r}_2) - \frac{2\pi}{\lambda} \boldsymbol{\alpha} \cdot (\mathbf{r}_{a1} - \mathbf{r}_{a2})\right] \right\}. \quad (19.100)$$

With this approximation, the same manipulations that led to (19.72) allow us to write

$$I_{im}(\boldsymbol{\alpha}) = CF(0) \text{besinc}^2\left(\frac{D_{ap}}{\lambda} |\boldsymbol{\alpha}_{s0} - \boldsymbol{\alpha}|\right) \left\{ 1 + |\gamma| \cos\left[\frac{2\pi}{\lambda} \boldsymbol{\alpha} \cdot (\mathbf{r}_{a1} - \mathbf{r}_{a2}) - \Phi_{\gamma}\right] \right\}, \quad (19.101)$$

where now

$$\gamma = \frac{F[(\mathbf{r}_1 - \mathbf{r}_2)/\lambda]}{F(0)}. \quad (19.102)$$

As expected, (19.101) shows that the image is an Airy pattern times a fringe pattern with a visibility determined by the object Fourier transform. A key point seen from (19.102) is that this Fourier transform is evaluated at a frequency determined by the baseline (spacing of the outer mirrors), even though this frequency would not be passed by the telescope itself. Subject only to practical constraints such as stability and phase shifts due to the atmosphere, arbitrarily high object frequencies can be measured.

Note that the argument of the numerator in (19.102) is dimensionless, as it must be since $F(\cdot)$ is the Fourier transform of a function of a direction-cosine vector, which is dimensionless. In general, we shall denote the frequency vector conjugate to $\boldsymbol{\alpha}$ as \mathbf{u} , with both vectors being dimensionless. Thus the numerator in (19.102) is $F(\mathbf{u})$ evaluated at $\mathbf{u} = (\mathbf{r}_1 - \mathbf{r}_2)/\lambda$. The reader should not confuse this frequency with the spatial frequency of the plane wave produced by a point on the source; the latter frequency is given by $\boldsymbol{\rho} = \boldsymbol{\alpha}/\lambda$. Thus, even though \mathbf{u} and $\boldsymbol{\alpha}$ are both frequency variables in some sense, they are Fourier-conjugate variables in different domains. When we need to specify the components of \mathbf{u} , we shall follow common practice in astronomy and call them u and v ; astronomers refer to the (angular) Fourier domain as the u - v plane.

Estimation of stellar diameter To a reasonable first approximation, stars are uniform discs. There may be some limb darkening since radiation travelling nearly tangent to

the surface must traverse a longer path than radiation exiting nearly perpendicular to the surface, and there may be small surface features akin to solar flares, but if we ignore these details, the visibility function is given by

$$\gamma(\mathbf{u}) = \frac{F(\mathbf{u})}{F(0)} = \text{besinc}(uD_\alpha), \tag{19.103}$$

where D_α is the angular diameter of the star and $u = |\mathbf{u}|$ is the magnitude of the angular frequency vector. This function has its first zero at $u = 1.22/D_\alpha$ and the second zero is at $2.23/D_\alpha$. It follows from (19.102) that the fringes vanish when

$$|\mathbf{r}_1 - \mathbf{r}_2| = 1.22 \frac{\lambda}{D_\alpha} \quad \text{or} \quad |\mathbf{r}_1 - \mathbf{r}_2| = 2.23 \frac{\lambda}{D_\alpha}. \tag{19.104}$$

For Betelgeuse at $\lambda = 0.5 \mu\text{m}$, the fringes vanish at mirror spacings of 2.9 and 5.3 m, so the 6 m beam used by Michelson and Pease was adequate to observe two nulls. They observed the fringes visually and adjusted the mirrors for zero visibility; the stellar diameter was then estimated simply from the corresponding mirror spacings.

A more modern approach would be to collect quantitative data at several mirror separations and use them to estimate the parameter D_α . A circuitous route would be to estimate the visibilities at each separation as discussed in Sec. 19.2.2 and then to fit a besinc to the result. Alternatively, the diameter could be estimated directly from the fringe data by ML methods. In either case, performance on this estimation task can be assessed by mean-square error (MSE) between the estimated and true diameters. Since there is only one parameter to be estimated, null functions are not an issue, and the objections to MSE raised in Sec. 14.1.2 do not apply.

Calculation of MSE is simplified if the noise level in the data is low. We know from Sec. 13.3.6 that ML estimators are asymptotically unbiased and efficient, which means that the MSE approaches the Cramér-Rao (CR) bound (Sec. 13.3.5) as the variance in the raw data (either fringe data or visibilities) approaches zero. Thus we can use the CR bound on the estimate of the diameter as a figure of merit for this problem.

To illustrate the procedure, suppose fringe data are recorded with a regularly spaced detector array for a single baseline. Suppose also that the star is exactly on the telescope axis so that $\boldsymbol{\alpha}_{s_0} = 0$, and that the aperture is small enough that (9.101) is applicable. The data, consisting of noisy samples of $I_{im}(\boldsymbol{\alpha})$, can then be written as¹⁰

$$g_m = K \text{besinc}^2\left(\frac{D_{ap}}{\lambda} |\boldsymbol{\alpha}_m|\right) \{1 + \text{besinc}(u_b D_\alpha) \cos(2\pi \mathbf{u}_f \cdot \boldsymbol{\alpha}_m)\} + n_m \equiv \bar{g}_m + n_m, \tag{19.105}$$

where K contains all of the radiometric factors [including aperture area and stellar brightness $F(0)$], $\mathbf{u}_f \equiv (\mathbf{r}_{a1} - \mathbf{r}_{a2})/\lambda$ is the fringe frequency in angular units, $\mathbf{u}_b \equiv (\mathbf{r}_1 - \mathbf{r}_2)/\lambda$ is the frequency associated with the baseline, and $u_b = |\mathbf{u}_b|$.

For i.i.d. Gaussian noise of variance σ^2 , the CR bound is given by (13.372) as

$$\text{Var}(\hat{D}_\alpha) \geq \sigma^2 \left[\sum_m \left(\frac{d\bar{g}_m}{dD_\alpha} \right)^2 \right]^{-1}. \tag{19.106}$$

¹⁰Note that the absolute-value signs on $\text{besinc}(u_b D_\alpha)$ have disappeared since the phase Φ_γ is either 0 or π , depending on whether $\text{besinc}(u_b D_\alpha)$ is positive or negative.

The parameter D_α appears only in the factor $\text{besinc}(u_b D_\alpha)$ in (19.105). The requisite derivative is given by Abramowitz and Stegun (1965, formula 9.1.30) as

$$\frac{d}{dD_\alpha} \text{besinc}(u_b D_\alpha) = -2 \frac{J_2(\pi u_b D_\alpha)}{D_\alpha}, \quad (19.107)$$

where $J_2(\cdot)$ is a Bessel function. With this derivative, the final result for the CR bound is

$$\text{Var}(\hat{D}_\alpha) \geq \sigma^2 \left\{ \sum_m \left[2K \text{besinc}^2(D_{ap} |\boldsymbol{\alpha}_m| / \lambda) \frac{J_2(\pi u_b D_\alpha)}{D_\alpha} \cos(2\pi \mathbf{u}_f \cdot \boldsymbol{\alpha}_m) \right]^2 \right\}^{-1}. \quad (19.108)$$

One problem with this result is that a single baseline may not be sufficient to determine the stellar diameter unambiguously; if the visibility is near zero, several different D_α yield the same value for $\text{besinc}(u_b D_\alpha)$. If J different visibilities are measured for baselines $\mathbf{u}_b = \mathbf{u}_{bj}$, the Fisher informations for different baselines add, and (19.108) becomes

$$\text{Var}(\hat{D}_\alpha) \geq \sigma^2 \left\{ \sum_{j=1}^J \sum_m \left[2K \text{besinc}^2\left(\frac{D_{ap} |\boldsymbol{\alpha}_m|}{\lambda}\right) \frac{J_2(\pi u_{bj} D_\alpha)}{D_\alpha} \cos(2\pi \mathbf{u}_f \cdot \boldsymbol{\alpha}_m) \right]^2 \right\}^{-1}. \quad (19.109)$$

A CR bound such as (19.108) or (19.109) can be used to optimize the baselines and the aperture diameter for accuracy of the estimate of the stellar diameter. Note that a larger aperture gives more photons but fewer fringes since the width of the Airy pattern is less, so the optimum aperture diameter is not obvious without numerical evaluation. Note also that the accuracy depends on the actual stellar diameter.

If we knew an approximate value for the stellar diameter in advance and wanted to use only a single baseline, we could choose the optimal one by maximizing $J_2(\pi u_b D_\alpha)$ with respect to u_b . Since $J_2(x)$ is maximum at $x = 3.054$, the optimal baseline is $u_b = 0.97 D_\alpha^{-1}$; for comparison, zero visibility occurs when $u_b = 1.22 D_\alpha^{-1}$. More realistically, we might know only that we were looking for stellar diameters in some range, and we could average the right-hand side of (19.108) or (19.109) over that range to obtain a figure of merit for the system.

19.2.4 Interferometers with multiple telescopes

Building on the discussion of the Michelson stellar interferometer in the last section, we now consider other configurations that are used in modern astronomical interferometers. The systems treated here differ from the Michelson stellar interferometer in that two or more separate telescopes are used, as shown in Fig. 19.11 and 19.12, and in the use of optical delay lines. The delay lines may be afocal imaging systems, like the $4f$ system discussed in Sec. 9.7.2 but with movable mirrors to fold the path, or they may include fiber optics.

The delay lines are needed to compensate for the optical path difference (OPD) from a star to the two telescope apertures. As discussed in Sec. 9.7.4, interference cannot occur unless the total OPD is small compared to the coherence length of the source (or, equivalently, the difference in propagation times is small compared to the coherence time). Coherence time is the reciprocal of the spectral bandwidth

of the source, so it can be increased by spectral filtering to reduce the bandwidth, but only at the expense of photons; a better solution is to equalize the paths with delay lines.

Delay lines are not necessary with a Michelson stellar interferometer. When the telescope is pointed exactly at the star of interest, the OPD to a point in the center of the image field is zero if the side mirrors are symmetrically located. As the telescope is scanned across the sky to look at different stars, the OPD remains zero since the side mirrors and apertures are attached to the primary mirror. In the configurations of Figs. 19.11 and 19.12, on the other hand, the OPD from a star to the telescope apertures varies as the telescopes are scanned, and the delay lines are needed to hold the total OPD constant.

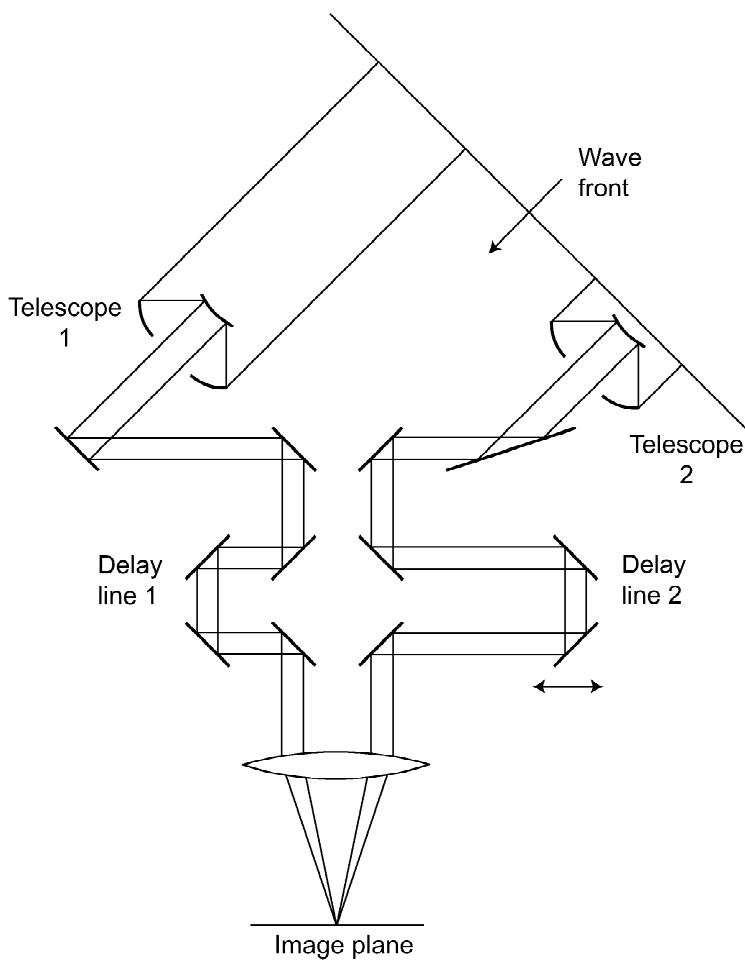

Fig. 19.11 Image-plane (Fizeau) interferometer with two telescopes (definitely not to scale). Details of the relay optics are omitted for clarity, but the image plane is common to the two telescopes.

Fig. 19.12 Pupil-plane (Michelson) interferometer with two telescopes. The beamsplitter causes the pupil planes for the two telescopes to overlap. The small photodetectors sample the image planes at a point, or equivalently integrate the combined amplitudes over the common pupil plane.

Pupil-plane vs. image-plane interference There are two distinct ways of forming the interference pattern in astronomical interferometry (Traub, 1999). The first, shown in Fig. 19.11, is analogous to the Michelson stellar interferometer. The two beams are brought together in a common image plane, with a slight angle between them, and an image modulated by a fringe pattern is observed. This method is sometimes called *image-plane interferometry*.

The second method uses a beamsplitter to combine the beams with no angle between them; it can be regarded as the limit of the Michelson stellar interferometer as the distance between the apertures, $|\mathbf{r}_{a2} - \mathbf{r}_{a1}|$, goes to zero. Hence the spatial frequency of the fringe pattern goes to zero, but we can still observe fringes by varying the delay lines. Qualitatively, a point source produces identical Airy patterns from the two telescopes, and the phase difference between the two images oscillates

with the time delay. In practice, the delay is continuously scanned, and the fringes are observed as temporal rather than spatial patterns. Since the relay optics and beamsplitter cause the images of the pupils of the two telescopes to overlap exactly, this method is called *pupil-plane interferometry*.

Fizeau and Michelson: History and semantics Armand-Hippolyte-Louis Fizeau (1819–1896) was a French physicist celebrated for his studies of the speed of light and for his early investigations into what we would now call partial coherence. By the 1860s, he was a member of the Académie des Sciences and a leading figure in French scientific circles.

In 1868 Fizeau suggested that a simple interferometer, constructed by placing two circular apertures over the pupil of a telescope, could be used to measure the diameters of astronomical bodies. A few years later Edouard Stéphan, director of the observatory at Marseilles, carried out the experiment suggested by Fizeau (Fizeau, 1873; Stéphan, 1874). Seventeen years elapsed before Michelson's first experiments in this field; in 1890 he measured the diameter of Jupiter, using essentially the same interferometer as suggested by Fizeau. An excellent short history of these developments is given by Lawson (2000). Lawson finds no evidence from the literature that Michelson was aware of the earlier French work until well after his experiments on Betelgeuse in 1920–1921, but he does speculate that Michelson might have had the opportunity to meet Fizeau during a trip to Paris in 1881.

The Fizeau interferometer is essentially the Michelson stellar interferometer without the periscope. Both instruments combine the beams in the image plane with a small angle between them, and both yield images modulated spatially with fringes. In current astronomical terminology, both are image-plane interferometers, and this method of beam combination is commonly referred to as the Fizeau mode or simply as a Fizeau interferometer.

On the other hand, the interferometer used by Michelson and Morley in their experiments on the speed of light combined the beams coaxially, with no angle between them, and allowed for scanning the mirrors temporally. Thus this instrument was a pupil-plane interferometer, and by extension all modern systems using coaxial beam combination and scanning mirrors are referred to as Michelson interferometers or are said to be operating in the Michelson mode. By this terminology, the Michelson stellar interferometer was a Fizeau interferometer, but many modern telescopes are Michelson interferometers.

Examples of Fizeau interferometers An example of a Fizeau interferometer is the Large Binocular Telescope (LBT), to be located on Mt. Graham in southeastern Arizona. Designed and constructed by a consortium of U.S., Italian and German institutions, the LBT is scheduled for completion in 2005. It consists of two 8.4 m, F/1.14 parabolic primaries on a single truss. It is equivalent in light-gathering power to a single 11.8 m telescope and in resolving power to a 22.8 m telescope. The F/15 secondary mirrors are adaptive, with individual feedback-controlled segments to compensate for atmospheric phase shifts. The system operates over a wavelength range of 0.4 to 400 μm in interferometric mode. One key advantage it has over other binocular telescopes is that it provides full coverage of the u - v plane.

An even more ambitious earth-based interferometer concept is called 20/20. Being designed by Roger Angel and collaborators at the University of Arizona, 20/20 will consist of two telescopes, each (incongruously) 21 m in diameter. The

primary mirrors will consist of seven 8.4 m segments to be consistent with current mirror-fabrication facilities. The primaries will be F/0.7 and must therefore be markedly aspheric to get diffraction-limited performance. Atmospheric disturbances will be corrected to the diffraction limit of each telescope by 2.1 m adaptive secondary mirrors, also segmented to match the primaries. The two telescopes will move on a 100 m Dia. track in such a way that the baseline is always perpendicular to the line of sight to the source of interest, thus obviating the delay lines. Images will be combined in a Fizeau interferometer in order to get resolutions corresponding to baselines up to 100 m. In addition to its huge optical collection efficiency, 20/20 will have a field of view of about 30 arc sec, much larger than would be possible with conventional Michelson interferometers.

Both 20/20 and the LBT will be able to operate in a nulling mode where the light from a bright star will cancel out by destructive interference while light from a possible planet near the star will not be nulled. Since the beams must be combined coaxially to achieve the null, this mode (Bracewell and McPhie, 1979) is a variant on Michelson interferometry.

A spaceborne example of a Fizeau interferometer is the European Space Agency's DIVA satellite (Deutsches Interferometer für Vielkanalphotometrie und Astrometrie or, less nationalistically, Double Interferometer for Visual Astrometry). DIVA is essentially identical to the original Fizeau proposal as implemented by Stéphan. It uses a single telescope mirror with two 7.5 cm square masks separated (center to center) by 15 cm. It will be used to measure the positions, proper motions and parallaxes of all stars brighter than 15th magnitude.

Examples of Michelson interferometers An example of a Michelson interferometer is the NPOI (Navy Prototype Optical Interferometer) located on Anderson Mesa near Flagstaff, Arizona. Though NPOI consists of six telescopes, it can use pairwise Michelson recombination of the beams, and in this mode can be regarded as a set of two-aperture Michelson interferometers operating in parallel (Armstrong, *et al.*, 1998; Hummel, 2000). NPOI was the first long-baseline system to achieve interferometric beam combination in the visible region.

The VLT (Very Large Telescope) being constructed by the European Southern Observatory at Paranal, Chile, will consist of four 8.2 m telescopes, which can be operated separately or as an interferometer, plus three 1.8 m "outriggers" which will be used to get additional baselines in interferometry. When operated as an interferometer, this system is known as the VLTI (VLT Interferometer).

Many of key design decisions on the VLTI were made by constructing and testing a two-aperture system called VINCI (VLT INterferometer Commissioning Instrument). VINCI uses the Michelson mode with a fiberoptic beam combiner, an idea adapted from IOTA-FLUOR (Infrared-Optical Telescope Array, Fiberoptic Link Unit for Optical Recombination), a three-element Michelson interferometer on Mt. Hopkins in southern Arizona. In essence, a single-mode optical fiber is placed on the optical axis of each telescope, and a fiber coupler is used to combine the beams coherently.

There are many plans to put Michelson interferometers in space. A study team convened by the European Space Agency concluded that the Michelson concept was preferable to the Fizeau because of stability considerations, especially with very long baselines.

A space-based Michelson interferometer in the active design stage is called the Space Interferometry Mission (SIM). Scheduled for launch in 2009, SIM will consist of two 30 cm apertures on a fixed 10 m baseline. It requires 10 nm stabilization for astrometry and 1 nm stabilization for nulling, and it will provide 4 μ as accuracy in position and parallax measurements of stars.

A follow-on mission would be called the Terrestrial Planet Finder (TPF). At this stage the acronym TPF denotes not a specific system but a set of concepts being explored for detecting earth-like planets around nearby stars. One possibility is a group of free-flying telescopes, each 3–4 m Dia., connected as an interferometer with baselines up to 1000 m.

Even more ambitious space interferometers known generically as Planet Imager and Life Finder are being actively discussed. Some of these concepts envision baselines as much as 1000 km. Though the challenge of providing nanometer stabilization over megameter distances is formidable to say the least, the resolution achievable by such systems would be spectacular. Daniel Goldin, former NASA director, has said that his dream is that his grandchildren will see images with Landsat resolution of a planet around another star. If the dream is ever to be achievable, it will require huge space-based interferometers.

EPILOGUE

The hardest part about writing this book was stopping. At the end of each chapter, we could see many other directions to explore, either segments of the recent literature that were not adequately represented or new problems for which we had assembled the tools but not yet begun to use them. Our inclination was to follow as many of these paths as possible, stretching our methodologies to their limits, but of course there would have been no end. We had to draw a line and send this tome to press. To give ourselves the courage to do so, we submit this modest epilogue, suggesting to the reader the paths we might have followed had we had several other lifetimes to do so, and we invite the reader to accompany us on the portions of the journey that we still hope to take.

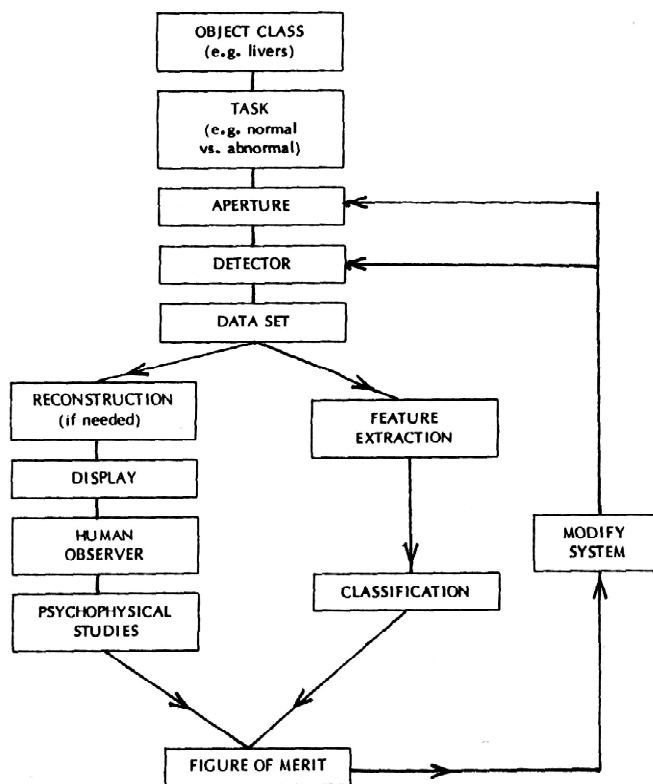

Fig. 1 Roadmap for the systematic optimization of gamma-ray imaging systems (from Myers *et al.*, 1986).

Systematic system optimization We begin the journey with a backward glance and a look at the roadmap to see where we are. In 1985, as the concept of task-based assessment of image quality was taking hold in the medical-imaging community, the diagram in Fig. 1 was presented at a conference at Georgetown University. This diagram embodies two basic principles that we have tried to stress in this book. First, it recognizes that meaningful measures of system quality must be based on the performance of specific observers on specific tasks of practical interest. Second,

it envisions an imaging system as an integrated whole, with all components contributing to task performance and hence needing to be considered together.

A crucial feature of this diagram is the feedback path. After we have learned how to evaluate imaging systems, the next logical step is to incorporate the evaluation into a program of systematic, iterative optimization of task performance.

In the two decades since we first sketched this diagram, many researchers have contributed to the methodology implied in it. We now know much more about image formation, noise in imaging systems, image reconstruction algorithms and the properties of human and model observers.

The challenge for the future of image science is thus twofold: We must continue to refine our understanding of every block in diagrams like the above and we must think seriously about closing the loop and carrying out a full system optimization.

The search for excellence A basic difficulty in actually carrying out the plan suggested in the figure is that the specification of an imaging system is so complex. Consider the example of lens design, where the routine procedure is to assume some merit function and design the lens to optimize it. We would, of course, advocate that the merit function be chosen in relation to specific tasks, but no matter what merit function is used, the search for an optimum is difficult.

Even after the designer has selected the number and arrangement of the individual elements in the lens, there are still many parameters to be chosen, including interelement spacings, curvatures and indices of refraction. Iterative algorithms such as simulated annealing and genetic algorithms can be used to find a more-or-less global optimum in this parameter space, but there is no guarantee that some completely different arrangement of elements with a different set of free parameters might not perform better. Task-based assessment allows objective comparison of competing designs but does not obviate the role of human creativity in selecting the competitors in the first place.

If it doesn't fit, get a bigger hammer! Imaging systems acquire huge amounts of data and often require formidable data-processing resources even to produce one image. Since image quality is inherently a statistical concept, accurate evaluation of a single system requires a huge number of images, and systematic optimization requires, in effect, evaluation of a huge number of imaging systems.

Daunting though this prospect may seem, we can be encouraged by the rapid advances in computational capabilities. In its most expansive form, Moore's law says that every aspect of computer power (chip density, CPU speed, memory, data-transfer rates) will double every 18 months or so. For three decades shortsighted prognosticators have been predicting the end of this trend, but they have consistently been proven wrong. If the trend holds for another three decades, the gain in all facets of computer power will be about $2^{20} \simeq 10^6$. If we crudely benchmark a typical personal computer at the turn of the millennium (January 1, 2001, of course) as a single 1 GHZ processor with 100 MB of memory, we can envision the image scientist of 2031 having access to 1 PHz of processing speed and 100 TB of memory (T = tera = 10^{12} , P = peta = 10^{15}). These numbers might imply a huge number of processors and memory spread around the world, but they do not require an inordinate amount of technological optimism; the pessimistic view is that they will not be correct until 2041 or 2051.

What will image scientists of the not-so-distant future do with such computer power? Possibilities abound. Three-dimensional reconstructions on $1000 \times 1000 \times 1000$ grids will be routine, and rapid temporal sequences with hundreds or thousands of 3D frames will make high-resolution 4D imaging possible. Huge databases will be available for image archiving, and rapid access to the databases will facilitate automated image interpretation. Simulation tools will make the phrase “photographic realism” obsolete, and the authors of this book will quit chiding their colleagues for megalopinakophobia.

Most importantly, the computational arguments against meaningful system evaluation will disappear, and we can begin to close the loop and really optimize imaging systems. Along the way we have to increase our understanding of every component of the system, from radiation source to final observer, and we have to be creative in devising ways of improving them.

It's the data, stupid! A famous American politician told his campaign staff, “It’s the economy, stupid!” thereby imploring them not to lose sight of the most significant factor in their endeavor. In imaging, the key factor is the data; robust data are as important to an image scientist as a robust economy is to a politician. In this analogy, image processing plays the role of spin—it can put a good face on a bad data set but cannot really overcome its limitations.

A data-driven approach to image science would obey three dicta: 1. Use all of the image data; 2. Get more image data; 3. Get more nonimaging data for use in conjunction with image data.

One might think that modern imaging does use all of the image data, but in fact there are information losses at several stages. As a simple example, a time exposure of a time-varying object discards potentially useful temporal data. A more complex example concerns position-sensitive photon-counting detectors where multiple sensor outputs are reduced to estimates of x and y coordinates for each photon. Information loss can occur in the estimation step and again when the estimates are binned into an image matrix. In fact, any binning or quantization of data is a potential source of information loss; moreover, we often use lossy algorithms for data compression. The challenge is to understand how serious these losses are, in terms of specific imaging tasks, and to devise ways of minimizing them.

Getting more imaging data may mean improving the spatial or temporal resolution of a system or it may mean acquiring information from different angular views, different wavelength bands or completely different imaging modalities. Often these advances come only after intensive research and considerable economic investment, so it is imperative to understand how they facilitate the intended application of the images.

Auxiliary nonimaging data are routinely used in conjunction with image data. A radiologist uses clinical indications and patient history along with radiographs in making a diagnosis. Analysts of landsat images use weather and climate data to aid in assessing the health of agricultural fields, and astronomers supplement their direct observations with data from celestial mechanics calculations and astrophysical simulations.

There are many other opportunities to integrate imaging and nonimaging data. The nonimaging data may concern the particular object being imaged or it may concern one or more classes of objects. In a medical context, for example, one might acquire further measurements on the particular patient being studied or one might

compile a database of disease characteristics and use it to guide the acquisition and interpretation of medical images. The challenge is to learn what specific supplementary information is most useful to the goal of the imaging and to devise ways of acquiring it systematically and optimally.

How good does it have to be? It is not uncommon for the designer of an imaging system to ask a user what resolution is needed. The reply may well be that there is no need for resolution better than some value “because there is nothing to see” at a finer scale. Both the question and the answer are misguided.

The question is misguided since performance on any task will always improve with better data, either lower noise or finer resolution. The user of the imaging system or the marketing manager of the company that manufactures it might then say that the performance is “good enough” at some noise level and resolution, so there is no benefit in making it better. For example, a physician might be interested in detecting a tumor 1 cm in diameter and might feel that some particular system is adequate for this task. Pressed to say how he knows, the diligent physician might do an ROC study and get, say, 0.9 for the area under the curve. Is that good enough? Not for the patient whose tumor is missed! And even if economic cost-benefit arguments are adduced for not trying to improve the performance on this task, there will always be other tasks, such as detecting smaller lesions or distinguishing benign from malignant ones.

The issue is more subtle when we look at characteristics of individual components rather than the overall imaging systems. For example, if the point response function of a lens is much smaller than the size of a detector pixel, one might conclude that further improvements in the lens are not needed. Similarly, for decades it has been conventional wisdom in nuclear medicine that detector improvements are unnecessary since the limitation is the collimator.

In neither of these examples, however, does the conclusion hold up under close scrutiny. If a lens has better resolution than the detector with which it is used, the lens designer might choose to use a larger numerical aperture even though that measure increases the aberrations and degrades the lens contribution to the spatial resolution. A gain in light-collection efficiency could then be achieved with negligible loss in overall resolution, and new applications of the system in low light levels could become possible. Similarly, in the nuclear medicine example, improved detector resolution might indeed be useless with conventional parallel-hole collimators, but new approaches to image formation with multiple pinholes or coded apertures could take advantage of the improved detector capability.

It is not an overstatement to say that increased technological capability in any component of an imaging system will always lead to improved task performance when the design of the overall system is approached in an integrated and creative fashion.

Integrated computational imaging systems In 2001 the Optical Society of America conducted a topical meeting called ICIS — Integrated Computational Imaging Systems. The premise is that image processing and image acquisition are becoming increasingly indistinguishable. It is no longer the case that a hardware designer develops a camera and some kind of computer interface while a software specialist develops ways of processing and displaying the data. The data-acquisition system is almost always under computer control, and the control signals are frequently de-

rived from the images themselves. Design of the hardware must take into account the needs and capabilities of the image analysis, and the nature of the processing can dictate what kind of data are acquired.

To a degree, this viewpoint is already used in the design of tomographic or other indirect imaging systems, where no image at all is obtained without processing, but there can still be a great symbiosis when image acquisition and processing are viewed as a whole and optimized in a coordinated way. As understanding of image quality advances, we can envision optimizing a system not for a class of objects but for a particular object; since we do not know what that object is before taking the image, we will have to modify and optimize the system during the image acquisition. The term *adaptive optics* can then take on a new meaning, adapting to the object being imaged and not just to corrupting influences such as the atmosphere.

To solve an inverse problem, concentrate on the forward problem Improved performance in an indirect imaging system can really come from only two sources: better data or better modeling of the data-acquisition system. The function of the reconstruction algorithm is only to narrow down the range of possible objects that are consistent with the data and the model of the system, and no algorithm can go beyond the limitations imposed by the data and the model.

To put this observation into practice, we need greatly improved models in many kinds of imaging. We need to move away from simplified system matrices with coarse voxels chosen purely for computational speed. In many applications we need accurate modeling of scattered and background radiation, and in imaging through turbid media we must move beyond the Born and Rytov approximations. We must avoid mathematical simplifications such as shift invariance and linearity when they are not justified. In optical systems, for example, we should account for shift-variant radiometric variations and off-axis aberrations as well as nonlinearities of the detector, and we should include the nonlinearities arising from partial coherence.

Achieving this level of accuracy in modeling will require careful system analysis and calibration and, of course, increased computer power, but it is the way to make progress in indirect imaging.

The last refuge Oscar Wilde said, “Consistency is the last refuge of the unimaginative.” In inverse problems, however, consistency conditions are a largely untapped resource that can supplement incomplete or inaccurate data. As we saw in Chap. 15, consistency conditions can be derived by characterizing the range of an imaging operator, and in principle they can be used to reduce noise or correct for motion or other unknown characteristics of an imaging system.

Most known consistency conditions are based on continuous-to-continuous models of the imaging system, and most apply to forms of tomography where there are null functions of the adjoint operator. They thus apply to what one might call mathematical tomography rather than the real world of discrete, noisy data. A major theoretical challenge is to elucidate the relationship between mathematical tomography and real tomography and to understand what the continuous consistency conditions tell us about consistency of discrete data.

Tasks and observers A task-based assessment of image quality is useful in practice only if the task is meaningful. In Chaps. 16–19 we saw several examples where

oversimplified tasks led to misleading conclusions about system design. Progress in objective assessment will require more complicated and more realistic tasks. A key question concerns extrapolation of conclusions from simple tasks to more complicated ones. For example, will a system optimized for detection of specified nonrandom signals also be optimal for tasks where the possible outcomes are not defined in advance?

As simulation approaches reality Image simulations are becoming ever more realistic, largely because of the entertainment industry. These words are being written shortly after the telecast of Super Bowl XXXVII, the American football championship. Graphics shown during that game cause one to wonder whether Superbowl LXVII will be played with real athletes or with simulations.

How can image scientists take advantage of techniques developed at Lucas Films and Dreamworks? Accurate depiction of the motion of animate objects will advance our understanding of dynamic imaging systems, and accurate modeling of variations in surface reflectance will aid in design and analysis of optical systems for viewing opaque objects.

Accurate simulation of fine-scale or textural variations requires a detailed understanding of the underlying object statistics and how they influence the image statistics. We need these statistical descriptions for several purposes, including evaluation of image quality, development of Bayesian reconstruction algorithms, image synthesis and pattern recognition.

New models of object textures must be devised, along with experimental methods for estimating the parameters of the models from real image data. Since objects are infinite-dimensional but only a finite number of image samples will be available, parsimonious low-dimensional descriptions must be sought, and ways of assessing whether they capture the essential features of the object variability must be developed.

Our perception of perception We also need to understand better the human perceptual process and to integrate it into the design and evaluation of imaging systems, including processing algorithms and display. The role of image reconstruction and enhancement is to match the raw image data to the human perceptual system, and effective design and meaningful assessment of these elements of the imaging chain require exploring the links between image science and cognitive science. Inclusion of frequency-selective channels and internal noise in our observer models is a first, halting, step to bring knowledge from visual perception into image science, but much more sophisticated models are possible. How are we to account for the strong nonlinearities of the visual system? What can we learn from the study of visual illusions that will affect the design of imaging systems?

Man vs. machine Computerized image analysis is becoming more powerful and commonplace. How do we optimize an image-acquisition system when the end user is a computer? Which tasks are best performed by the computer and which by humans? When humans perform well, can we decipher their strategy and build it into an algorithm? What is the tradeoff between computerized and computer-aided image analysis, and can we be quantitative about answering this question? For example, what is a meaningful performance measure for a computer algorithm that segments an image and presents it to humans in cartoon form? When does the

cartoon enhance the ability of the human to grasp essential details (perform tasks) and when does it result in real information loss?

New technologies Although this book has dealt with the mathematics and physics of imaging, it has said very little about the technologies so essential to modern imaging. Some technological advances, such as optical and x-ray detector arrays, have been developed in direct response to the needs of imaging systems; others, such as optical data storage and computer displays, have been developed for more generic uses but have obvious applicability to imaging.

The greatest opportunity for creativity, however, comes from technologies developed in other fields that have no initially obvious connections to imaging. For example, lasers were an extension of masers, microwave amplifiers pursued initially for communications purposes. Superconducting magnets were developed long before their need in magnetic resonance imaging was apparent. And artificial radioisotopes were the result of wartime work on nuclear weapons, with no vision for their use in nuclear medicine. Yet in all of these cases the new technologies were quickly put to use in imaging systems.

Some emerging technologies with potential in imaging include femtosecond optical pulses, entangled photon states, diffractive and reflective x-ray optics, Josephson junctions and other superconducting devices, ultrasensitive seismometers and novel interferometers. Not to be overlooked are stunning advances in software in the areas of database management, artificial intelligence and data mining. A modern image scientist/technologist needs to be conversant with far more than the imaging literature and to remain alert to seemingly unrelated developments that can impact imaging.

New signals Science always searches for new ways of probing the universe, and increasingly the result of the probe is a multidimensional data set that can be manipulated and displayed as an image. One way to make progress in image science, or science in general, is to think up new things to map and new ways of probing them. Tables I and II in the Prologue should provide lots of hints in the search for new signals to image, but we can also look for new ways of applying ideas from image science to things we might not initially think of as images.

Sometimes ideas can come full circle, originating in another area, then being appropriated by image scientists, and finally being returned with embellishments to the original field. For example, in this book we have made considerable use of the Wigner distribution function (WDF) as a tool for signal and image analysis, although it originated in quantum mechanics. Now, however, there is considerable interest in imaging the quantum-mechanical Wigner function itself, and it turns out that tomographic reconstruction algorithms are the way to do it.

New dimensions We have long since passed the point where the word image implied a static, 2D construct. Modern imaging systems are almost always 3D ($x-y-z$ or $x-y-t$) or 4D ($x-y-z-t$), but there are many options for creative addition of yet other dimensions. The challenges lie in acquiring the data sets, doing high-dimensional image reconstruction and displaying the results.

To return to an example just given, the quantum-mechanical Wigner distribution function has been applied so far to 1D quantum states, such as the state of a single mode of the radiation field. If we want to measure the WDF of an

N -dimensional quantum state, it requires a $2N$ -dimensional measurement/imaging system.

Similarly, if the quantity of interest is a statistical correlation function for a 2D field, it requires four variables for full specification, and correlations of 3D fields require six variables. There is no reason not to regard the correlation function, rather than the field itself, as the object to be imaged.

New pedagogies This book arose as an educational endeavor. It had its roots many years ago in a course on radiological imaging, and it eventually spawned several other courses on image science and noise. As the courses and the authors' educational and research interests evolved, it became apparent that the pedagogy of imaging was as challenging as the science and technology.

Students wanting to contribute at the cutting edge of image science must master a breadth of material comparable to—and perhaps even exceeding—the scope of mature disciplines such as chemistry and electrical engineering. They not only must study mathematics, statistics, physics and electronics, they must also understand how they interrelate and contribute to the whole gestalt of image science. They must be able to follow many diverse literatures and to pick and choose ideas and methodologies from them to solve their own problems in imaging. Like statisticians, they must appreciate the needs of their “clients,” the end users of the images, but they must also be involved in optimizing the systems and developing the uses themselves.

Accommodating this breadth will require new departmental organizations, new interdisciplinary seminars and new professional societies. Academic departments and professional organizations devoted to optics and photonics will expand their base to include imaging, and umbrella interdisciplinary programs will arise to coordinate imaging activities across departments. Even social interactions among students and researchers perusing different aspects of the imaging elephant will help to broaden viewpoints and ease misconceptions.

We—the authors of this volume—have our own experiences in this educational process and our own thoughts about the critical educational needs in image science, and it is not a particularly difficult inverse problem to reconstruct those views from the contents of the book. We also realize, however, that optimization of the process is an ongoing challenge, where diverse views and imaginative approaches can be of immense value. We encourage a dialogue among educators and students in image science, and we hope that this book can stimulate that exchange in some small way. We look forward to observing the further development of image science as an academic discipline and making whatever contributions to it that we can.

APPENDIX A

Matrix Algebra

This appendix is a compendium of useful definitions and formulas related to matrices and vectors. The intent is to provide a ready reference rather than a tutorial. The formulas are presented here with little discussion and few derivations, though some of the topics are discussed more didactically in the main text of the book. Cross references to the main text are given where appropriate.

Good introductory treatments of matrices and discrete linear algebra are given by Eves (1966), Mirsky (1982), Pettofrezzo (1966), Strang (1980) and Usmani (1987). Excellent comprehensive texts are Golub and van Loan (1989) and Harville (1997); the latter is a particularly good match to the needs of this book. Lists of matrix identities are given in Siotani (1985), Pilz (1991) and Rade and Westergren (1990).

A.1 NOTATION AND TERMINOLOGY

An $M \times N$ matrix \mathbf{A} is an ordered set of MN numbers arranged into an array with M rows and N columns. The number in the m^{th} row and n^{th} column, denoted A_{mn} , is called the mn^{th} element of \mathbf{A} . The element can be either real or complex. The set of all $M \times N$ matrices with real elements is denoted $\mathbb{R}^{M \times N}$, while the set of all $M \times N$ matrices with complex elements is denoted $\mathbb{C}^{M \times N}$.

A *square* matrix is one with an equal number of rows and columns, $M = N$. An $N \times N$ square matrix is said to have *order* N or *degree* N . A *rectangular* matrix is one that has an unequal number of rows and columns ($M \neq N$). A *diagonal* matrix is a square matrix with $A_{mn} = 0$ if $m \neq n$. In other words, the nonzero elements are along the diagonal only. A square matrix \mathbf{A} is said to be *upper triangular* if all

of the elements below the diagonal are zero, *i.e.*, $A_{mn} = 0$ when $n < m$. Similarly, it is *lower triangular* if all elements above the diagonal are zero, *i.e.*, $A_{mn} = 0$ when $n > m$.

Two matrices are said to be equal if all elements of one are equal to the corresponding elements of the other. Thus

$$\mathbf{A} = \mathbf{B} \quad \text{if and only if} \quad A_{mn} = B_{mn} \quad \text{for all } m \text{ and } n. \quad (\text{A.1})$$

If \mathbf{A} is an $M \times N$ matrix and $\mathbf{A} = \mathbf{B}$, then \mathbf{B} is also an $M \times N$ matrix.

An N -dimensional vector is an ordered set of N numbers. If these numbers are arranged in a column, the vector is referred to as a *column vector*, which can also be regarded as an $N \times 1$ matrix, with N rows and one column. In spite of this equivalence, vectors will be denoted with lower-case bold letters and matrices with upper-case ones. The word vector will be understood to mean column vector unless otherwise specified.

The *transpose* of an $M \times N$ matrix \mathbf{A} is an $N \times M$ matrix denoted \mathbf{A}^t obtained by interchanging rows and columns of \mathbf{A} . Thus

$$(\mathbf{A}^t)_{mn} = (\mathbf{A})_{nm} = A_{nm}. \quad (\text{A.2})$$

The transpose of an $N \times 1$ column vector is a $1 \times N$ *row vector*, *i.e.*, a matrix with 1 row and N columns.

A *symmetric* matrix is a square matrix that is identical to its transpose, *i.e.*,

$$(\mathbf{A}^t)_{mn} = (\mathbf{A})_{mn} = A_{mn} = A_{nm} \quad \text{if } \mathbf{A} \text{ is symmetric.} \quad (\text{A.3})$$

The *adjoint*¹ of an $M \times N$ matrix \mathbf{A} is an $N \times M$ matrix denoted \mathbf{A}^\dagger , obtained by interchanging rows and columns of \mathbf{A} and taking the complex conjugate of each element. Thus

$$(\mathbf{A}^\dagger)_{mn} = (\mathbf{A})_{nm}^* = A_{nm}^*. \quad (\text{A.4})$$

Adjoint and transpose are synonymous if all elements of \mathbf{A} are real. Note that $[\mathbf{A}^t]^t = \mathbf{A}$ and $[\mathbf{A}^\dagger]^\dagger = \mathbf{A}$.

A *Hermitian* matrix is a square matrix that is identical to its adjoint, *i.e.*,

$$(\mathbf{A}^\dagger)_{mn} = (\mathbf{A})_{mn} = A_{mn} = A_{nm}^* \quad \text{if } \mathbf{A} \text{ is Hermitian.} \quad (\text{A.5})$$

A diagonal matrix is necessarily symmetric, and it is Hermitian if the diagonal elements are real. A real, Hermitian matrix is necessarily symmetric.

A square matrix \mathbf{A} is said to be *skew-Hermitian* or *anti-Hermitian* if $\mathbf{A}^\dagger = -\mathbf{A}$. If \mathbf{A} is skew-Hermitian, then $i\mathbf{A}$ is Hermitian.

A.2 BASIC ALGEBRAIC OPERATIONS

A.2.1 Addition and subtraction

Addition and subtraction of matrices are performed on an element-by-element basis. If we write

$$\mathbf{C} = \mathbf{A} \pm \mathbf{B}, \quad (\text{A.6})$$

¹Many older books use the term adjoint or *adjugate* to refer to a matrix of cofactors (to be defined in Sec. A.5.4). Our usage is common in the modern literature where a matrix is regarded as a linear operator.

it implies that

$$C_{mn} = A_{mn} \pm B_{mn}. \tag{A.7}$$

Subtraction is the inverse of addition, *i.e.*,

$$(\mathbf{A} + \mathbf{B}) - \mathbf{B} = \mathbf{A}. \tag{A.8}$$

Matrix addition is commutative and distributive:

$$\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}. \tag{A.9}$$

$$(\mathbf{A} + \mathbf{B}) + \mathbf{C} = \mathbf{A} + (\mathbf{B} + \mathbf{C}). \tag{A.10}$$

The zero matrix, denoted $\mathbf{0}$, is a matrix of all zeros. It is the identity element for addition, so

$$\mathbf{A} + \mathbf{0} = \mathbf{A} \quad \text{and} \quad \mathbf{0} + \mathbf{A} = \mathbf{A}. \tag{A.11}$$

A.2.2 Scalar multiplication

A matrix \mathbf{A} is said to be multiplied by a scalar α if every element of \mathbf{A} is multiplied by α , *i.e.*,

$$[\alpha\mathbf{A}]_{mn} = \alpha A_{mn}, \tag{A.12}$$

where α and A_{mn} can both be complex. Scalar multiplication is commutative and associative:

$$\beta(\alpha\mathbf{A}) = \alpha(\beta\mathbf{A}), \tag{A.13}$$

$$(\alpha + \beta)\mathbf{A} = \alpha\mathbf{A} + \beta\mathbf{A}, \tag{A.14}$$

where α and β are arbitrary real or complex numbers. Scalar multiplication is also associative with respect to addition:

$$\alpha(\mathbf{A} + \mathbf{B}) = \alpha\mathbf{A} + \alpha\mathbf{B}. \tag{A.15}$$

A.2.3 Matrix multiplication

In order to define a matrix-matrix product, which we write as

$$\mathbf{C} = \mathbf{AB}, \tag{A.16}$$

the matrices must be *conformable*. That is, if \mathbf{B} is a $P \times N$ matrix, then \mathbf{A} must be an $M \times P$ matrix for some M . The product \mathbf{C} is then an $M \times N$ matrix with elements given by

$$C_{mn} = \sum_{p=1}^P A_{mp}B_{pn}, \quad m = 1, \dots, M, \quad n = 1, \dots, N. \tag{A.17}$$

Matrix-vector multiplication is a special case of matrix-matrix multiplication. If \mathbf{A} is an $M \times N$ matrix and \mathbf{x} is an $N \times 1$ column vector, we can write

$$\mathbf{y} = \mathbf{Ax}, \tag{A.18}$$

where \mathbf{y} is an $M \times 1$ column vector with elements given by

$$y_m = \sum_{n=1}^N A_{mn} x_n. \quad (\text{A.19})$$

Matrix-matrix and matrix-vector multiplication are distributive and associative:

$$\mathbf{A}(\mathbf{B} + \mathbf{C}) = \mathbf{A}\mathbf{B} + \mathbf{A}\mathbf{C}; \quad (\text{A.20})$$

$$\mathbf{A}(\mathbf{x} + \mathbf{y}) = \mathbf{A}\mathbf{x} + \mathbf{A}\mathbf{y}; \quad (\text{A.21})$$

$$\mathbf{A}(\mathbf{B}\mathbf{C}) = (\mathbf{A}\mathbf{B})\mathbf{C}; \quad (\text{A.22})$$

$$\mathbf{A}(\mathbf{B}\mathbf{x}) = (\mathbf{A}\mathbf{B})\mathbf{x}. \quad (\text{A.23})$$

On the other hand, matrix-matrix multiplication is not necessarily commutative. The statement $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A}$ makes no sense unless \mathbf{A} and \mathbf{B} are square matrices of the same size, and even then it is not true in general. If \mathbf{A} and \mathbf{B} are both $N \times N$ matrices and $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A}$, we say that \mathbf{A} and \mathbf{B} *commute*. Two diagonal $N \times N$ matrices necessarily commute.

The identity operator for matrix multiplication is the *unit matrix*, a square matrix with ones along the diagonal and zeros everywhere else. In an N -dimensional space, the unit matrix is denoted \mathbf{I}_N , though the subscript may be deleted if it is clear from context. The elements of \mathbf{I}_N are given by

$$[\mathbf{I}_N]_{mn} = \delta_{mn}, \quad m, n = 1, \dots, N, \quad (\text{A.24})$$

where δ_{mn} is the *Kronecker delta* symbol, which takes the value 1 if $m = n$ and 0 if $m \neq n$. The unit matrix \mathbf{I}_N commutes with all $N \times N$ matrices.

A.2.4 Adjoins and transposes of products

From the definitions of matrix products and adjoints, it follows that

$$(c\mathbf{A})^\dagger = c^* \mathbf{A}^\dagger; \quad (\text{A.25})$$

$$(\mathbf{A}\mathbf{B})^\dagger = \mathbf{B}^\dagger \mathbf{A}^\dagger; \quad (\text{A.26})$$

$$(\mathbf{A}_1 \mathbf{A}_2 \dots \mathbf{A}_k)^\dagger = \mathbf{A}_k^\dagger \mathbf{A}_{k-1}^\dagger \dots \mathbf{A}_1^\dagger, \quad (\text{A.27})$$

where c is any scalar and the matrices are assumed to be conformable.

Similar results apply to transposes:

$$(c\mathbf{A})^t = c \mathbf{A}^t; \quad (\text{A.28})$$

$$(\mathbf{A}\mathbf{B})^t = \mathbf{B}^t \mathbf{A}^t; \quad (\text{A.29})$$

$$(\mathbf{A}_1 \mathbf{A}_2 \dots \mathbf{A}_k)^t = \mathbf{A}_k^t \mathbf{A}_{k-1}^t \dots \mathbf{A}_1^t. \quad (\text{A.30})$$

A.2.5 Inner product of two vectors

If \mathbf{a} and \mathbf{b} are vectors in an N -dimensional Euclidean space, their *inner product* or *scalar product* is denoted variously as $\mathbf{a} \cdot \mathbf{b}$, (\mathbf{a}, \mathbf{b}) or $\mathbf{a}^\dagger \mathbf{b}$. The latter notation is suggestive of matrix-matrix multiplication. If we regard \mathbf{a} as an $N \times 1$ matrix with elements $A_{n1} = a_n$, then \mathbf{a}^\dagger is its adjoint, a $1 \times N$ matrix or row vector with elements $A_{1n} = [A_{n1}]^* = a_n^*$. The product $\mathbf{a}^\dagger \mathbf{b}$ is then a 1×1 matrix or scalar, with the single element given by the usual rule for matrix-matrix multiplication,

$$\mathbf{a}^\dagger \mathbf{b} = \sum_{n=1}^N a_n^* b_n. \quad (\text{A.31})$$

With this definition² of scalar product, the *norm* or length of a vector \mathbf{a} is given by

$$\|\mathbf{a}\| = \sqrt{\mathbf{a}^\dagger \mathbf{a}} = \sqrt{\sum_{n=1}^N |a_n|^2}. \quad (\text{A.32})$$

If $\mathbf{b} = \mathbf{A}\mathbf{c}$ in (A.31), with \mathbf{A} an $N \times M$ matrix and \mathbf{c} an $M \times 1$ vector, we have

$$\mathbf{a}^\dagger \mathbf{A}\mathbf{c} = \sum_{n=1}^N a_n^* (\mathbf{A}\mathbf{c})_n = \sum_{n=1}^N \sum_{m=1}^M a_n^* A_{nm} c_m = [\mathbf{A}^\dagger \mathbf{a}]^\dagger \mathbf{c}. \quad (\text{A.33})$$

For more discussion of inner products in a general Hilbert-space setting, see Chap. 1.

A.2.6 Outer product of two vectors

If \mathbf{a} is an $N \times 1$ vector and \mathbf{b} is $M \times 1$, their *outer product* or *tensor product* $\mathbf{b}\mathbf{a}^\dagger$ is an $M \times N$ matrix with components given by

$$[\mathbf{b}\mathbf{a}^\dagger]_{ij} = b_i a_j^*. \quad (\text{A.34})$$

Similarly, $\mathbf{a}\mathbf{b}^\dagger$ is an $N \times M$ matrix with elements

$$[\mathbf{a}\mathbf{b}^\dagger]_{ij} = a_i b_j^*. \quad (\text{A.35})$$

These two equations show that

$$[\mathbf{a}\mathbf{b}^\dagger]^\dagger = \mathbf{b}\mathbf{a}^\dagger, \quad (\text{A.36})$$

in accord with (A.26).

Outer-product matrices can be used in matrix-matrix or matrix-vector products following the usual rules. For example, if \mathbf{c} is an $M \times 1$ vector,

$$\mathbf{a}\mathbf{b}^\dagger \mathbf{c} = \mathbf{a}(\mathbf{b}^\dagger \mathbf{c}) = \mathbf{a} \sum_{m=1}^M b_m^* c_m, \quad (\text{A.37})$$

²Equation (A.31) gives the Euclidean or \mathbb{L}_2 definition of scalar product; other possible definitions are discussed in Chap. 1, Sec. 1.1.4.

so $\mathbf{ab}^\dagger\mathbf{c}$ is an $N \times 1$ vector with elements

$$\left[\mathbf{ab}^\dagger\mathbf{c}\right]_n = a_n \sum_{m=1}^M b_m^* c_m. \quad (\text{A.38})$$

Because of the associative laws, parentheses are superfluous in expressions like $\mathbf{ab}^\dagger\mathbf{c}$, which can be viewed as either the matrix \mathbf{ab}^\dagger acting on the vector \mathbf{c} or the scalar $\mathbf{b}^\dagger\mathbf{c}$ times the vector \mathbf{a} .

For more discussion of outer products, see Sec. 1.3.7 in Chap. 1.

A.2.7 Direct products

If \mathbf{A} is an $M \times N$ matrix and \mathbf{B} is a $P \times Q$ matrix, then the *direct product* or *Kronecker product* $\mathbf{A} \star \mathbf{B}$ is an $(MP) \times (NQ)$ matrix of the form

$$\mathbf{A} \star \mathbf{B} = \begin{bmatrix} a_{11}\mathbf{B} & a_{12}\mathbf{B} & \cdots & a_{1N}\mathbf{B} \\ a_{21}\mathbf{B} & a_{22}\mathbf{B} & \cdots & a_{2N}\mathbf{B} \\ \cdot & \cdot & \cdots & \cdot \\ \cdot & \cdot & \cdots & \cdot \\ a_{M1}\mathbf{B} & a_{M2}\mathbf{B} & \cdots & a_{MN}\mathbf{B} \end{bmatrix}. \quad (\text{A.39})$$

The notation of (A.39) indicates that each element of the matrix \mathbf{B} is multiplied by the scalar a_{11} and the resulting $P \times Q$ matrix is placed in the upper left position of $\mathbf{A} \star \mathbf{B}$, and similarly for the other elements indicated.

Elementary properties of the direct product are (Siotani *et al.*, 1985):

$$(c\mathbf{A}) \star \mathbf{B} = \mathbf{A} \star (c\mathbf{B}) = c(\mathbf{A} \star \mathbf{B}); \quad (\text{A.40})$$

$$(\mathbf{A} \star \mathbf{B}) \star \mathbf{C} = \mathbf{A} \star (\mathbf{B} \star \mathbf{C}); \quad (\text{A.41})$$

$$(\mathbf{A} \star \mathbf{B})^\dagger = \mathbf{A}^\dagger \star \mathbf{B}^\dagger; \quad (\text{A.42})$$

$$(\mathbf{A} \star \mathbf{B})(\mathbf{C} \star \mathbf{D}) = (\mathbf{AC}) \star (\mathbf{BD}); \quad (\text{A.43})$$

$$(\mathbf{A} + \mathbf{B}) \star \mathbf{C} = (\mathbf{A} \star \mathbf{C}) + (\mathbf{B} \star \mathbf{C}). \quad (\text{A.44})$$

For reference, we list some relations between direct products and matrix inverses (see Sec. A.3), determinants (Sec. A.5) and traces (Sec. A.6):

$$(\mathbf{A} \star \mathbf{B})^{-1} = \mathbf{A}^{-1} \star \mathbf{B}^{-1} \quad \text{for nonsingular } \mathbf{A} \text{ and } \mathbf{B}; \quad (\text{A.45})$$

$$\det(\mathbf{A} \star \mathbf{B}) = [\det(\mathbf{A})]^P [\det(\mathbf{B})]^M \quad \text{for } \mathbf{A}: M \times M \text{ and } \mathbf{B}: P \times P; \quad (\text{A.46})$$

$$\text{tr}\{\mathbf{A} \star \mathbf{B}\} = \text{tr}\{\mathbf{A}\} \text{tr}\{\mathbf{B}\}. \quad (\text{A.47})$$

A.2.8 Hadamard products and other operations

If \mathbf{A} and \mathbf{B} are $M \times N$ matrices, their *Hadamard product* $\mathbf{A} \odot \mathbf{B}$ is another $M \times N$ matrix with elements given by

$$[\mathbf{A} \odot \mathbf{B}]_{mn} = A_{mn} B_{mn}. \quad (\text{A.48})$$

The Hadamard product is thus an element-by-element product. The matrix of all ones, denoted $\mathbf{1}$, is the identity element for Hadamard multiplication. An exhaustive treatment of Hadamard products is given by Horn (1990).

We can extend the idea of Hadamard product to vectors just by regarding them as $N \times 1$ matrices. To be consistent with (A.48), we could denote the Hadamard product of two vectors as $\mathbf{a} \odot \mathbf{b}$, but it will often be convenient just to juxtapose the symbols and write \mathbf{ab} , defining this product by $[\mathbf{ab}]_n \equiv a_n b_n$. With matrices, the symbol \odot serves to distinguish the Hadamard product from the ordinary matrix-matrix product, but with vectors the only products we have so far are the inner product $\mathbf{a}^\dagger \mathbf{b}$ and the outer product \mathbf{ab}^\dagger , so we are free to use \mathbf{ab} for Hadamard product.

Many other operations can also be defined componentwise on vectors and matrices. For example, we can define an element-by-element ratio of two vectors by $[\mathbf{a}/\mathbf{b}]_n = a_n/b_n$, and a logarithm by $[\ln(\mathbf{a})]_n = \ln(a_n)$.

We can extend the concept further to functions, regarded as vectors in a Hilbert space (see Chap. 1). Thus, if the vector \mathbf{a} denotes the function $a(x)$ and \mathbf{b} denotes $b(x)$, then \mathbf{ab} denotes $a(x)b(x)$ and $\ln(\mathbf{a})$ denotes $\ln[a(x)]$, so long as the resulting vectors are in the same Hilbert space as the original ones.

A.3 MATRIX INVERSION

A.3.1 Rank and invertibility

The *row rank* of a matrix is the number of linearly independent rows, while the *column rank* is the number of linearly independent columns. A basic theorem (Strang, 1980) states that the row rank and column rank are equal, so they are called simply the *rank*.

An $N \times N$ matrix \mathbf{A} is called *invertible* or *nonsingular* if its rank = N . If that is the case, there exists a matrix \mathbf{A}^{-1} , called the *inverse* of \mathbf{A} , such that

$$\mathbf{A}^{-1} \mathbf{A} = \mathbf{A} \mathbf{A}^{-1} = \mathbf{I}_N. \tag{A.49}$$

By this definition, all rectangular matrices are singular. For rectangular matrices, no true inverse exists, but various *generalized inverses* or *pseudoinverses* can be defined. See Chap. 1 for a detailed discussion of this topic.

A simple example of a square but singular matrix is the outer product \mathbf{ab}^\dagger , where \mathbf{a} and \mathbf{b} are both $N \times 1$ vectors. This matrix has rank one since the i^{th} row equals the j^{th} row times the factor a_i^*/b_j^* [see (A.35)], so it is singular for $N > 1$.

See Sec. A.5.4 for a general expression for the inverse of a matrix in terms of determinants. Algorithms for computation of inverses can be found in Golub and van Loan (1989) or Press *et al.* (1992), but most readers will never need these details since standard packages such as Matlab and Mathematica can be used to find numerical or symbolic inverses.

A.3.2 General properties of matrix inverses

If we assume that all of the indicated inverses exist, the following general relations hold:

$$[\mathbf{A}^{-1}]^\dagger = [\mathbf{A}^\dagger]^{-1}; \tag{A.50}$$

$$[c\mathbf{A}]^{-1} = \frac{1}{c} \mathbf{A}^{-1}, \quad (c \text{ a scalar}); \quad (\text{A.51})$$

$$[\mathbf{AB}]^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}, \quad (\mathbf{A} \text{ and } \mathbf{B} \text{ both } N \times N); \quad (\text{A.52})$$

$$[\mathbf{A}^k]^{-1} = [\mathbf{A}^{-1}]^k, \quad (k \text{ a positive integer}). \quad (\text{A.53})$$

If a matrix \mathbf{H} is Hermitian, its inverse \mathbf{H}^{-1} is also Hermitian (if it exists).

A square matrix \mathbf{U} is called *unitary* if its adjoint equals its inverse, *i.e.*, $\mathbf{U}^\dagger = \mathbf{U}^{-1}$. A unitary matrix with real elements satisfies $\mathbf{U}^\dagger = \mathbf{U}^t = \mathbf{U}^{-1}$ and is referred to as an *orthogonal* matrix. The columns of a unitary matrix form an orthonormal set, and the rows form another orthonormal set.

A.3.3 Inversion formulas for special cases

If \mathbf{A} is a diagonal $N \times N$ matrix, its inverse is obtained by taking the reciprocal of each diagonal element, *i.e.*,

$$[\mathbf{A}^{-1}]_{mn} = \frac{1}{A_{nn}} \delta_{mn} \quad \text{if } A_{mn} = A_{nn} \delta_{mn}. \quad (\text{A.54})$$

Thus the unit matrix is its own inverse.

If \mathbf{A} and $\mathbf{A} + \mathbf{pq}^\dagger$ are both nonsingular, with \mathbf{p} and \mathbf{q} being $N \times 1$ vectors and \mathbf{A} being an $N \times N$ matrix, then

$$[\mathbf{A} + \mathbf{pq}^\dagger]^{-1} = \mathbf{A}^{-1} - \frac{\mathbf{A}^{-1}\mathbf{pq}^\dagger\mathbf{A}^{-1}}{1 + \mathbf{q}^\dagger\mathbf{A}^{-1}\mathbf{p}}. \quad (\text{A.55})$$

A generalization of this result is the *matrix-inversion lemma*, also known as the *binomial inverse theorem* (Woodbury, 1950). Several forms of this useful theorem are (Tylavsky and Sohie, 1986):

$$[\mathbf{A} - \mathbf{UBV}]^{-1} = \mathbf{A}^{-1} + \mathbf{A}^{-1}\mathbf{U}[\mathbf{B}^{-1} - \mathbf{VA}^{-1}\mathbf{U}]^{-1}\mathbf{VA}^{-1} \quad (\text{A.56a})$$

$$= \mathbf{A}^{-1} + \mathbf{A}^{-1}\mathbf{UB}[\mathbf{I} - \mathbf{U}^\dagger\mathbf{A}^{-1}\mathbf{UB}]^{-1}\mathbf{U}^\dagger\mathbf{A}^{-1} \quad (\mathbf{U} = \mathbf{V}^\dagger) \quad (\text{A.56b})$$

$$= \mathbf{A}^{-1} + \mathbf{A}^{-1}\mathbf{UB}[\mathbf{I} - \mathbf{VA}^{-1}\mathbf{UB}]^{-1}\mathbf{VA}^{-1} \quad (\text{A.56c})$$

$$= \mathbf{A}^{-1} + \mathbf{A}^{-1}\mathbf{U}[\mathbf{I} - \mathbf{BVA}^{-1}\mathbf{U}]^{-1}\mathbf{BVA}^{-1} \quad (\text{A.56d})$$

Form (A.56a) requires that \mathbf{A} and \mathbf{B} be nonsingular, while the other three forms require only that \mathbf{A} be nonsingular. Of course, all forms require that the various matrices be conformable. An excellent discussion of these results is given by Tylavsky and Sohie (1986).

The inverse of partitioned matrices is also of interest. Given a nonsingular $N \times N$ matrix \mathbf{A} and a nonsingular $M \times M$ matrix \mathbf{B} , we can form a partitioned $(M+N) \times (M+N)$ matrix with $N \times M$ and $M \times N$ submatrices of all zeros on the off-diagonals. The inverse of this partitioned matrix is given by

$$\begin{bmatrix} \mathbf{A} & \mathbf{0} \\ \mathbf{0} & \mathbf{B} \end{bmatrix}^{-1} = \begin{bmatrix} \mathbf{A}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{B}^{-1} \end{bmatrix}. \quad (\text{A.57})$$

Finally, we consider the inverse of complex matrices. Let $\mathbf{C} = \mathbf{A} + i\mathbf{B}$, where \mathbf{A} and \mathbf{B} are real $N \times N$ matrices. Then \mathbf{C}^{-1} , if it exists, is given by (Rade and Westergren, 1990, p. 105)

$$\begin{aligned} [\mathbf{A} + i\mathbf{B}]^{-1} &= [\mathbf{A} + \mathbf{B}\mathbf{A}^{-1}\mathbf{B}]^{-1} - i\mathbf{A}^{-1}\mathbf{B}[\mathbf{A} + \mathbf{B}\mathbf{A}^{-1}\mathbf{B}]^{-1} \\ &= \mathbf{B}^{-1}\mathbf{A}[\mathbf{B} + \mathbf{A}\mathbf{B}^{-1}\mathbf{A}]^{-1} - i[\mathbf{B} + \mathbf{A}\mathbf{B}^{-1}\mathbf{A}]^{-1}, \end{aligned} \quad (\text{A.58})$$

where the first form requires the existence of \mathbf{A}^{-1} and the second form requires \mathbf{B}^{-1} .

A.3.4 Neumann series

Consider a nonsingular $N \times N$ matrix of the form $\mathbf{I} - \mathbf{\Omega}$. Provided the series converges uniformly, we can express $[\mathbf{I} - \mathbf{\Omega}]^{-1}$ by a *Neumann series* (named for Carl Neumann, not John von),

$$[\mathbf{I} - \mathbf{\Omega}]^{-1} = \sum_{j=0}^{\infty} \mathbf{\Omega}^j. \quad (\text{A.59})$$

This expansion is the operator generalization of the familiar expression for the sum of a geometric series:

$$\frac{1}{1-x} = \sum_{j=0}^{\infty} x^j, \quad (\text{A.60})$$

where x is a scalar. Equation (A.60) is valid if the series converges uniformly, which requires that $|x| < 1$. The corresponding convergence requirement for (A.59) is that all eigenvalues of $\mathbf{\Omega}$ be less than unity in absolute value. (See Secs. 1.4.1 and 1.7.6 in Chap. 1.)

To prove that (A.59) is correct, we multiply the right-hand side by $[\mathbf{I} - \mathbf{\Omega}]$, obtaining

$$\begin{aligned} [\mathbf{I} - \mathbf{\Omega}] \sum_{j=0}^{\infty} \mathbf{\Omega}^j &= \sum_{j=0}^{\infty} \mathbf{\Omega}^j - \sum_{j=0}^{\infty} \mathbf{\Omega}^{j+1} \\ &= \mathbf{I} + \sum_{j=1}^{\infty} \mathbf{\Omega}^j - \sum_{j=0}^{\infty} \mathbf{\Omega}^{j+1}. \end{aligned} \quad (\text{A.61})$$

We now let $m = j - 1$ in the first sum, with the result

$$[\mathbf{I} - \mathbf{\Omega}] \sum_{j=0}^{\infty} \mathbf{\Omega}^j = \mathbf{I} + \sum_{m=0}^{\infty} \mathbf{\Omega}^{m+1} - \sum_{j=0}^{\infty} \mathbf{\Omega}^{j+1} = \mathbf{I}. \quad (\text{A.62})$$

If we denote the series in (A.59) by \mathbf{S} , (A.62) shows that $[\mathbf{I} - \mathbf{\Omega}]\mathbf{S} = \mathbf{I}$. A similar calculation shows that $\mathbf{S}[\mathbf{I} - \mathbf{\Omega}] = \mathbf{I}$.

For more discussion of the Neumann series, see Chap. 1.

A.4 EIGENVECTORS AND EIGENVALUES

Section 1.4 in Chap. 1 is a detailed discussion of eigenvectors and eigenvalues, so only a brief survey is given here.

A.4.1 Basic concepts

The vector \mathbf{u} is the *eigenvector* (German: characteristic vector) of a square $N \times N$ matrix \mathbf{A} and the scalar λ is the corresponding *eigenvalue* if

$$\mathbf{A}\mathbf{u} = \lambda\mathbf{u}. \quad (\text{A.63})$$

Equation (A.63) can also be written as $[\mathbf{A} - \lambda\mathbf{I}]\mathbf{u} = 0$. In this form it is recognized as a set of N homogeneous linear equations for N unknowns (the components of \mathbf{u}). As discussed in Sec. A.5.5, these equations have a nontrivial solution if and only if

$$\det(\mathbf{A} - \lambda\mathbf{I}) = 0, \quad (\text{A.64})$$

where $\det(\cdot)$ denotes determinant (see Sec. A.5.1 for a definition).

When the determinant in (A.64) is expanded, a polynomial $P(\lambda)$ of degree N in the variable λ results, and (A.64) becomes³

$$P(\lambda) = \det[\mathbf{A} - \lambda\mathbf{I}] = (-1)^N [\lambda^N + a_1\lambda^{N-1} + a_2\lambda^{N-2} + \dots + a_N]. \quad (\text{A.65})$$

This equation is known as the *characteristic equation* for \mathbf{A} . The *Fundamental Theorem of Algebra* (Gellert *et al.*, 1977) assures us that the characteristic equation has N solutions (roots of the polynomial), though the roots are neither necessarily real nor necessarily distinct.

The characteristic equation can be solved (usually numerically) for each of these roots, which we shall denote as λ_n , $n = 1, \dots, N$. Corresponding to each λ_n is an eigenvector \mathbf{u}_n .

A.4.2 Some general theorems

If a square matrix is diagonal ($A_{mn} = A_n \delta_{mn}$), its diagonal elements are immediately the eigenvalues, *i.e.*, $\lambda_n = A_{nn}$. The eigenvector \mathbf{u}_n has a 1 in the n^{th} position and 0 in all other positions, $[\mathbf{u}_n]_m = \delta_{nm}$. It is straightforward to show that (A.63) is satisfied with this λ_n and \mathbf{u}_n . Moreover, if the matrix is triangular, the diagonal elements are again the eigenvalues, though the eigenvectors are not so simple in this case.

Schur's lemma (Rade and Westergren, 1990) states that any square matrix can be reduced to upper triangular form by means of a unitary transformation. That is, it is possible to find a unitary matrix \mathbf{U} such that

$$\mathbf{A}' = \mathbf{U}^\dagger \mathbf{A} \mathbf{U} \quad (\text{A.66})$$

has only zero elements below the diagonal. Since the eigenvalues are unchanged by unitary transformation (see Chap. 1, Sec. 1.4.2), the diagonal elements of \mathbf{A}' are also the eigenvalues of \mathbf{A} . Thus determination of the eigenvalues is equivalent to finding the unitary matrix \mathbf{U} that reduces \mathbf{A} to triangular form. Algorithms for this purpose are discussed in detail in Golub and van Loan (1989).

If a square matrix is approximately diagonal (*i.e.*, the off-diagonal elements are small), it is of interest to know how well the diagonal elements approximate the

³In (A.65), it can be shown (Eves, 1966, p. 200) that $a_N = \det(\mathbf{A})$ and $a_1 = \text{tr}(\mathbf{A})$. Furthermore, all coefficients can be derived from traces of powers of \mathbf{A} (Pettoufrezzo, 1966, p. 84).

eigenvalues. *Gershgorin's theorem* (Golub and van Loan, 1989, p. 341) provides an answer to this question. Consider a disc in the complex z plane centered at $z = A_{nn}$. This disc consists of all points such that

$$|z - A_{nn}| \leq \sum_{m=1}^N |A_{nm}|(1 - \delta_{mn}), \quad (\text{A.67})$$

where the factor $(1 - \delta_{mn})$ serves to omit the term $m = n$ from the sum. The disc in (A.67) is frequently called the n^{th} *Gershgorin disc*. The theorem says that all eigenvalues of \mathbf{A} must lie in the union of all N Gershgorin discs. If the matrix is diagonal, each disc has zero radius and the diagonal element is exactly the eigenvalue. Off-diagonal elements increase the radius of the discs and hence the uncertainty in the eigenvalues relative to the diagonal elements.

A square matrix is said to be *diagonally dominant* if

$$\sum_{m=1}^N |A_{nm}|(1 - \delta_{mn}) < A_{nn} \quad \text{for all } n. \quad (\text{A.68})$$

If this condition is satisfied, the matrix is invertible.

A.4.3 Hermitian matrices

Considerably stronger statements can be made about eigenvalues and eigenvectors if the matrix in question is Hermitian (or symmetric if all elements are real). A detailed discussion is given in Secs. 1.4.4–1.4.6 in Chap. 1, but the main results are listed here for reference.

- (i) The eigenvalues of a Hermitian matrix are real;
- (ii) Eigenvectors corresponding to different eigenvalues of a Hermitian matrix are orthogonal;
- (iii) The N eigenvectors of an $N \times N$ Hermitian matrix are linearly independent and span the space N -dimensional Euclidean space \mathbb{E}^N (see Sec. 1.1.2 in Chap. 1);
- (iv) A Hermitian matrix can always be diagonalized by a unitary transformation;
- (v) Two different Hermitian matrices \mathbf{A} and \mathbf{B} can be diagonalized by the *same* unitary transformation if and only if they commute, $\mathbf{AB} = \mathbf{BA}$.
- (vi) For two different positive-definite Hermitian matrices \mathbf{A} and \mathbf{B} that do not necessarily commute, there exists a nonsingular matrix \mathbf{W} such that $\mathbf{W}^\dagger \mathbf{A} \mathbf{W} = \mathbf{I}$ and $\mathbf{W}^\dagger \mathbf{B} \mathbf{W} = \mathbf{D}$, where \mathbf{D} is diagonal. This matrix satisfies $\mathbf{B} \mathbf{W} = \mathbf{A} \mathbf{W} \mathbf{D}$. (See Sec. A.8 for discussion of positive-definite matrices, and see Fukunaga (1990) or Sec. 1.4.6 for a discussion of the transformation.)

Note that point (ii) would allow two or more different eigenvectors not to be orthogonal if they share the same eigenvalue, though point (iii) ensures that they are linearly independent. If the vectors $\{\mathbf{e}_k, k = 1, \dots, K\}$ are linearly independent,

we can construct a set of mutually orthonormal vectors $\{\mathbf{u}_k, k = 1, \dots, K\}$ by the process known as *Gram-Schmidt orthogonalization*. The algorithm is as follows:

$$\begin{aligned} (1) \quad & \mathbf{u}_1 = \frac{1}{\|\mathbf{e}_1\|} \mathbf{e}_1 ; \\ (2) \quad & \mathbf{v}_2 = \mathbf{e}_2 - (\mathbf{e}_2, \mathbf{u}_1)\mathbf{u}_1, \quad \mathbf{u}_2 = \frac{1}{\|\mathbf{v}_2\|} \mathbf{v}_2 ; \\ & \dots \dots \\ (K) \quad & \mathbf{v}_K = \mathbf{e}_K - (\mathbf{e}_K, \mathbf{u}_1)\mathbf{u}_1 - \dots - (\mathbf{e}_K, \mathbf{u}_{K-1})\mathbf{u}_{K-1}, \quad \mathbf{u}_K = \frac{1}{\|\mathbf{v}_K\|} \mathbf{v}_K . \end{aligned}$$

In step (2), the vector \mathbf{e}_1 is projected onto the normalized vector \mathbf{u}_1 and the projection is then subtracted from \mathbf{e}_2 , guaranteeing that \mathbf{v}_2 is orthogonal to \mathbf{u}_1 . After normalization, we have two orthonormal vectors \mathbf{u}_1 and \mathbf{u}_2 . The process is then repeated, at each step constructing a new vector \mathbf{v}_k orthogonal to all of the previous \mathbf{u}_j for $j < k$, and then normalizing the result to get \mathbf{u}_k .

If the initial set $\{\mathbf{e}_k\}$ is a set of eigenvectors of the Hermitian matrix \mathbf{H} , and all of these eigenvectors have the same eigenvalue λ , then the new orthonormal vectors $\{\mathbf{u}_k\}$ are also eigenvectors and also all have the eigenvalue λ . Thus, if we assume that the Gram-Schmidt process has been applied if needed, we can be assured that the $\{\mathbf{u}_n, n = 1, \dots, N\}$ form a complete orthonormal basis in \mathbf{E}^N . The orthonormality is expressed mathematically by

$$\mathbf{u}_m^\dagger \mathbf{u}_n = \delta_{nm}, \quad n, m = 1, \dots, N. \quad (\text{A.69})$$

The completeness of the set $\{\mathbf{u}_n\}$ means that it can be used to represent the unit matrix in the form

$$\mathbf{I}_N = \sum_{n=1}^N \mathbf{u}_n \mathbf{u}_n^\dagger. \quad (\text{A.70})$$

This relation is frequently referred to as the *closure* relation or the *resolution of the identity*.

The basis set consisting of the eigenvectors of a Hermitian matrix \mathbf{H} can also be used to represent \mathbf{H} itself as

$$\mathbf{H} = \sum_{n=1}^N \lambda_n \mathbf{u}_n \mathbf{u}_n^\dagger. \quad (\text{A.71})$$

This representation, called the *spectral decomposition* of \mathbf{H} , is discussed in detail in Chap. 1 and exploited throughout the book.

A.5 DETERMINANTS

A.5.1 Definitions

If \mathbf{A} is an $N \times N$ matrix with elements A_{mn} , then the *determinant* of \mathbf{A} , denoted $\det(\mathbf{A})$, is a scalar defined formally by

$$\det(\mathbf{A}) = \sum_{perm} (-1)^k A_{1s_1} A_{2s_2} \dots A_{Ns_N}, \quad (\text{A.72})$$

where the indices s_1, s_2, \dots, s_N are a permutation of $1, 2, \dots, N$ and are hence distinct, and the sum runs over all possible permutations. Since there are $N!$ permutations, the sum has $N!$ terms in general (though some or all of them may be zero). The sign of each term is determined by the number k of inversions in the permutation. Cyclic permutations thus always occur with a plus sign.

The determinant can also be defined in terms of eigenvalues. If $\{\lambda_n, n = 1, \dots, N\}$ are the eigenvalues of the $N \times N$ matrix \mathbf{A} , then

$$\det(\mathbf{A}) = \prod_{n=1}^N \lambda_n. \tag{A.73}$$

If \mathbf{A} is singular, at least one of the eigenvalues is zero, and it follows from this equation that $\det(\mathbf{A}) = 0$.

A geometrical interpretation of determinant is that $|\det(\mathbf{A})|$ is the volume of the N -dimensional parallelepiped formed by the column (or row) vectors of \mathbf{A} . This result is familiar in ordinary 3D vector analysis. Three vectors \mathbf{a} , \mathbf{b} and \mathbf{c} define a parallelepiped with volume $|\mathbf{a} \cdot \mathbf{b} \times \mathbf{c}|$, where \times denotes the usual vector cross product, and the triple scalar product $\mathbf{a} \cdot \mathbf{b} \times \mathbf{c}$ is computed as a determinant.

A.5.2 Special cases

If \mathbf{A} is a 2×2 matrix, its determinant is given by

$$\det(\mathbf{A}) = A_{11}A_{22} - A_{12}A_{21}. \tag{A.74}$$

If \mathbf{A} is a 3×3 matrix, its determinant is given by

$$\begin{aligned} \det(\mathbf{A}) = & A_{11}A_{22}A_{33} + A_{12}A_{23}A_{31} + A_{13}A_{21}A_{32} - A_{11}A_{23}A_{32} \\ & - A_{12}A_{21}A_{33} - A_{13}A_{22}A_{31}. \end{aligned} \tag{A.75}$$

If \mathbf{A} is an $N \times N$ diagonal matrix,

$$\det(\mathbf{A}) = \prod_{n=1}^N A_{nn}. \tag{A.76}$$

This equation is valid also if \mathbf{A} is an upper or lower triangular matrix. An immediate consequence of (A.76) is that the determinant of the unit matrix is unity: $\det(\mathbf{I}) = 1$.

A.5.3 Properties of determinants

The determinant of the product of two $N \times N$ matrices is the product of their determinants:

$$\det(\mathbf{AB}) = \det(\mathbf{A}) \det(\mathbf{B}). \tag{A.77}$$

Since the determinant of the unit matrix is unity, it follows that

$$\det(\mathbf{A}^{-1}) = \frac{1}{\det(\mathbf{A})}. \tag{A.78}$$

Directly from the definition, it follows that multiplying every element of an $N \times N$ matrix by a constant multiplies its determinant by the same constant to the N^{th} power:

$$\det(c\mathbf{A}) = c^N \det(\mathbf{A}), \quad (c \text{ a scalar}). \tag{A.79}$$

Multiplying every element in a single row or column by c multiplies the determinant by c .

A determinant is unchanged if rows and columns are interchanged, so

$$\det(\mathbf{A}^t) = \det(\mathbf{A}). \quad (\text{A.80})$$

The adjoint is formed by interchanging rows and columns and taking the complex conjugate of each element, so it follows that

$$\det(\mathbf{A}^\dagger) = [\det(\mathbf{A})]^*. \quad (\text{A.81})$$

For a Hermitian matrix, $\mathbf{A}^\dagger = \mathbf{A}$ so $\det(\mathbf{A})$ is real. This result is in accord with (A.73) since, as proved in Chap. 1, the eigenvalues of a Hermitian matrix are real. If \mathbf{U} is a unitary matrix, then $\mathbf{U}^{-1} = \mathbf{U}^\dagger$. By (A.78) and (A.81),

$$|\det(\mathbf{U})| = 1. \quad (\text{A.82})$$

This result also follows from (A.73) since the eigenvalues of a unitary matrix are complex roots of unity.

An important consequence of (A.81) and (A.82) is that the determinant is unchanged by a unitary transformation:

$$\det(\mathbf{U}\mathbf{A}\mathbf{U}^\dagger) = \det(\mathbf{A}). \quad (\text{A.83})$$

A unitary transformation is a special case of a similarity transformation. It is shown in Sec. 1.4.2 that similarity transformations do not alter eigenvalues. Therefore, with (A.73),

$$\det(\mathbf{S}\mathbf{A}\mathbf{S}^{-1}) = \det(\mathbf{A}), \quad (\text{A.84})$$

where \mathbf{S} is any nonsingular $N \times N$ matrix.

Additional symmetry properties of determinants are as follows:

- (i) Interchange of two rows (columns) changes the sign of the determinant.
- (ii) A determinant does not change if one row (column) is multiplied by a constant and added to another row (column).
- (iii) A determinant equals zero if all elements of a row (column) are zero.
- (iv) A determinant equals zero if one row (column) equals another row (column) times a constant.

It is often necessary to consider the determinant of the sum of two matrices. The following identity, discussed fully in Harville (1997), is quite useful:

$$\det(\mathbf{R} + \mathbf{S}\mathbf{T}\mathbf{U}) = \det(\mathbf{R}) \det(\mathbf{T}) \det(\mathbf{T}^{-1} + \mathbf{U}\mathbf{R}^{-1}\mathbf{S}). \quad (\text{A.85})$$

For many additional properties of determinants, see Muir (1960) and Andrews and Burge (1993), and for an early treatment of considerable historical interest, see Dodgson (1867). (Charles Lutwidge Dodgson, under the pseudonym Lewis Carroll, also wrote *Alice's Adventures in Wonderland*.)

A.5.4 Cofactors and inverses

If \mathbf{A} is a nonsingular $N \times N$ matrix, the $(nm)^{th}$ element of its inverse is given by

$$[\mathbf{A}^{-1}]_{mn} = \frac{\text{cof}_{nm}(\mathbf{A})}{\det(\mathbf{A})}, \quad (\text{A.86})$$

where $\text{cof}_{nm}(\mathbf{A})$ is the *cofactor*, defined as $(-1)^{n+m}$ times the determinant of the $(N-1) \times (N-1)$ matrix obtained by deleting the n^{th} row and m^{th} column from \mathbf{A} . That determinant itself is called a *minor* of \mathbf{A} . It follows from (A.86) that the inverse does not exist if $\det(\mathbf{A}) = 0$.

The special case $N = 2$ yields

$$\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}^{-1} = \frac{1}{A_{11}A_{22} - A_{12}A_{21}} \begin{bmatrix} A_{22} & -A_{12} \\ -A_{21} & A_{11} \end{bmatrix}. \quad (\text{A.87})$$

From (A.74), the denominator is recognized as $\det(\mathbf{A})$.

Cofactors can also be used to evaluate determinants. The key result is

$$\det(\mathbf{A}) = \sum_{m=1}^N A_{nm} \text{cof}_{nm}(\mathbf{A}), \quad (\text{A.88})$$

where n denotes an arbitrary row. The utility of this result is that the determinant of an $N \times N$ matrix is expressed as a sum of determinants of $(N-1) \times (N-1)$ matrices. The process can be repeated $N-1$ times until only trivial determinants of 1×1 matrices need to be determined.

A.5.5 Cramer's rule

Consider a set of linear equations in the form

$$\mathbf{y} = \mathbf{A}\mathbf{x}, \quad (\text{A.89})$$

where \mathbf{A} is a nonsingular $N \times N$ matrix and \mathbf{x} and \mathbf{y} are $N \times 1$ column vectors. If \mathbf{y} is known, the solution for \mathbf{x} is given by $\mathbf{x} = \mathbf{A}^{-1}\mathbf{y}$, and the j^{th} element of \mathbf{x} can be found by *Cramer's rule*:

$$x_j = \frac{\det(\mathbf{A}_j)}{\det(\mathbf{A})}, \quad (\text{A.90})$$

where \mathbf{A}_j is the $N \times N$ matrix obtained by replacing the j^{th} column of \mathbf{A} with \mathbf{y} .

If all components of \mathbf{y} are zero, the system of equations is said to be *homogeneous*. In that case $\det(\mathbf{A}_j)$ is identically zero (see Sec. A.5.3), so the only way the system $\mathbf{A}\mathbf{x} = \mathbf{0}$ can have a nontrivial solution for \mathbf{x} is if $\det(\mathbf{A}) = 0$.

A.6 TRACES

A.6.1 Definitions

The *trace* or *spur* of a matrix is simply the sum of its diagonal elements:

$$\text{tr}(\mathbf{A}) = \sum_{n=1}^N A_{nn}. \quad (\text{A.91})$$

If \mathbf{a} and \mathbf{b} are both $N \times 1$ column vectors, the trace of their outer product is the same as the inner product:

$$\text{tr}(\mathbf{a}\mathbf{b}^\dagger) = \mathbf{b}^\dagger\mathbf{a} = \sum_{n=1}^N b_n^* a_n. \quad (\text{A.92})$$

A.6.2 Properties of traces

Some basic properties of the trace are as follows:

$$\text{tr}(\mathbf{A} + \mathbf{B}) = \text{tr}(\mathbf{A}) + \text{tr}(\mathbf{B}); \quad (\text{A.93})$$

$$\text{tr}(\alpha\mathbf{A}) = \alpha \text{tr}(\mathbf{A}), \quad (\text{A.94})$$

where α is a scalar. If \mathbf{A} is an $M \times N$ matrix and \mathbf{B} is $N \times M$, then

$$\text{tr}(\mathbf{A}\mathbf{B}) = \text{tr}(\mathbf{B}\mathbf{A}). \quad (\text{A.95})$$

The trace of a product of square matrices is invariant to cyclic permutation:

$$\text{tr}(\mathbf{A}\mathbf{B}\mathbf{C}) = \text{tr}(\mathbf{C}\mathbf{A}\mathbf{B}) = \text{tr}(\mathbf{B}\mathbf{C}\mathbf{A}), \quad (\text{A.96})$$

and similarly for products with any number of factors. It follows from (A.96) that the trace of a matrix is invariant to unitary transformations.

The trace of a square matrix is the sum of its eigenvalues (Pettofrezzo, 1966, p. 85):

$$\text{tr}(\mathbf{A}) = \sum_{j=1}^N \lambda_j(\mathbf{A}), \quad (\text{A.97})$$

where $\lambda_j(\mathbf{A})$ is the j^{th} eigenvalue of \mathbf{A} . If the matrix can be diagonalized by a similarity transformation (as can all Hermitian matrices), (A.97) follows immediately from (A.96) since $\text{tr}(\mathbf{S}^{-1}\mathbf{A}\mathbf{S}) = \text{tr}(\mathbf{A})$. The result in (A.97) is, however, more general; it holds for any square matrix.

Similarly, the trace of a square matrix \mathbf{A} raised to the k^{th} power is given by

$$\text{tr}(\mathbf{A}^k) = \sum_{j=1}^N [\lambda_j(\mathbf{A})]^k, \quad k \text{ a positive integer}. \quad (\text{A.98})$$

A.7 FUNCTIONS OF MATRICES

Many different matrix functions can be defined as a power series, the general form of which is

$$f(\mathbf{A}) = \sum_{n=0}^{\infty} c_n \mathbf{A}^n. \quad (\text{A.99})$$

The matrix \mathbf{A} must be square, say $N \times N$, in order for its powers \mathbf{A}^n to be defined, but it can be nonsymmetric and/or singular in what follows. If \mathbf{A} has real elements and all coefficients c_n are real, $f(\mathbf{A})$ is a mapping from $\mathbb{R}^{N \times N} \rightarrow \mathbb{R}^{N \times N}$; if the elements can be complex, it is a mapping from $\mathbb{C}^{N \times N} \rightarrow \mathbb{C}^{N \times N}$.

One application of such a power-series function is the *Cayley-Hamilton theorem* (Eves, 1966), which states that every square matrix \mathbf{A} satisfies its own characteristic equation. That is, $P(\mathbf{A}) = 0$, where $P(\lambda)$ is the polynomial defined by (A.65) but with the scalar λ replaced by the matrix \mathbf{A} .

A.7.1 Matrix exponentials

The matrix exponential is defined by taking $c_n = 1/n!$ in (A.99), leading to

$$\exp(\mathbf{A}) = \sum_{n=0}^{\infty} \frac{1}{n!} \mathbf{A}^n. \quad (\text{A.100})$$

If \mathbf{A} and \mathbf{B} commute, then

$$\exp(\mathbf{A}) \exp(\mathbf{B}) = \exp(\mathbf{B}) \exp(\mathbf{A}) = \exp(\mathbf{A} + \mathbf{B}). \quad (\text{A.101})$$

Somewhat more generally, if \mathbf{A} and \mathbf{B} both commute with their commutator, $\mathbf{AB} - \mathbf{BA}$, then

$$\exp[-\alpha(\mathbf{A} + \mathbf{B}) + \frac{1}{2}\alpha^2(\mathbf{AB} - \mathbf{BA})] = \exp(-\alpha\mathbf{A}) \exp(-\alpha\mathbf{B}). \quad (\text{A.102})$$

The matrix exponential $\exp(\alpha\mathbf{A})$ is never singular. In fact, its inverse is given by

$$[\exp(\alpha\mathbf{A})]^{-1} = \exp(-\alpha\mathbf{A}). \quad (\text{A.103})$$

All unitary matrices can be represented as

$$\mathbf{U} = \exp(i\mathbf{H}), \quad (\text{A.104})$$

where \mathbf{H} is Hermitian. In this form, the adjoint of \mathbf{U} is

$$\mathbf{U}^\dagger = \exp(-i\mathbf{H}), \quad (\text{A.105})$$

and the unitarity follows from (A.103).

A few additional properties of matrix exponentials are:

$$\det[\exp(\mathbf{A})] = \exp[\text{tr}(\mathbf{A})], \quad (\text{A.106})$$

$$\mathbf{B}[\exp(\mathbf{A})]\mathbf{B}^{-1} = \exp(\mathbf{BAB}^{-1}), \quad (\text{A.107})$$

for any nonsingular matrix \mathbf{B} .

A.7.2 Trigonometric functions

Matrix sines and cosines are defined by

$$\sin(\mathbf{A}) = \mathbf{A} - \frac{1}{3!} \mathbf{A}^3 + \frac{1}{5!} \mathbf{A}^5 + \dots; \quad (\text{A.108})$$

$$\cos(\mathbf{A}) = \mathbf{I} - \frac{1}{2!} \mathbf{A}^2 + \frac{1}{4!} \mathbf{A}^4 + \dots \quad (\text{A.109})$$

It follows that

$$\exp(i\mathbf{A}) = \cos(\mathbf{A}) + i \sin(\mathbf{A}). \quad (\text{A.110})$$

If \mathbf{A} and \mathbf{B} commute, then

$$\cos(\mathbf{A} + \mathbf{B}) = \cos(\mathbf{A}) \cos(\mathbf{B}) - \sin(\mathbf{A}) \sin(\mathbf{B}); \quad (\text{A.111})$$

$$\sin(\mathbf{A} + \mathbf{B}) = \sin(\mathbf{A}) \cos(\mathbf{B}) + \cos(\mathbf{A}) \sin(\mathbf{B}). \quad (\text{A.112})$$

A.7.3 Other functions

Several important results arise from a consideration of $\mathbf{I} - \mathbf{A}$, where \mathbf{A} is an $N \times N$ matrix and \mathbf{I} is the corresponding unit matrix. An extension of the Neumann series, discussed in Sec. A.3.4, shows that (Siotani *et al.*, 1985)

$$(\mathbf{I} - \mathbf{A})^{-m} = \sum_{n=0}^{\infty} \frac{\Gamma(m+n)}{\Gamma(m)n!} \mathbf{A}^n \quad \text{for any real } m > 0, \quad (\text{A.113})$$

if all eigenvalues of \mathbf{A} are less than unity in absolute value.

The determinant of $\mathbf{I} - \mathbf{A}$ also has some interesting properties. For example, if all of the eigenvalues of \mathbf{A} are less than unity in absolute value, then (Siotani *et al.*, 1985):

$$-\ln[\det(\mathbf{I} - \mathbf{A})] = \text{tr } \mathbf{A} + \frac{1}{2} \text{tr } \mathbf{A}^2 + \frac{1}{3} \text{tr } \mathbf{A}^3 + \dots \quad (\text{A.114})$$

If \mathbf{A} is a scalar (1×1 matrix), then determinant, trace and matrix are identical and (A.114) is the familiar expansion for the logarithm.

A.8 DEFINITE MATRICES AND QUADRATIC FORMS

A.8.1 Definitions

Given an $N \times N$ matrix \mathbf{A} and an $N \times 1$ vector \mathbf{x} , we define a scalar *quadratic form* $Q_A(\mathbf{x})$ by

$$Q_A(\mathbf{x}) = \mathbf{x}^\dagger \mathbf{A} \mathbf{x}. \quad (\text{A.115})$$

If the matrix \mathbf{A} is Hermitian, $Q_A(\mathbf{x})$ is called a *Hermitian form*.

The matrix \mathbf{A} is said to be *positive-definite* if its associated quadratic form $Q_A(\mathbf{x}) > 0$ for all \mathbf{x} (except the trivial one with all elements zero). If $Q_A(\mathbf{x}) \geq 0$ for all \mathbf{x} , then \mathbf{A} is said to be *positive-semidefinite* or *nonnegative-definite*. Similarly, \mathbf{A} is *negative-definite* if $Q_A(\mathbf{x}) < 0$ for all nontrivial \mathbf{x} and *negative-semidefinite* if $Q_A(\mathbf{x}) \leq 0$ for all \mathbf{x} . If none of these conditions prevail, then \mathbf{A} is merely *indefinite*.

A.8.2 Conditions for definiteness

A necessary and sufficient condition for the $N \times N$ matrix \mathbf{A} to be positive-definite is that all of the eigenvalues of \mathbf{A} be greater than zero. By (A.73), this condition implies that $\det(\mathbf{A}) > 0$, but the converse does not necessarily hold; it is possible to have a positive determinant and an even number of negative eigenvalues. For example, a diagonal 3×3 matrix with $(1, -1, -1)$ along the diagonal has determinant $+1$ but is indefinite.

A stronger condition for definiteness is obtained by considering subdeterminants. A *minor* of order $N - k$ is obtained by deleting k rows and k columns ($k < N$) from the $N \times N$ matrix \mathbf{A} and taking the determinant of the resulting $(N - k) \times (N - k)$ matrix. For example, we might delete the rows labelled by $n = n_1, n_2, \dots, n_k$ and the columns labelled by $m = m_1, m_2, \dots, m_k$. The minor is called a *principal minor* if the row and column labels are identical. A *leading principal minor* is one for which the row and column labels are successive integers from 1 to k . A necessary and sufficient condition for a Hermitian matrix to be positive-definite is that all of its leading principal minors be greater than zero (Eves, 1966). This condition rules out the 3×3 example given above; if we delete

the first and second row and the first and second column, all that is left is the single element -1 , and the corresponding principal minor is -1 .

An important general theorem on positive-definite matrices states that:

If \mathbf{A} is a positive-definite matrix in $\mathbb{C}^{N \times N}$ and \mathbf{B} is a matrix of rank K in $\mathbb{C}^{N \times K}$, then the $K \times K$ matrix $\mathbf{B}^\dagger \mathbf{A} \mathbf{B}$ is also positive-definite.

This theorem is proved for real matrices on p. 140 of Golub and van Loan (1989), but their proof generalizes readily to the complex case.

An immediate consequence, which follows by setting $\mathbf{A} = \mathbf{I}$ in this theorem, is that any $K \times K$ matrix of the form $\mathbf{B}^\dagger \mathbf{B}$ is positive-definite if the $N \times K$ matrix \mathbf{B} has rank K . Any matrix of the form $\mathbf{B}^\dagger \mathbf{B}$, without any restriction on \mathbf{B} , is at least positive-semidefinite. Moreover, it follows from (A.26) that $\mathbf{B}^\dagger \mathbf{B}$ is Hermitian. Thus, as soon as we can show that a matrix has the form $\mathbf{B}^\dagger \mathbf{B}$, we know that it is Hermitian and at least positive-semidefinite.

A stronger statement can be also made regarding Hermitian positive-definite matrices. Any such matrix \mathbf{H} can be uniquely factored in the form

$$\mathbf{H} = \mathbf{G} \mathbf{G}^\dagger, \quad (\text{A.116})$$

where \mathbf{G} is square and lower triangular, with positive elements along the diagonal. This form, known as the *Cholesky factorization*, is at the heart of many numerical algorithms in linear algebra.

A.8.3 Square-root matrices

If the $N \times N$ Hermitian matrix \mathbf{H} is positive-semidefinite, we can define its square root $\mathbf{H}^{\frac{1}{2}}$, an $N \times N$ Hermitian matrix that satisfies

$$\mathbf{H}^{\frac{1}{2}} \mathbf{H}^{\frac{1}{2}} = \mathbf{H}. \quad (\text{A.117})$$

The easiest way to construct $\mathbf{H}^{\frac{1}{2}}$ is by means of the spectral decomposition (A.71). If we know the eigenvalues $\{\lambda_n\}$ and eigenvectors $\{\mathbf{u}_n\}$, then we can write the square-root matrix as

$$\mathbf{H}^{\frac{1}{2}} = \sum_{n=1}^N \sqrt{\lambda_n} \mathbf{u}_n \mathbf{u}_n^\dagger. \quad (\text{A.118})$$

To show that (A.117) is satisfied by (A.118), we make use of the orthonormality condition (A.69).

If \mathbf{H} is nonsingular, the inverse of the square-root matrix exists and is given by (Johnson and Wichern, 1988)

$$\mathbf{H}^{-\frac{1}{2}} = \sum_{n=1}^N \frac{1}{\sqrt{\lambda_n}} \mathbf{u}_n \mathbf{u}_n^\dagger. \quad (\text{A.119})$$

A.9 DIFFERENTIATION FORMULAS

A.9.1 Derivatives and integrals of a matrix with respect to a real parameter

If $\mathbf{A}(t)$ is an $M \times N$ matrix with complex elements $A_{mn}(t)$ which depend on the real scalar parameter t , then we can define derivative and integral matrices by

$$\left[\frac{d}{dt} \mathbf{A}(t) \right]_{nm} = \frac{d}{dt} A_{nm}(t); \quad (\text{A.120})$$

$$\left[\int_a^b dt \mathbf{A}(t) \right]_{nm} = \int_a^b dt A_{nm}(t). \quad (\text{A.121})$$

The following manipulation rules for the derivative matrix can be verified:

$$\frac{d}{dt} [\mathbf{A}(t) + \mathbf{B}(t)] = \frac{d}{dt} \mathbf{A}(t) + \frac{d}{dt} \mathbf{B}(t); \quad (\text{A.122})$$

$$\frac{d}{dt} [\mathbf{A}(t) \mathbf{B}(t)] = \mathbf{A}(t) \frac{d}{dt} \mathbf{B}(t) + \left[\frac{d}{dt} \mathbf{A}(t) \right] \mathbf{B}(t). \quad (\text{A.123})$$

Note that the last term in (A.123) is not $\mathbf{B}d\mathbf{A}/dt$ unless the two matrices commute.

If $N = M$ and the inverse of \mathbf{A} exists, it can also be differentiated (Rade and Westergren, 1990) as follows:

$$\frac{d}{dt} \mathbf{A}^{-1} = -\mathbf{A}^{-1} \frac{d\mathbf{A}}{dt} \mathbf{A}^{-1}. \quad (\text{A.124})$$

A.9.2 Differentiation of a scalar-valued function with respect to a real vector

Let $\phi(\mathbf{x})$ be a complex differentiable scalar-valued function and \mathbf{x} be a vector in \mathbb{R}^N . We define the *gradient* of $\phi(\mathbf{x})$, denoted $\partial\phi(\mathbf{x})/\partial\mathbf{x}$ or $\nabla\phi(\mathbf{x})$, as a vector in \mathbb{R}^N such that its n^{th} component is the partial derivative of $\phi(\mathbf{x})$ with respect to x_n , *i.e.*,

$$\left[\frac{\partial}{\partial \mathbf{x}} \phi(\mathbf{x}) \right]_n = [\nabla\phi(\mathbf{x})]_n = \frac{\partial}{\partial x_n} \phi(\mathbf{x}). \quad (\text{A.125})$$

From this definition it can be shown that

$$\frac{\partial}{\partial \mathbf{x}} \mathbf{a}^t \mathbf{x} = \mathbf{a}, \quad (\text{A.126})$$

$$\frac{\partial}{\partial \mathbf{x}} \mathbf{x}^t \mathbf{A} \mathbf{x} = (\mathbf{A} + \mathbf{A}^t) \mathbf{x} = 2\mathbf{A} \mathbf{x} \quad \text{if } \mathbf{A} \text{ is symmetric,} \quad (\text{A.127})$$

where \mathbf{a} is a constant $N \times 1$ vector, \mathbf{A} is a constant $N \times N$ matrix, and both \mathbf{a} and \mathbf{A} can be complex.

We also define the derivative with respect to the transpose of a vector as the transpose of the derivative vector itself, so

$$\frac{\partial}{\partial \mathbf{x}^t} \phi(\mathbf{x}) = \left[\frac{\partial}{\partial \mathbf{x}} \phi(\mathbf{x}) \right]^t. \quad (\text{A.128})$$

If we regard $\partial\phi(\mathbf{x})/\partial\mathbf{x}$ as a column vector, then $\partial\phi(\mathbf{x})/\partial\mathbf{x}^t$ is a row vector.

The *Hessian matrix*, or matrix of second derivatives, is the $N \times N$ matrix with elements given by

$$\left[\frac{\partial^2}{\partial\mathbf{x}\partial\mathbf{x}^t} \phi(\mathbf{x}) \right]_{mn} = \frac{\partial^2}{\partial x_m \partial x_n} \phi(\mathbf{x}). \quad (\text{A.129})$$

This expression can be interpreted as the outer product (see Secs. A.2.6 and 1.3.7) of the column-vector operator $\partial/\partial\mathbf{x}$ with the row vector $\partial\phi(\mathbf{x})/\partial\mathbf{x}^t$. Some books use the notation ∇^2 for the Hessian, but that is too easily confused with the Laplacian; the Laplacian of a scalar function is a scalar, while the Hessian is a matrix. A better notation for the Hessian operator would be $\nabla\nabla^t$.

A.9.3 Differentiation with respect to real matrices

By analogy to (A.125), we define the derivative of the scalar function $\phi(\mathbf{A})$ with respect to the real $M \times N$ matrix \mathbf{A} as the new $M \times N$ matrix $\partial\phi(\mathbf{A})/\partial\mathbf{A}$, with elements given by

$$\left[\frac{\partial\phi(\mathbf{A})}{\partial\mathbf{A}} \right]_{mn} = \frac{\partial\phi(\mathbf{A})}{\partial A_{mn}}. \quad (\text{A.130})$$

An extensive list of identities for evaluating such matrix derivatives is given by Fukunaga (1990) and a very detailed treatment is given by Harville (1997). A few of the more interesting relations are listed here. All matrices are assumed to be real and conformable, but no other restrictions apply except those listed explicitly.

$$\frac{\partial}{\partial\mathbf{A}} \text{tr}(\mathbf{B}\mathbf{A}) = \mathbf{B}^t; \quad (\text{A.131})$$

$$\frac{\partial}{\partial\mathbf{A}} \text{tr}(\mathbf{U}\mathbf{A}\mathbf{V}\mathbf{A}^t) = \mathbf{U}\mathbf{A}\mathbf{V} + \mathbf{U}^t \mathbf{A}\mathbf{V}^t, \quad (\mathbf{U} \text{ and } \mathbf{V} \text{ square}); \quad (\text{A.132})$$

$$\frac{\partial}{\partial\mathbf{A}} \text{tr}(\mathbf{A}^t \mathbf{B}\mathbf{A}) = (\mathbf{B} + \mathbf{B}^t)\mathbf{A}, \quad (\mathbf{B} \text{ square}); \quad (\text{A.133})$$

$$\frac{\partial}{\partial A_{mn}} \det(\mathbf{A}) = \text{cof}_{mn}(\mathbf{A}); \quad (\text{A.134})$$

$$\frac{\partial\{\ln[\det(\mathbf{A})]\}}{\partial\mathbf{A}} = 2\mathbf{A}^{-1} - \text{diag}(\mathbf{A}^{-1}), \quad (\mathbf{A} \text{ symmetric, nonsingular}); \quad (\text{A.135})$$

$$\frac{\partial[\det(\mathbf{A})]}{\partial\mathbf{A}} = \det(\mathbf{A}) [2\mathbf{A}^{-1} - \text{diag}(\mathbf{A}^{-1})], \quad (\mathbf{A} \text{ symmetric, nonsingular}), \quad (\text{A.136})$$

where the notation $\text{diag}(\mathbf{M})$ denotes the matrix \mathbf{M} with its off-diagonal elements set to zero.

The following relations, taken from Fukunaga (1990), are useful in linear-discriminant analysis:

$$\begin{aligned} \frac{\partial}{\partial\mathbf{A}} \{ \text{tr}[(\mathbf{A}^t \mathbf{S}_2 \mathbf{A})^{-1} (\mathbf{A}^t \mathbf{S}_1 \mathbf{A})] \} &= \frac{\partial}{\partial\mathbf{A}} \{ \text{tr}[(\mathbf{A}^t \mathbf{S}_1 \mathbf{A})(\mathbf{A}^t \mathbf{S}_2 \mathbf{A})^{-1}] \} \\ &= -2\mathbf{S}_2 \mathbf{A} (\mathbf{A}^t \mathbf{S}_2 \mathbf{A})^{-1} (\mathbf{A}^t \mathbf{S}_1 \mathbf{A}) (\mathbf{A}^t \mathbf{S}_2 \mathbf{A})^{-1} + 2\mathbf{S}_1 \mathbf{A} (\mathbf{A}^t \mathbf{S}_2 \mathbf{A})^{-1}. \end{aligned} \quad (\text{A.137})$$

A.9.4 Differentiation of a real function with respect to a complex scalar

In Secs. A.9.2 and A.9.3, the differentiation was performed with respect to vectors and matrices that were restricted to be real, but in optimization problems we often want to minimize a real, scalar-valued function of a complex $N \times 1$ vector \mathbf{x} . Minimization requires that the function be unchanged by an infinitesimal perturbation in either the real or imaginary part of any component of \mathbf{x} . Thus a total of $2N$ derivatives must vanish. In Sec. A.9.5 we shall develop techniques for dealing with such problems, but as a prelude in this section we take a look at one interpretation of differentiation with respect to a complex scalar x (soon to be one component of a complex vector).

We write the scalar x in terms of its real and imaginary parts, x' and x'' respectively, as

$$x = x' + ix'' . \quad (\text{A.138})$$

The complex conjugate of x is given by

$$x^* = x' - ix'' . \quad (\text{A.139})$$

The inverse relations are

$$x' = \frac{1}{2}(x + x^*), \quad x'' = \frac{1}{2i}(x - x^*) . \quad (\text{A.140})$$

Next we define a complex derivative operator D by

$$D = \frac{\partial}{\partial x'} + i \frac{\partial}{\partial x''} . \quad (\text{A.141})$$

It is important to realize that this operator takes individual partial derivatives with respect to x' and x'' and then combines them into a complex number. This is not the same as taking a total derivative with respect to the complex x , an operation discussed in detail in App. B. The operator D can be applied to real-valued or complex-valued functions of the complex x , while the usual complex derivative d/dz is defined only for complex-valued (in fact, analytic) functions.

The analogy of (A.141) to (A.125) should not be overlooked. If we think of x as a vector in the complex plane (see App. B) with components x' and x'' and corresponding unit vectors 1 and i , then D is a vector derivative like $\partial/\partial\mathbf{x}$ but with just two components.

From the definition of D , we have

$$D^* = \frac{\partial}{\partial x'} - i \frac{\partial}{\partial x''} ; \quad (\text{A.142})$$

$$DD^* = \left(\frac{\partial}{\partial x'} + i \frac{\partial}{\partial x''} \right) \left(\frac{\partial}{\partial x'} - i \frac{\partial}{\partial x''} \right) = \frac{\partial^2}{\partial x'^2} + \frac{\partial^2}{\partial x''^2} . \quad (\text{A.143})$$

Note that DD^* is the usual 2D Laplacian operator.

The following relations can be verified:

$$D[\phi(x) + \psi(x)] = D\phi(x) + D\psi(x) ; \quad (\text{A.144})$$

$$D[\phi(x)\psi(x)] = \phi(x)D\psi(x) + \psi(x)D\phi(x) ; \quad (\text{A.145})$$

$$D[|x|^n] = n|x|^{n-2}x . \quad (\text{A.146})$$

These results are obvious extensions of familiar properties of real derivatives. On the other hand, if the operator D is applied to complex-valued functions, there are some surprises. For example,

$$Dx = \left(\frac{\partial}{\partial x'} + i \frac{\partial}{\partial x''} \right) (x' + ix'') = 0; \tag{A.147}$$

$$D^*x = \left(\frac{\partial}{\partial x'} - i \frac{\partial}{\partial x''} \right) (x' + ix'') = 2. \tag{A.148}$$

A symmetrized operator behaves more intuitively:

$$\frac{1}{2}(D + D^*)x = 1; \quad \frac{1}{2}(D + D^*)x^n = nx^{n-1}. \tag{A.149}$$

To see the reasons for these peculiarities, we can regard (A.147) and (A.148) as specifying a coordinate transformation from (x', x'') to (x, x^*) . The usual chain rule for differentiation then yields

$$\frac{\partial \phi(x', x'')}{\partial x} = \frac{\partial \phi(x', x'')}{\partial x'} \frac{\partial x'}{\partial x} + \frac{\partial \phi(x', x'')}{\partial x''} \frac{\partial x''}{\partial x} = \frac{1}{2} \frac{\partial \phi(x', x'')}{\partial x'} + \frac{1}{2i} \frac{\partial \phi(x', x'')}{\partial x''}. \tag{A.150}$$

Similarly,

$$\frac{\partial \phi(x', x'')^*}{\partial x} = \frac{\partial \phi(x', x'')}{\partial x'} \frac{\partial x'^*}{\partial x} + \frac{\partial \phi(x', x'')}{\partial x''} \frac{\partial x''^*}{\partial x} = \frac{1}{2} \frac{\partial \phi(x', x'')}{\partial x'} - \frac{1}{2i} \frac{\partial \phi(x', x'')}{\partial x''}. \tag{A.151}$$

If $\phi(x', x'')$ is real, $\partial \phi(x', x'')/\partial x^* = [\partial \phi(x', x'')/\partial x]^*$.

As an example, suppose

$$\phi(x', x'') = |x|^2 = xx^* = (x')^2 + (x'')^2. \tag{A.152}$$

Then, directly from (A.150), we have

$$\frac{\partial \phi(x', x'')}{\partial x} = \frac{1}{2}(2x') + \frac{1}{2i}(2x'') = x' - ix'' = x^*. \tag{A.153}$$

But note that this same result can be obtained more easily just by regarding x and x^* as independent variables, so that $\partial(xx^*)/\partial x = x^*$. By the same token,

$$\frac{\partial(xx^*)}{\partial x^*} = \frac{1}{2}(2x') - \frac{1}{2i}(2x'') = x' + ix'' = x. \tag{A.154}$$

In summary, we have the following interrelationships among various differential operators:

$$D = \left(\frac{\partial}{\partial x'} + i \frac{\partial}{\partial x''} \right) = 2 \frac{\partial}{\partial x^*}; \tag{A.155}$$

$$D^* = \left(\frac{\partial}{\partial x'} - i \frac{\partial}{\partial x''} \right) = 2 \frac{\partial}{\partial x}; \tag{A.156}$$

$$\frac{1}{2}(D + D^*) = \left(\frac{\partial}{\partial x^*} + \frac{\partial}{\partial x} \right) = \frac{\partial}{\partial x'}; \tag{A.157}$$

$$\frac{1}{2i}(D - D^*) = -i \left(\frac{\partial}{\partial x^*} - \frac{\partial}{\partial x} \right) = \frac{\partial}{\partial x''}. \tag{A.158}$$

The apparent paradox of (A.147) - (A.149) is now resolved. For example, (A.155) can be used to rewrite (A.147) as $2\partial x/\partial x^* = 0$, while (A.156) and (A.148) lead to $2\partial x/\partial x = 2$; both of these results are eminently reasonable if we regard x and x^* as independent variables.

A.9.5 Differentiation of a function with respect to a complex vector

We are now in a position to define derivatives with respect to a complex vector. Consider a scalar-valued function of N complex variables x_1, \dots, x_N or, equivalently, $2N$ real variables $x'_1, \dots, x'_N, x''_1, \dots, x''_N$. We can write this function as $\phi(\mathbf{x}', \mathbf{x}'')$, where \mathbf{x}' is a vector of real parts and \mathbf{x}'' is a vector of imaginary parts, or simply as $\Phi(\mathbf{x})$, where $\mathbf{x} = \mathbf{x}' + i\mathbf{x}''$.

The vector derivatives with respect to real and imaginary parts are defined by

$$\left[\frac{\partial \Phi(\mathbf{x})}{\partial \mathbf{x}'} \right]_n = \frac{\partial \Phi(\mathbf{x})}{\partial x'_n}, \quad \left[\frac{\partial \Phi(\mathbf{x})}{\partial \mathbf{x}''} \right]_n = \frac{\partial \Phi(\mathbf{x})}{\partial x''_n}. \quad (\text{A.159})$$

Both $\partial \Phi(\mathbf{x})/\partial \mathbf{x}'$ and $\partial \Phi(\mathbf{x})/\partial \mathbf{x}''$ are $N \times 1$ column vectors.

Now we define the vector counterpart of D from (A.141) by

$$\nabla = \frac{\partial}{\partial \mathbf{x}'} + i \frac{\partial}{\partial \mathbf{x}''} \quad (\text{A.160a})$$

or, equivalently,

$$[\nabla \Phi(\mathbf{x})]_n = \frac{\partial \Phi(\mathbf{x})}{\partial x'_n} + i \frac{\partial \Phi(\mathbf{x})}{\partial x''_n}. \quad (\text{A.160b})$$

It is reasonable to call this operator ∇ since it is a natural generalization of the familiar real gradient operator. If we have a space with N real coordinates $x_j, j = 1, \dots, N$, and associated orthonormal basis vectors \mathbf{u}_j , then

$$\nabla = \sum_{j=1}^N \mathbf{u}_j \frac{\partial}{\partial x_j}, \quad (x_j, \mathbf{u}_j \text{ real}). \quad (\text{A.161})$$

The operator defined by (A.160) has the same structure in $2N$ dimensions if we think of \mathbf{u}_j and $i\mathbf{u}_j$ as comprising a set of $2N$ orthonormal unit vectors.

The vector counterpart of D^* is the adjoint of ∇ , a row-vector operator defined such that

$$\nabla^\dagger = \frac{\partial}{\partial \mathbf{x}''^t} - i \frac{\partial}{\partial \mathbf{x}'^t}. \quad (\text{A.162})$$

By extension of (A.155) and (A.156), we can also write

$$\nabla = 2 \frac{\partial}{\partial \mathbf{x}^*} \quad \text{or} \quad [\nabla \Phi(\mathbf{x})]_n = 2 \frac{\partial \Phi(\mathbf{x})}{\partial x_n^*}; \quad (\text{A.163})$$

$$\nabla^\dagger = 2 \frac{\partial}{\partial \mathbf{x}^t} \quad \text{or} \quad [\nabla^\dagger \Phi(\mathbf{x})]_n = 2 \frac{\partial \Phi(\mathbf{x})}{\partial x_n}, \quad (\text{A.164})$$

where $\partial/\partial x_n$ and $\partial/\partial x_n^*$ are to be interpreted according to (A.150) and (A.151).

The generalized Hessian is given by

$$\nabla \nabla^\dagger = \left(\frac{\partial}{\partial \mathbf{x}'} + i \frac{\partial}{\partial \mathbf{x}''} \right) \left(\frac{\partial}{\partial \mathbf{x}''^t} - i \frac{\partial}{\partial \mathbf{x}'^t} \right) \quad (\text{A.165a})$$

or, equivalently,

$$[\nabla \nabla^\dagger \Phi(\mathbf{x})]_{nm} = 4 \frac{\partial^2 \Phi(\mathbf{x})}{\partial x_n^* \partial x_m}. \quad (\text{A.165b})$$

Several useful results can be derived from these definitions. In what follows, \mathbf{x} and \mathbf{a} are $N \times 1$ column vectors and \mathbf{A} is an $N \times N$ matrix; \mathbf{A} and \mathbf{a} may be complex but are independent of \mathbf{x} .

$$\nabla \mathbf{a}^\dagger \mathbf{x} = 0; \quad (\text{A.166})$$

$$\nabla \mathbf{x}^\dagger \mathbf{a} = 2\mathbf{a}; \quad (\text{A.167})$$

$$\nabla^\dagger \mathbf{x}^\dagger \mathbf{a} = 0; \quad (\text{A.168})$$

$$\nabla^\dagger \mathbf{a}^\dagger \mathbf{x} = 2\mathbf{a}^\dagger; \quad (\text{A.169})$$

$$\nabla \mathbf{x}^\dagger \mathbf{A} \mathbf{x} = 2\mathbf{A} \mathbf{x}; \quad (\text{A.170})$$

$$\nabla^\dagger \mathbf{x}^\dagger \mathbf{A} \mathbf{x} = 2(\mathbf{x}^\dagger \mathbf{A}); \quad (\text{A.171})$$

$$\nabla \nabla^\dagger \mathbf{x}^\dagger \mathbf{A} \mathbf{x} = 4\mathbf{A}. \quad (\text{A.172})$$

A.10 TAYLOR EXPANSIONS

Many useful approximations are realized by expanding a scalar-valued function in a Taylor series and neglecting higher-order terms. The Taylor series for an analytic function of a single complex variable is discussed in App. B, Sec. B.3.4. Here we address the additional complications that arise when one expands a scalar-valued function of a real or complex vector. For background, we first review the Taylor expansion of a real function of a real scalar.

A.10.1 Real univariate Taylor series

If $\phi(x)$ is a real-valued function of a single real scalar and its first $K + 1$ derivatives exist in an interval around $x = a$, then in this interval (Rade and Westergren, 1990)

$$\phi(x) = \sum_{k=0}^K \frac{\phi^{(k)}(a)}{k!} (x - a)^k + R_{K+1}, \quad (\text{A.173})$$

where $\phi^{(k)}(x)$ is the k^{th} derivative of $\phi(x)$, and R_{K+1} is a remainder term which satisfies

$$R_{K+1} = \left[\frac{\phi^{(K+1)}(b)}{(K+1)!} \right] (x - a)^{K+1}, \quad (\text{A.174})$$

for some b between a and x . If all derivatives exist in the interval, we can let $K \rightarrow \infty$, in which case $R_{K+1} \rightarrow 0$ and

$$\phi(x) = \sum_{k=0}^{\infty} \frac{\phi^{(k)}(a)}{k!} (x - a)^k. \quad (\text{A.175})$$

This infinite series is known as the *Taylor series* for $\phi(x)$. The special case $a = 0$ yields the *Maclaurin series*.

Another useful form is obtained by a simple change of variables. Letting $a \rightarrow x'$ and $x - a \rightarrow a'$ (and then promptly dropping the primes), we have

$$\phi(x + a) = \sum_{k=0}^{\infty} \frac{\phi^{(k)}(x)}{k!} a^k, \quad (\text{A.176})$$

provided, of course, that all of the derivatives exist. It is interesting to rewrite (A.176) in operator form as

$$\phi(x+a) = \exp\left[a\frac{d}{dx}\right]\phi(x), \quad (\text{A.177})$$

where the exponential differential operator is to be interpreted as

$$\exp\left[a\frac{d}{dx}\right] = \sum_{k=0}^{\infty} \frac{a^k}{k!} \frac{d^k}{dx^k}. \quad (\text{A.178})$$

This operator is sometimes referred to as a *displacement operator* since it displaces the function $\phi(x)$ to $\phi(x+a)$.

A.10.2 Real multivariate Taylor series

One advantage of (A.178) is that it generalizes readily to the vector case. The multivariate Taylor expansion for a scalar-valued function of a real vector \mathbf{x} is

$$\begin{aligned} \phi(\mathbf{x}+\mathbf{a}) &= \exp\left(\mathbf{a}^t \frac{\partial}{\partial \mathbf{x}}\right)\phi(\mathbf{x}) = \phi(\mathbf{x}) + \left(\mathbf{a}^t \frac{\partial}{\partial \mathbf{x}}\right)\phi(\mathbf{x}) + \frac{1}{2}\left(\mathbf{a}^t \frac{\partial}{\partial \mathbf{x}}\right)\left(\mathbf{a}^t \frac{\partial}{\partial \mathbf{x}}\right)\phi(\mathbf{x}) + \dots \\ &= \phi(\mathbf{x}) + \mathbf{a}^t \frac{\partial \phi(\mathbf{x})}{\partial \mathbf{x}} + \frac{1}{2}\mathbf{a}^t \frac{\partial^2 \phi(\mathbf{x})}{\partial \mathbf{x} \partial \mathbf{x}^t} \mathbf{a} + \dots \end{aligned} \quad (\text{A.179})$$

In component form, we have

$$\phi(\mathbf{x}+\mathbf{a}) = \phi(\mathbf{x}) + \sum_{i=1}^N a_i \frac{\partial}{\partial x_i} \phi(\mathbf{x}) + \frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N a_i a_j \frac{\partial^2}{\partial x_i \partial x_j} \phi(\mathbf{x}) + \dots \quad (\text{A.180})$$

For the real vectors being considered here, $\partial^2 \phi(\mathbf{x})/\partial \mathbf{x} \partial \mathbf{x}^t$ is the Hessian matrix, and (A.179) shows that it is also the matrix of coefficients of second-order terms in the Taylor expansion.

In optimization problems, it is common to pick a direction specified by a unit vector $\hat{\mathbf{n}}$ and attempt to maximize or minimize a function $\phi(\mathbf{x})$ along this direction. Since the direction is fixed, the function can be represented by a *one-dimensional* Taylor series, even though it is a function of a vector (Gill *et al.*, 1981, p. 53). The required expansion is a special case of (A.179):

$$\begin{aligned} \phi(\mathbf{x}+h\hat{\mathbf{n}}) &= \exp\left(h\hat{\mathbf{n}}^t \frac{\partial}{\partial \mathbf{x}}\right)\phi(\mathbf{x}) \\ &= \phi(\mathbf{x}) + \hat{\mathbf{n}}^t \frac{\partial \phi(\mathbf{x})}{\partial \mathbf{x}} h + \frac{1}{2}\hat{\mathbf{n}}^t \frac{\partial^2 \phi(\mathbf{x})}{\partial \mathbf{x} \partial \mathbf{x}^t} \hat{\mathbf{n}} h^2 + \dots \end{aligned} \quad (\text{A.181})$$

This result provides interpretations of the gradient and Hessian. For any direction $\hat{\mathbf{n}}$, $\hat{\mathbf{n}}^t[\partial \phi(\mathbf{x})/\partial \mathbf{x}]$ is the 1D derivative in that direction and $\hat{\mathbf{n}}^t[\partial^2 \phi(\mathbf{x})/\partial \mathbf{x} \partial \mathbf{x}^t]\hat{\mathbf{n}}$ is the corresponding second derivative or curvature.

A.10.3 Complex univariate Taylor series

Consider a scalar-valued function of a complex scalar $x = x' + ix''$. One way to write a Taylor expansion for this function, denoted $\Phi(x)$ or $\phi(x', x'')$, is to consider it as a function of a real 2D vector with components x' and x'' . Then (A.179) yields

$$\begin{aligned} \phi(x' + a', x'' + a'') &= \exp\left(a' \frac{\partial}{\partial x'} + a'' \frac{\partial}{\partial x''}\right) \phi(x', x'') \\ &= \phi(x', x'') + \left(a' \frac{\partial}{\partial x'} + a'' \frac{\partial}{\partial x''}\right) \phi(x', x'') \\ &+ \frac{1}{2} \left(a' \frac{\partial}{\partial x'} + a'' \frac{\partial}{\partial x''}\right) \left(a' \frac{\partial}{\partial x'} + a'' \frac{\partial}{\partial x''}\right) \phi(x', x'') + \dots \end{aligned} \quad (\text{A.182})$$

This expansion works for any function of x' and x'' so long as all derivatives with respect to x' and x'' exist.

In terms of x and x^* , we can write this expansion as

$$\Phi(x + a) = \exp\left(a \frac{\partial}{\partial x} + a^* \frac{\partial}{\partial x^*}\right) \Phi(x) = \sum_{k=0}^{\infty} \frac{1}{k!} \left(a \frac{\partial}{\partial x} + a^* \frac{\partial}{\partial x^*}\right)^k \Phi(x), \quad (\text{A.183})$$

which, by use of (A.155) and (A.156) can also be written

$$\Phi(x + a) = \exp\left[\frac{1}{2}(aD^* + a^*D)\right] \Phi(x). \quad (\text{A.184})$$

A.10.4 Complex multivariate Taylor series

A scalar-valued function of an ND complex vector \mathbf{x} can be regarded as a function $\phi(\mathbf{x}', \mathbf{x}'')$ of $2N$ variables, so (A.182) generalizes to

$$\phi(\mathbf{x}' + \mathbf{a}', \mathbf{x}'' + \mathbf{a}'') = \exp\left(\mathbf{a}'^t \frac{\partial}{\partial \mathbf{x}'} + \mathbf{a}''^t \frac{\partial}{\partial \mathbf{x}''}\right) \phi(\mathbf{x}', \mathbf{x}''). \quad (\text{A.185})$$

Similarly, with the help of (A.160), the generalization of (A.184) is

$$\begin{aligned} \Phi(\mathbf{x} + \mathbf{a}) &= \exp\left[\frac{1}{2}(\mathbf{a}\nabla^\dagger + \mathbf{a}^\dagger\nabla)\right] \Phi(\mathbf{x}) \\ &= \Phi(\mathbf{x}) + \left[\frac{1}{2}(\mathbf{a}\nabla^\dagger + \mathbf{a}^\dagger\nabla)\right] \Phi(\mathbf{x}) + \frac{1}{2} \left[\frac{1}{2}(\mathbf{a}\nabla^\dagger + \mathbf{a}^\dagger\nabla)\right] \left[\frac{1}{2}(\mathbf{a}\nabla^\dagger + \mathbf{a}^\dagger\nabla)\right] \Phi(\mathbf{x}) + \dots \end{aligned} \quad (\text{A.186})$$

A.11 MATRIX AND VECTOR INEQUALITIES

A.11.1 Classical inequalities

An important relation with many applications in this book is the Cauchy-Schwarz inequality (Johnson and Wichern, 1988, p. 63), which states that

$$|\mathbf{a}^\dagger \mathbf{b}|^2 \leq (\mathbf{a}^\dagger \mathbf{a})(\mathbf{b}^\dagger \mathbf{b}). \quad (\text{A.187})$$

The equality holds if and only if $\mathbf{b} = c\mathbf{a}$, where c is a scalar. One interpretation of this inequality can be seen by defining the angle between \mathbf{a} and \mathbf{b} by

$$\cos \theta_{ab} = \frac{\mathbf{a}^\dagger \mathbf{b}}{\sqrt{(\mathbf{a}^\dagger \mathbf{a})(\mathbf{b}^\dagger \mathbf{b})}}. \quad (\text{A.188})$$

If \mathbf{a} and \mathbf{b} are real, the Cauchy-Schwarz inequality states that $\cos^2 \theta_{ab} \leq 1$, with equality holding if and only if \mathbf{a} and \mathbf{b} are parallel.

Additional useful inequalities arise when other vector norms are considered. The \mathbb{L}_p norm is defined by

$$\|\mathbf{x}\|_p = \left[\sum_{n=1}^N |x_n|^p \right]^{1/p}. \quad (\text{A.189})$$

In terms of this norm, *Minkowski's inequality* states that

$$\|\mathbf{x} + \mathbf{y}\|_p \leq \|\mathbf{x}\|_p + \|\mathbf{y}\|_p, \quad (\text{A.190})$$

and *Hölder's inequality* for Hadamard products (see Sec. A.2.8) states that

$$\|\mathbf{x} \odot \mathbf{y}\|_1 \leq \|\mathbf{x}\|_p \|\mathbf{y}\|_q, \quad \frac{1}{p} + \frac{1}{q} = 1, \quad p, q \geq 1. \quad (\text{A.191})$$

A.11.2 Inequalities involving definite matrices

It is common in the literature to encounter statements such as $\mathbf{A} > \mathbf{B}$ or $\mathbf{A} \geq \mathbf{B}$, where \mathbf{A} and \mathbf{B} are two $N \times N$ matrices. These statements must be interpreted with care. Unlike the equality sign defined in (A.1), an inequality sign applied to matrices does *not* hold on an element-by-element basis. Rather, the statement $\mathbf{A} > \mathbf{B}$ means that for positive-definite matrices \mathbf{A} and \mathbf{B} , $\mathbf{A} - \mathbf{B}$ is positive-definite, while $\mathbf{A} \geq \mathbf{B}$ means that $\mathbf{A} - \mathbf{B}$ is positive-semidefinite. The relation $\mathbf{A} > \mathbf{B}$ holds if and only if $\mathbf{x}^\dagger \mathbf{A} \mathbf{x} > \mathbf{x}^\dagger \mathbf{B} \mathbf{x}$ for all nonzero \mathbf{x} . Similar interpretations hold for $<$ and \leq . This convention is called the *Loewner ordering* of the matrices \mathbf{A} and \mathbf{B} .

With the Loewner convention, some very powerful inequalities can be adduced for definite matrices (Pilz, 1991). A few useful ones are given here.

If $\mathbf{A} > \mathbf{B}$, then

- (i) $\mathbf{B}^{-1} > \mathbf{A}^{-1}$;
- (ii) $\text{tr}(\mathbf{A}\mathbf{C}) > \text{tr}(\mathbf{B}\mathbf{C})$ for all positive-definite (and conformable) \mathbf{C} ;
- (iii) $\det(\mathbf{A}) > \det(\mathbf{B})$;
- (iv) $\lambda_i(\mathbf{A}) > \lambda_i(\mathbf{B})$ for all i .

In these results, $>$ can be consistently replaced by $<$, \leq or \geq and the results still hold. Inequality (iv) assumes that the eigenvalues are ordered so that $\lambda_1 \geq \lambda_2 \geq \lambda_3 \dots$. Thus the entire eigenvalue spectrum of \mathbf{A} must lie above that for \mathbf{B} if $\mathbf{A} > \mathbf{B}$.

Another inequality involving a positive-definite matrix is the *extended Cauchy-Schwarz inequality*. It states that

$$|\mathbf{a}^\dagger \mathbf{b}|^2 \leq (\mathbf{a}^\dagger \mathbf{K} \mathbf{a})(\mathbf{b}^\dagger \mathbf{K}^{-1} \mathbf{b}), \quad (\text{A.192})$$

where \mathbf{K} is positive-definite. Equality holds if and only if $\mathbf{b} = c\mathbf{K}\mathbf{a}$, where c is a scalar.

A.11.3 Matrix norms

The norm of an $N \times N$ matrix \mathbf{A} can be defined as

$$\|\mathbf{A}\| = \max_{\mathbf{x} \neq 0} \frac{\|\mathbf{Ax}\|}{\|\mathbf{x}\|}, \quad (\text{A.193})$$

where \mathbf{x} is an $N \times 1$ vector and $\|\cdot\|$ on the right denotes any desired vector norm. Thus it follows by definition that

$$\|\mathbf{Ax}\| \leq \|\mathbf{A}\| \|\mathbf{x}\|. \quad (\text{A.194})$$

To be more precise about the operational form of the matrix norm, we must specify the associated vector norm to be used in (A.193). Three common choices for the latter are \mathbb{L}_1 , \mathbb{L}_∞ and \mathbb{L}_2 , and the corresponding matrix norms are (Usmani, 1987)

$$\|\mathbf{A}\|_1 = \max_j \sum_i |A_{ij}|; \quad (\text{A.195})$$

$$\|\mathbf{A}\|_\infty = \max_i \sum_j |A_{ij}|; \quad (\text{A.196})$$

$$\|\mathbf{A}\|_2 = \sqrt{\text{maximum eigenvalue of } \mathbf{A}^\dagger \mathbf{A}}. \quad (\text{A.197})$$

A common term for $\|\mathbf{A}\|_2$ is *spectral norm*. Each of these matrix norms leads to a useful inequality when substituted into (A.194).

A more familiar-looking matrix norm is the *usual norm*, defined via

$$\|\mathbf{A}\|^2 = \sum_{i,j} |A_{ij}|^2. \quad (\text{A.198})$$

Associated with this norm is a scalar product of two matrices, defined as (Harville, 1997)

$$\mathbf{A} \cdot \mathbf{B} = \text{tr}\{\mathbf{A}^\dagger \mathbf{B}\}. \quad (\text{A.199})$$

In terms of this scalar product, the matrix version of the Cauchy-Schwarz inequality is (Harville, 1997)

$$|\mathbf{A} \cdot \mathbf{B}|^2 \leq \|\mathbf{A}\|^2 \|\mathbf{B}\|^2. \quad (\text{A.200})$$

The equality holds if and only if $\mathbf{A} = \mathbf{0}$, $\mathbf{B} = \mathbf{0}$ or $\mathbf{A} = c\mathbf{B}$ for some scalar c .

APPENDIX B

Complex Variables

This appendix is intended as a brief survey of complex numbers, functions of a single complex variable and complex integration. Results needed in the main text are presented without proof and with relatively little discussion. For more details, the reader is referred to any of the many introductory texts on complex variables; particularly lucid ones are Carrier *et al.*, (1966), Churchill *et al.* (1974), Ahlfors (1979) and Wunsch (1994). More general texts with good sections on complex variables include Morse and Feshbach (1953), Arfken and Weber (1995) and Friedman (1991). Proofs of all statements made in this appendix can be found in these references.

B.1 COMPLEX ALGEBRA

B.1.1 What is a complex number?

A complex number is an ordered pair of real numbers obeying certain algebraic rules. If z_1 denotes the ordered pair (x_1, y_1) and z_2 denotes the pair (x_2, y_2) , addition and multiplication are defined as follows:

$$\text{Addition: } z_3 = z_1 + z_2 \Rightarrow x_3 = x_1 + x_2, \quad y_3 = y_1 + y_2 \quad (\text{B.1})$$

$$\text{Multiplication: } z_3 = z_1 z_2 \Rightarrow x_3 = x_1 x_2 - y_1 y_2, \quad y_3 = x_1 y_2 + x_2 y_1, \quad (\text{B.2})$$

where $z_3 = (x_3, y_3)$. Subtraction and division are defined as the inverses of addition and multiplication, respectively. The usual algebraic laws (commutative, associative and distributive) are valid for complex numbers.

Equality of two complex numbers means equality for corresponding members of the pairs:

$$\text{Axiom of equality: } z_1 = z_2 \Rightarrow x_1 = x_2 \quad \text{and} \quad y_1 = y_2. \quad (\text{B.3})$$

In particular,

$$\text{Complex zero: } z_1 = 0 \Rightarrow x_1 = 0 \quad \text{and} \quad y_1 = 0. \quad (\text{B.4})$$

Thus 0 is understood to mean the ordered pair $(0, 0)$.

B.1.2 Representations

A conventional representation of a complex number $z = (x, y)$ is:

$$z = x + iy, \quad (\text{B.5})$$

where $i = \sqrt{-1}$. Since $\sqrt{-1}$ was once thought to be nonexistent,¹ y is referred to as the imaginary part of z , denoted $\text{Im}(z)$, while x is the real part or $\text{Re}(z)$.

The representation (B.5) is a compact way of summarizing the algebraic properties of complex numbers. It is easy to verify, for example, that the multiplication rule follows from (B.5) along with the usual rule for multiplying polynomials.

Fig. B.1 Representation of a complex number as a vector in a plane.

A graphical way of portraying a complex number is as a point in a plane (see Fig. B.1), with x and y as Cartesian coordinates (x, y) . Equivalently, the complex number can be regarded as a 2D vector from the origin to the point (x, y) . Though often attributed to Gauss, this representation apparently predated him (Boyer and Merzbach, 1989, p. 507).

The Argand or polar representation of z is

$$z = |z| \cos \theta + i|z| \sin \theta, \quad (\text{B.6})$$

where $|z|$ and θ are known, respectively, as the *modulus* and *argument* of z . The notation $\theta = \arg(z)$ is common. It follows easily from (B.6) and Fig. B.1 that

$$|z|^2 = x^2 + y^2 \quad \text{and} \quad \arg(z) = \theta = \tan^{-1} \left(\frac{y}{x} \right). \quad (\text{B.7})$$

¹Apparently the first to suggest the existence of an imaginary number was an obscure fifteenth-century French mathematician Nicolas Chuquet. For a fascinating history of the development of complex numbers, see Boyer and Merzbach (1989).

B.1.3 Complex exponentials and DeMoivre's theorem

The complex exponential $\exp(i\theta)$ can be defined in terms of the same Taylor series used for real variables. Recognizing that the Taylor series for $\exp(i\theta)$ equals the Taylor series for $\cos \theta$ plus i times the Taylor series for $\sin \theta$, we have

$$e^{i\theta} = \cos \theta + i \sin \theta. \tag{B.8}$$

With (B.8), representation (B.6) for a general complex number takes the more compact form,

$$z = |z|e^{i\theta}. \tag{B.9}$$

This form is especially handy for multiplication and division of complex numbers. If $z_1 = |z_1| \exp(i\theta_1)$ and $z_2 = |z_2| \exp(i\theta_2)$, then

$$z_1 z_2 = |z_1| |z_2| e^{i(\theta_1 + \theta_2)}, \quad \frac{z_1}{z_2} = \frac{|z_1|}{|z_2|} e^{i(\theta_1 - \theta_2)}. \tag{B.10}$$

From this result we can easily derive DeMoivre's theorem, which states that

$$z^n = [|z|(\cos \theta + i \sin \theta)]^n = [|z| e^{i\theta}]^n = |z|^n (\cos n\theta + i \sin n\theta). \tag{B.11}$$

B.1.4 Complex conjugate

The complex conjugate of $z = x + iy$ is defined by

$$z^* = x - iy = |z| e^{-i\theta} = |z|(\cos \theta - i \sin \theta). \tag{B.12}$$

The following properties follow from this definition:

$$\begin{aligned} (z^*)^* &= z, & z z^* &= |z|^2, & (z_1 \pm z_2)^* &= z_1^* \pm z_2^*, \\ (z_1 z_2)^* &= z_1^* z_2^*, & \left(\frac{z_1}{z_2}\right)^* &= \frac{z_1^*}{z_2^*}. \end{aligned} \tag{B.13}$$

The real and imaginary parts of z are given in terms of z and z^* by

$$x = \frac{1}{2}(z + z^*), \quad y = \frac{1}{2i}(z - z^*). \tag{B.14}$$

With (B.6), (B.8) and (B.14), we obtain the Euler formulas,

$$\cos \theta = \frac{e^{i\theta} + e^{-i\theta}}{2}, \quad \sin \theta = \frac{e^{i\theta} - e^{-i\theta}}{2i}. \tag{B.15}$$

B.1.5 Roots of unity

An N^{th} root of unity is a number z such that $z^N = 1$, where N is an integer. If we restricted z to be real, the only solutions to this equation would be $z = 1$ for N odd or $z = \pm 1$ for N even. With complex numbers there are other possibilities. Consider the complex number W_N defined by

$$W_N = e^{-2\pi i/N}. \tag{B.16}$$

Raising W_N to the N^{th} power gives

$$(W_N)^N = (e^{-2\pi i/N})^N = e^{-2\pi i} = \cos 2\pi - i \sin 2\pi = 1. \tag{B.17}$$

Thus W_N is indeed an N^{th} root of unity, but it is not the only one. We can get other roots by raising W_N to other integer powers. To show that $[W_N]^k$ is an N^{th} root of unity for any integer k , note that

$$[(W_N)^k]^N = \left[(e^{-2\pi i/N})^k \right]^N = e^{-2\pi i k} = \cos 2\pi k - i \sin 2\pi k = 1. \quad (\text{B.18})$$

The full set of N^{th} roots of unity is $\{\exp(-2\pi i k/N), k = 0, 1, \dots, N-1\}$ since k and $k+N$ define the same complex number. There are always exactly N distinct N^{th} roots of unity.

B.2 FUNCTIONS OF A COMPLEX VARIABLE

A function $f(z)$ is a mapping from the complex number $z = x + iy$ to the complex number $f(z) = u + iv$, or equivalently from a point in the x - y plane to a point in the u - v plane. We thus write

$$f(z) = u(x, y) + iv(x, y). \quad (\text{B.19})$$

If a single point (x, y) maps to a single (u, v) or if two or more (x, y) points map to the same (u, v) , we say the function is *single-valued*. If a single (x, y) maps to two or more (u, v) , the function is *multiple-valued* or *multivalued*. Examples of single-valued functions include z^2 , $1/z$ and $\cos z$, while examples of multivalued functions include \sqrt{z} , $\arg(z)$ and $\cos^{-1}(z)$.

B.2.1 Limits

The statement,

$$\lim_{z \rightarrow z_0} f(z) = w_0, \quad (\text{B.20})$$

means that for every positive real number ϵ there exists a positive real number δ such that

$$|f(z) - w_0| < \epsilon \quad \text{when} \quad |z - z_0| < \delta \quad (z \neq z_0). \quad (\text{B.21})$$

In other words, $f(z)$ can be made arbitrarily close to w_0 by taking z sufficiently close to z_0 , except possibly at the point z_0 itself.

A very important consequence of this definition is that when a limit of $f(z)$ exists at any point z_0 , it must be unique. The value of the limit cannot depend on the direction of approach to z_0 in the complex plane. We can write

$$\lim_{z \rightarrow z_0} f(z) = \lim_{\substack{x \rightarrow x_0 \\ y \rightarrow y_0}} u(x, y) + i \lim_{\substack{x \rightarrow x_0 \\ y \rightarrow y_0}} v(x, y), \quad (\text{B.22})$$

and the limits on x and y can be taken in either order.

Consider two different functions $f(z)$ and $F(z)$ and suppose that both of them have limits as $z \rightarrow z_0$, *i.e.*,

$$\lim_{z \rightarrow z_0} f(z) = w_0, \quad \lim_{z \rightarrow z_0} F(z) = W_0. \quad (\text{B.23})$$

Then the following properties hold:

$$\lim_{z \rightarrow z_0} [f(z) + F(z)] = w_0 + W_0, \quad \lim_{z \rightarrow z_0} [f(z) F(z)] = w_0 W_0,$$

$$\lim_{z \rightarrow z_0} \left[\frac{f(z)}{F(z)} \right] = \frac{w_0}{W_0} \quad \text{if} \quad W_0 \neq 0. \quad (\text{B.24})$$

If $P(z)$ is a polynomial of any finite order,

$$P(z) = a_0 + a_1z + a_2z^2 + \dots + a_Nz^N, \quad (\text{B.25})$$

then

$$\lim_{z \rightarrow z_0} P(z) = P(z_0). \quad (\text{B.26})$$

B.2.2 Continuity

A single-valued function $f(z)$ is said to be *continuous* at z_0 if and only if

$$f(z_0) \text{ exists,} \quad \lim_{z \rightarrow z_0} f(z) \text{ exists,} \quad \text{and} \quad \lim_{z \rightarrow z_0} f(z) = f(z_0). \quad (\text{B.27})$$

These three conditions imply that $f(z)$ is defined in some neighborhood of z_0 .

From the theorems above on limits, it can be shown that if two functions are continuous, their sum and product are continuous, and their quotient is continuous except for those values of z where the denominator vanishes. Every polynomial $P(z)$ is continuous at all z .

B.2.3 Derivatives

The derivative of a function of a complex variable is defined in the same manner as for a function of a real variable:

$$f'(z) = \lim_{\Delta z \rightarrow 0} \frac{f(z + \Delta z) - f(z)}{\Delta z}. \quad (\text{B.28})$$

The function $f(z)$ is differentiable in any region where this limit exists. Since a limit must be unique if it exists, the derivative must be independent of the direction of Δz in the complex plane. An example of a function that is continuous but not differentiable (except at $z = 0$) is $|z|^2$.

From the definition (B.28), the following rules for differentiation can be proved:

$$\frac{d}{dz}C = 0, \quad \frac{d}{dz}[Cf(z)] = C \left[\frac{df(z)}{dz} \right], \quad \frac{d}{dz}(z^n) = nz^{n-1}, \quad (\text{B.29})$$

where C is a constant and n is a positive integer. If $f_1(z)$ and $f_2(z)$ are two functions whose derivatives exist, then

$$\begin{aligned} \frac{d}{dz}[f_1(z) + f_2(z)] &= \frac{df_1(z)}{dz} + \frac{df_2(z)}{dz}, \\ \frac{d}{dz}[f_1(z) f_2(z)] &= f_1(z) \frac{df_2(z)}{dz} + f_2(z) \frac{df_1(z)}{dz}, \\ \frac{d}{dz} \left[\frac{f_1(z)}{f_2(z)} \right] &= \frac{f_2(z) \frac{df_1(z)}{dz} - f_1(z) \frac{df_2(z)}{dz}}{[f_2(z)]^2}, \quad (f_2(z) \neq 0). \end{aligned} \quad (\text{B.30})$$

B.2.4 Analytic functions

A function $f(z)$ is said to be *analytic* at z_0 if its derivative exists at every point in some neighborhood of z_0 (including the point z_0 itself). The terms *regular* and *holomorphic* are synonymous with analytic. If $f(z)$ is analytic at every point in the neighborhood of z_0 but not at z_0 itself, z_0 is called a *singular point* or *singularity* of $f(z)$. If $f(z)$ is analytic at some point z_0 , then *all* derivatives of $f(z)$ can be shown to exist at that point.

A function $f(z)$ is analytic at ∞ if $f(1/z)$ is analytic at 0. A function that is analytic everywhere (except possibly at ∞) is called *entire*. For example, a polynomial is entire.

B.2.5 Cauchy-Riemann conditions

Analyticity of $f(z)$ imposes stringent requirements on its real and imaginary parts, as defined in (B.19). Let $u(x, y)$ and $v(x, y)$ and their partial derivatives with respect to x and y be single-valued and continuous in some neighborhood of a point $z_0 = x_0 + iy_0$. Then a necessary and sufficient condition that $f(z)$ be analytic at that point is that the *Cauchy-Riemann conditions* be satisfied:

$$\frac{\partial u(x, y)}{\partial x} = \frac{\partial v(x, y)}{\partial y}, \quad \frac{\partial u(x, y)}{\partial y} = -\frac{\partial v(x, y)}{\partial x}. \quad (\text{B.31})$$

As a corollary of the Cauchy-Riemann conditions, $u(x, y)$ and $v(x, y)$ are *harmonic functions*; *i.e.*, they satisfy the 2D Laplace equation:

$$\nabla^2 u(x, y) = \nabla^2 v(x, y) = 0. \quad (\text{B.32})$$

Equation (B.32) shows that only certain functions can be used as the real or imaginary part of an analytic function, while (B.31) shows that the real and imaginary parts cannot be chosen independently.

As examples, z^n (n an integer) and $\cos z$ are entire (analytic for all z), but $|z|$ and z^* are not analytic anywhere.

B.2.6 Maxima, minima and zeros

For real functions of a real variable, maxima and minima are commonplace and easy to understand. The situation is very different with functions of complex variables. Since $f(z)$ is usually itself complex, it consists of two numbers ($u(z), v(z)$) which must be reduced to a single number if we are to even inquire about maxima and minima; the natural way to do this is to form the modulus $|f(z)|$. Motivated by our experience with real functions, we might then attempt to find the values of z for which $|f(z)|$ is a maximum or minimum. However, if $f(z)$ is an analytic function, an important theorem known as the *maximum-modulus theorem* states that no maximum can exist!

More precisely, if $f(z)$ is analytic within a circle of radius R centered on z_0 , then

$$|f(z_0)| \leq M, \quad (\text{B.33})$$

where M is the maximum value of $|f(z)|$ on that circle. Since $|f(z)|$ at any point z_0 is less than or equal to its value at some point on a circle surrounding z_0 , the

point z_0 cannot be a maximum of the modulus. If $f(z)$ is an entire function, we can extend the radius of the circle to infinity and conclude that $|f(z)|$ cannot have a maximum except at $z = \infty$.

As a corollary of the maximum-modulus theorem, if $f(z)$ is analytic and bounded [$|f(z)| \leq K$, K a constant] for all z , then $f(z)$ must be a constant. In other words, the only bounded, entire function is a constant. This result is known as *Liouville's theorem*.

An extension of the maximum-modulus theorem applies to all derivatives of an analytic function (which are themselves analytic). If $f(z)$ is analytic at z_0 , then

$$|f^{(n)}(z_0)| \leq \frac{Mn!}{R^n}, \tag{B.34}$$

where M and R have the same meaning as above. Thus none of the derivatives of an analytic function can have maxima.

With real functions, the difference between maxima and minima is of little consequence; if $f(x)$ has a maximum at $x = x_0$, then $-f(x)$ has a minimum there. Complex functions are different. Though the modulus of an analytic function cannot have a maximum, it can indeed have a minimum. For example, if $f(z) = z^2$, $|f(z)|$ is minimum at $z = 0$. More generally, $|f(z)|$ takes on its minimum value of zero at all points where $f(z) = 0$.

However, the zeros of analytic functions also have some counterintuitive properties. They can occur only at isolated points and not along lines or areas of the complex plane. More precisely, unless a function is identically zero, about each point where the function is analytic there must be a neighborhood throughout which the function is nonzero, except possibly at the point itself. As a corollary, if $f(z)$ is analytic and zero over a finite line or area, it must be zero everywhere.

B.3 COMPLEX INTEGRATION

With real integrals, the value of a definite integral is fully specified by the function and the limits of integration. With complex integrals, however, the specific line or path of integration in the complex plane can also be important. When this path is a closed contour around some region R , we refer to the integral as a contour integral. Some of the most powerful results of complex analysis relate to contour integrals.

B.3.1 Definition of a line integral

By analogy to definite integrals of real functions, the integral of a complex function $f(z)$ along a line L from $z = \alpha$ to $z = \beta$ is defined by dividing the line into N small segments, adding up the contributions from each segment, and letting $N \rightarrow \infty$. If the j^{th} segment extends from z_j to z_{j+1} and we define $\Delta_j z$ as $z_{j+1} - z_j$, then the integral is defined by

$$\int_L dz f(z) = \lim_{N \rightarrow \infty} \sum_{j=1}^N f(z'_j) \Delta_j z, \tag{B.35}$$

where z'_j is any point on L between z_j and z_{j+1} . Equivalently, with (B.5) and (B.19), we can also write

$$\int_L dz f(z) = \int_L (dx + idy) [u(x, y) + iv(x, y)] , \quad (\text{B.36})$$

where dx and dy are not independent but are constrained by the condition that (x, y) must lie on the line L .

B.3.2 Integrals of analytic functions

Though in general the line integral from $z = \alpha$ to $z = \beta$ depends on the specific line connecting the two points, an important exception occurs if $f(z)$ is analytic. If L and L' are two lines from α to β , R is the region between L and L' (including L and L' themselves), and $f(z)$ is analytic in R , then

$$\int_L dz f(z) = \int_{L'} dz f(z) . \quad (\text{B.37})$$

This result gives us the freedom to deform the path of integration at will without changing the value of the integral, so long as the path remains entirely within the region of analyticity.

If the starting and ending points of a line integral are the same ($\alpha = \beta$), the path of integration is a closed loop referred to as a *contour*. By convention, contours are assumed to be traversed in a counter-clockwise direction unless otherwise stated.

A consequence of (B.37) known as the *Cauchy-Goursat theorem* says that the integral of an analytic function around a closed path is zero. That is, if $f(z)$ is analytic inside and on contour C , then

$$\oint_C dz f(z) = 0 . \quad (\text{B.38})$$

B.3.3 Integrals of z^n

Consider the integral of the function z^n around a closed contour C which encloses the origin. If $n \geq 0$, z^n is analytic and the integral is immediately zero by (B.38). If $n < 0$, on the other hand, z^n is singular at the origin and (B.38) is not applicable. We can, however, use (B.37) to deform the contour, allowing it to shrink to a circle of radius ϵ about the origin. On this new contour, $z = \epsilon \exp(i\theta)$ and $dz = izd\theta$, so we have

$$\oint_C dz z^n = i\epsilon^{n+1} \int_0^{2\pi} d\theta e^{i(n+1)\theta} . \quad (\text{B.39})$$

The remaining integral is easily performed with the help of DeMoivre's theorem, (B.11), and we find

$$\oint_C dz z^n = \begin{cases} 2\pi i & \text{if } n = -1 \\ 0 & \text{otherwise} \end{cases} . \quad (\text{B.40})$$

B.3.4 Cauchy integral formula

Suppose $f(z)$ is analytic inside and on contour C , and that the point z_0 is inside C . Then the celebrated *Cauchy integral formula* states that

$$\frac{1}{2\pi i} \oint_C dz \frac{f(z)}{z - z_0} = f(z_0). \quad (\text{B.41})$$

Without going through a formal proof, we can make this result plausible by using (B.37) to again justify shrinking the contour to a circle of radius ϵ around the point z_0 . As $\epsilon \rightarrow 0$, the analytic function $f(z) \rightarrow f(z_0)$, a constant that can be taken out of the integral. Application of (B.40) then yields (B.41).

An extension of the Cauchy integral formula states that

$$\frac{n!}{2\pi i} \oint_C dz \frac{f(z)}{(z - z_0)^{n+1}} = f^{(n)}(z_0), \quad (\text{B.42})$$

where $f^{(n)}(z_0)$ denotes the n^{th} derivative evaluated at z_0 .

B.3.5 Series representations of complex functions

We have already seen that a polynomial of finite order is an analytic function. A *Taylor series* can be regarded as a polynomial of infinite order, and it too represents an analytic function. Specifically, if $f(z)$ is analytic at $z = z_0$, it can be expanded in a Taylor series of the form

$$f(z) = \sum_{n=0}^{\infty} a_n (z - z_0)^n, \quad (\text{B.43})$$

where the coefficients are given by

$$a_n = \frac{1}{n!} f^{(n)}(z_0) = \frac{1}{2\pi i} \oint_C dz' \frac{f(z')}{(z' - z_0)^{n+1}}. \quad (\text{B.44})$$

Any closed contour C can be used here, so long as $f(z)$ is analytic inside and on C . The Taylor series converges to $f(z)$ within a circle of radius R about z_0 , where R is the distance from z_0 to the nearest singularity of $f(z)$. A *Maclaurin series* is the special case of a Taylor series when $z_0 = 0$.

If $f(z)$ is singular at z_0 , it can still be represented as a power series in $z - z_0$, but negative powers are required. Suppose $f(z)$ is analytic in an annular region defined by two circles of radius R_1 and R_2 ($R_2 > R_1 > 0$) centered on z_0 . Then a series representation of $f(z)$, called a *Laurent series*, is given by

$$f(z) = \sum_{n=-\infty}^{\infty} a_n (z - z_0)^n, \quad (\text{B.45})$$

where the coefficients are

$$a_n = \frac{1}{2\pi i} \oint_C dz' \frac{f(z')}{(z' - z_0)^{n+1}}. \quad (\text{B.46})$$

Here the contour C can be any closed contour in the annular region, and the Laurent series will converge to $f(z)$ in that region. If $f(z)$ has no other singularities besides the one at z_0 inside the inner circle, radius R_1 can approach zero, and the Laurent series will converge to $f(z)$ at all points inside the circle of radius R_2 , save only z_0 itself.

B.3.6 Poles and residues

If the Laurent series for $f(z)$ around z_0 terminates at a maximum negative power of $-m$ (i.e., $a_n = 0$ for $n < -m$) then the singularity at point z_0 is a *pole of order m* . A pole of order 1 is called a *simple pole*. If the series must be carried to $n = -\infty$, then z_0 is an *essential singularity*. If $a_n = 0$ for all $n < 0$, then the Laurent series reduces to the Taylor series and $f(z)$ is analytic at z_0 . The coefficient a_{-1} is called the *residue* of $f(z)$ at $z = z_0$.

A function might have many poles, say at $z = z_j$, $j = 1, \dots, J$. One conceptual way to calculate the residues is to expand $f(z)$ in J different Laurent series, one for each singularity, and read off the coefficient a_{-1} in each series. The problem with doing this in practice is that we end up with many coefficients that are of no interest. The following operational rule is a useful shortcut: To calculate the residue of $f(z)$ at a pole of order m at $z = z_j$, let $\phi(z) = (z - z_j)^m f(z)$. Then

$$\text{Residue of } f(z) \text{ at } z_j = \frac{\phi^{(m-1)}(z_j)}{(m-1)!}. \quad (\text{B.47})$$

For a simple pole ($m = 1$), the residue at z_j is just the limit as $z \rightarrow z_j$ of $(z - z_j)f(z)$.

B.3.7 Residue theorem

Let C be a closed contour within and on which $f(z)$ is analytic except for a finite number of singular points at $z = z_j$, $j = 1, \dots, J$. Then

$$\oint_C dz f(z) = 2\pi i \sum_j [\text{residue of } f(z) \text{ at } z = z_j]. \quad (\text{B.48})$$

B.3.8 Use of residues to evaluate real integrals

One of the most important applications of complex integration is to perform *real* integrals. As an illustration, consider the integral

$$I = \int_{-\infty}^{\infty} dx \frac{\cos(\beta x)}{x^2 + \alpha^2}, \quad (\text{B.49})$$

where α and β are real and positive; later α and β will be allowed to be negative. The integrand is real and the integral is along the real axis, but nevertheless contour integration is useful. To see this, note first that we can also write

$$I = \int_{-\infty}^{\infty} dx \frac{e^{i\beta x}}{x^2 + \alpha^2}, \quad (\text{B.50})$$

since the integral of $\sin(\beta x)/(x^2 + \alpha^2)$ over the symmetric interval vanishes. We can now recognize (B.50) as the Fourier transform of $(x^2 + \alpha^2)^{-1}$ if we identify β as $-2\pi\xi$ (see Chap. 3).

Fig. B.2 Contour used in evaluation of (B.50).

The next step is to convert the integral along the real axis into a contour integral in the complex plane. A suitable contour, shown in Fig. B.2, is one that runs from $-R$ to R along the real axis, then is closed by a counter-clockwise semicircle of radius R . Along the straight-line portion of C , $z = x$, and this portion of the contour integral approaches the desired integral I as $R \rightarrow \infty$. Along the semicircle, $z = R \exp(i\theta) = R \cos \theta + iR \sin \theta$, $dz = iR \exp(i\theta)d\theta$, and θ runs from 0 to π . We thus have

$$\oint_C dz \frac{e^{i\beta z}}{z^2 + \alpha^2} = I + \lim_{R \rightarrow \infty} \int_0^\pi d\theta \frac{iR e^{i\theta} e^{i\beta R \cos \theta} e^{-\beta R \sin \theta}}{(R \cos \theta + iR \sin \theta)^2 + \alpha^2}. \tag{B.51}$$

Since both R and β are positive, the factor $\exp(-\beta R \sin \theta)$ vanishes exponentially as $R \rightarrow \infty$. Thus the limit in (B.51) is zero, and I is equal to the contour integral; all that remains is to evaluate that integral. To do so we write

$$I = \oint_C dz \frac{e^{i\beta z}}{z^2 + \alpha^2} = \oint_C dz \frac{e^{i\beta z}}{(z + i\alpha)(z - i\alpha)}. \tag{B.52}$$

Since the exponential is an analytic function, the only singularities of the integrand are at the points $z = \pm i\alpha$, both of which are simple poles. The pole at $z = -i\alpha$ is outside the contour and does not affect the integral. By (B.47) the residue of the integrand at $z = i\alpha$ is $\exp[i\beta(i\alpha)]/2i\alpha$. Then (B.48) shows that

$$I = \frac{\pi}{\alpha} e^{-\beta\alpha}, \quad \beta > 0, \quad \alpha > 0. \tag{B.53}$$

If we wished to evaluate I for negative β or α , we could repeat the above calculation with a contour having a semicircle in the lower half of the complex plane. Alternatively, we can simply note from (B.49) that I is an even function of β and α . Either way, the general result for any real β and α is

$$I = \frac{\pi}{|\alpha|} e^{-|\beta\alpha|}, \quad \beta, \quad \alpha \text{ real}. \tag{B.54}$$

B.3.9 Cauchy principal value

In the example in Sec. B.3.8, we were interested in an integral along the real axis, and when we converted it to a contour integral, the poles were found to lie off the real axis. In other words, for real x the integrand remained finite. Sometimes,

however, we are faced with an improper real integral with a singularity exactly on the path of integration. An example would be

$$I = \int_{-\infty}^{\infty} dx \frac{f(x)}{x}, \quad (\text{B.55})$$

where $f(x)$ does not vanish at $x = 0$.

We would like to convert this integral to a contour integral of $f(z)/z$. If $f(z)$ vanishes sufficiently rapidly at ∞ in either the upper or lower half-plane, we can close the contour with an infinite semicircle as in Sec. B.3.8, but there is no general guidance on how to handle the singularity at $z = 0$. We might consider deforming the contour slightly to avoid the singularity, but it matters greatly whether we indent the contour above or below the pole (see Fig. B.3a and b). If the pole is outside the deformed contour, no matter how slightly, it does not contribute to the integral, but if it is inside, its full residue enters into (B.48).

Fig. B.3 Possible contours that can be used for evaluation of (B.55). Only the portion of the contour on or near the real axis is shown; the contour will be closed by a semicircle in the upper or lower half-plane, depending on the behavior of $f(z)$. The contour in part c corresponds to the Cauchy Principal value. Choice among these contours must be made on physical rather than mathematical grounds.

Another option, often dictated by the physics or symmetry of a particular application, is to take the *Cauchy principal value* of the integral, defined for real integrals by

$$\mathcal{P} \int_{-\infty}^{\infty} dx \frac{f(x)}{x} = \lim_{\epsilon \rightarrow 0} \left\{ \int_{-\infty}^{-\epsilon} dx \frac{f(x)}{x} + \int_{\epsilon}^{\infty} dx \frac{f(x)}{x} \right\}. \quad (\text{B.56})$$

In terms of contour integrals, this definition is equivalent to using the interrupted contour of Fig. B.3c. Use of this contour is equivalent to counting *half* of the residue at any pole that lies exactly on the real axis, essentially averaging the results that would be obtained by the contours of Figs. B.3a and b.

To illustrate the use of the Cauchy principal value, let us compute the integral

$$I = \mathcal{P} \int_{-\infty}^{\infty} dx \frac{e^{i\beta x}}{x}, \quad (\text{B.57})$$

which is the Fourier transform of the generalized function $\mathcal{P}\{1/x\}$ (see Sec. 3.3.7) if we let $\beta = -2\pi\xi$. As in Sec. B.3.8, we can close the contour with a semicircle in the upper half-plane if $\beta > 0$. Since the integrand vanishes exponentially along this semicircle, the contour integral equals the desired integral along the real axis. The

only pole is at $z = 0$, exactly on the contour, and the residue of the integrand at that pole is 1. Since only half of that residue counts for a principal-value integral, we have

$$I = i\pi, \quad \beta > 0. \tag{B.58}$$

The situation gets a bit more interesting if $\beta < 0$. In that case, we close the integral in the lower half-plane, but this means we are traversing the contour in a *clockwise* direction. Since all of our theorems are based on a counter-clockwise convention, we must reverse the direction, introducing a minus sign in the integral. Again the pole is on the contour and the residue is 1, so $I = -i\pi$ for $\beta < 0$. Combining these results and using the signum function defined in Sec. 2.3.2, we can write

$$I = i\pi \operatorname{sgn}(\beta). \tag{B.59}$$

This same result could also have been obtained from (B.57) and (B.58) by noting that I is an odd function of β .

B.3.10 Summing a series

Just as complex integration can be used to perform real integrals, it can also be used to sum a real series. A very neat trick for this purpose is presented in Morse and Feshbach (1953), p. 413.

Suppose we are concerned with an infinite sum of the form

$$S = \sum_{n=-\infty}^{\infty} f(n), \tag{B.60}$$

where we require $f(n)$ to be finite for all integers n and to vanish faster than $1/n$ as $n \rightarrow \infty$ in order for S to converge. We can convert $f(n)$ to a function of a complex variable simply by replacing n with z , and we assume that $|zf(z)|$ is bounded at infinity.

To evaluate S , we consider the contour integral

$$I = \pi \oint_C dz f(z) \cot \pi z. \tag{B.61}$$

The function $\pi \cot \pi z$ has simple poles of residue 1 at $z = 0, \pm 1, \pm 2, \dots$, and it is bounded at infinity except along the real axis.

Now suppose we take the contour C as a full circle of radius R that does not intersect any poles of $\cot \pi z$. The length of this contour is $2\pi R$, so the integral must satisfy the inequality, $I \leq 2\pi RM$, where M is the maximum value of the modulus of the integrand on the contour. However, since $|f(z)|$ vanishes faster than $1/R$ as $R \rightarrow \infty$ and the cotangent is bounded, the integral in (B.61) is, in fact, zero. Nevertheless, the residue theorem still holds, and we can also compute I from (B.48). As $R \rightarrow \infty$ all poles associated with either $f(z)$ or $\cot \pi z$ are enclosed in the contour and contribute to the integral. The poles of the cotangent are at $z = n$, while the poles of $f(z)$ are at $z = z_j, j = 1, \dots, J$. By construction, the sum of the residues of the integrand at the poles of the cotangent is just S , so we have

$$I = 0 = 2\pi i \left[S + \sum_{j=1}^J (\text{residue of } \pi f(z) \cot(\pi z) \text{ at } z = z_j) \right], \tag{B.62}$$

where the sum runs over *poles of $f(z)$ only*. Thus

$$S = \sum_{n=-\infty}^{\infty} f(n) = - \sum_{j=1}^J [\text{residue of } \pi f(z) \cot(\pi z) \text{ at } z = z_j] . \quad (\text{B.63})$$

A similar formula for alternating series results from the use of the function $\pi \csc \pi z$, which has simple poles of residue $(-1)^n$ at $z = \pm n$. The counterpart of (B.63) is

$$\sum_{n=-\infty}^{\infty} (-1)^n f(n) = - \sum_{j=1}^J [\text{residue of } \pi f(z) \csc(\pi z) \text{ at } z = z_j] . \quad (\text{B.64})$$

These two formulas are often very useful when $f(z)$ is a simple function with a few, easily calculated residues.

APPENDIX C

Probability

INTRODUCTION

A thorough grounding in probability theory is necessary in order to understand and model random variables and processes. Classification decisions and estimates based on random processes are themselves random; thus probability theory is required to describe the nature of such inferences. It is the purpose of this appendix to review the basic tools from probability theory used to describe one or two random variables; these tools are generalized to their vector forms in Chap. 8. In Sec. C.1 we start with a discussion of the calculus of probability, including the concepts of sample points and sample spaces, set theory, and the several basic approaches to probability. We then adopt an axiomatic approach to probability and consider the description of single and multiple random variables, and functions of such random variables (Secs. C.2, C.3, C.4). Some well-known probability laws for random variables are discussed in Secs. C.5 and C.6, and methods for generating random variables of a specified probability law are given in Sec. C.7.

The reader who is interested in reviewing these topics in greater depth is advised to consult one of the many general texts on these subjects, such as Johnson *et al.* (1992, 1994, 1995), Casella and Berger (1990), Davenport (1970) and Feller (1968). More sophisticated mathematical treatments are given by Shiriyayev (1984) and Breiman (1992). A handy reference book is Evans *et al.* (1993).

C.1 Calculus of probability

Probability theory is a useful tool in the description of processes or experiments that have some uncertainty or randomness about them. In this appendix we will be concerned with descriptions of the ensemble statistics of the random variables in the experiment. Ensemble statistics, also referred to as population statistics, are hypothetical descriptions of the randomness of an experiment given perfect knowledge. This is to be contrasted with sample statistics, the description of data based on information derived from a finite number of random samples, which are not considered here.

In the next sections we provide a framework for describing experiments and their random outcomes using the language of set theory.

C.1.1 Outcomes, events, and spaces

We call a single run of an experiment a *trial*. At the conclusion of each trial, some experimental *outcome* or *sample* is recorded which has some randomness associated with it. Another trial would result in the recording of another realization of the experimental outcome. The randomness in the experiment means each sample may well take on a different, unpredictable value. For example, in a photon-counting experiment the outcome might be the detected number of counts. The outcomes of an experiment can be arbitrarily parsed into a chosen number of *events*. For example, the outcomes of a photon-counting experiment could be binned into three possible events: A_1 : the measured number of counts n is less than N_0 , A_2 : n is equal to N_0 , or A_3 : n is greater than N_0 . In this example, the events A_1 , A_2 , and A_3 are called *mutually exclusive* because the occurrence of one event on a trial precludes the others from occurring due to their disjoint nature. The set of all possible events for an experiment is termed the *event space* or *sample space*, denoted S . The event space we have set up for our photon-counting example is clearly arbitrary; we could just as well have designated each allowable value for n as an event. Each possible event associated with an experiment can be thought of as a sample point in the sample space. Every experiment has a *certain event*, though, which is the union of all events in the event space.

C.1.2 Concepts from set theory

Events and event spaces are central concepts in probability. We often find that we are interested not only in single events and event spaces for an experiment, but also in combinations of events and relationships between event spaces. It is natural to use the language of set theory for this purpose.

Let S denote the sample space of an experiment. Any possible outcome ζ of the experiment is said to be a member of the space S . This set membership is represented mathematically by $\zeta \in S$.

When an experiment has been performed and we say that some event A has occurred, this signifies that the outcome ζ of the experiment satisfies the conditions that specify event A . As in the photon-counting example of the previous section, some outcomes in S signify that event A occurred, while other outcomes signify that the event did not occur. Thus, any event can be regarded as a subset of the possible outcomes in the space S .

It is said that an event A is contained in another event B (or $A \subset B$) if every outcome that belongs to the subset defining the event A also belongs to the subset defining the event B . Equivalently, we say that A is a subset of B . For example, if A is the event that the number of photons detected in time t is less than N_1 , and B is the event that the number of photons detected in the same interval is less than N_2 , and $N_1 \leq N_2$, then A is contained in B .

If two events are defined such that A is contained in B and B is contained in A , then it follows that $A = B$. It is also easy to demonstrate that if A is contained in B and B is contained in the event C , then A is contained in C .

Some events are impossible. We cannot detect a negative number of photons, and physical constraints limit the maximum density of an image recorded on film. A subset that contains no outcomes is called the empty set and is denoted \emptyset .

Set theory operations In the sections below we present the basic relationships between various event combinations in the language of set theory. We shall build on these concepts in later sections of this appendix as we develop similar concepts regarding relationships between two or more random variables.

Union. The union of the events A and B is defined to be the set that contains all outcomes in either A or B or both; the union operation is a logical OR operation. The union operation is written $A \cup B$. Figure C.1 is a *Venn* diagram demonstrating the union operation. The following relationships involving the union of events are easily verified:

$$\text{Commutative law: } A \cup B = B \cup A. \quad (\text{C.1a})$$

$$\text{Associative law: } A \cup (B \cup C) = (A \cup B) \cup C = A \cup B \cup C. \quad (\text{C.1b})$$

$$\text{Union with itself: } A \cup A = A. \quad (\text{C.1c})$$

$$\text{Union with empty set: } A \cup \emptyset = A. \quad (\text{C.1d})$$

$$\text{Union with sample space: } A \cup S = S. \quad (\text{C.1e})$$

Intersection. The intersection operation, denoted $A \cap B$, results in the set of outcomes common to both A and B . This operation is also depicted graphically in Fig. C.1. The intersection operation is the logical AND operation. The following relationships are easily shown to be true:

$$\text{Commutative law: } A \cap B = B \cap A. \quad (\text{C.2a})$$

$$\text{Associative law: } (A \cap B) \cap C = A \cap (B \cap C) = A \cap B \cap C. \quad (\text{C.2b})$$

$$\text{Distributive law: } A \cap (B \cup C) = (A \cap B) \cup (A \cap C). \quad (\text{C.2c})$$

$$\text{Intersection with itself: } A \cap A = A. \quad (\text{C.2d})$$

$$\text{Intersection with empty set: } A \cap \emptyset = \emptyset. \quad (\text{C.2e})$$

$$\text{Intersection with sample space: } A \cap S = A. \quad (\text{C.2f})$$

Now we can define mutual exclusivity in set theory terms: A and B are mutually exclusive or disjoint if $A \cap B = \emptyset$.

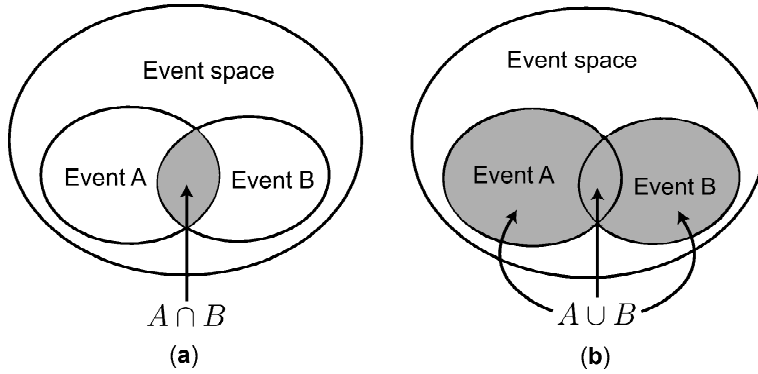

Fig. C.1 (a) A Venn diagram demonstrating the intersection operation as the shaded region where events A and B overlap. (b) A Venn diagram demonstrating the union operation; the shaded area is the union of event spaces A and B .

Complement. The complement of set A , denoted \bar{A} , is defined as the set consisting of all elements of S that are not in A . Then

$$\bar{\emptyset} = S; \tag{C.3a}$$

$$\bar{S} = \emptyset; \tag{C.3b}$$

$$A \cup \bar{A} = S; \tag{C.3c}$$

$$A \cap \bar{A} = \emptyset. \tag{C.3d}$$

De Morgan law. Using the Venn diagram of Fig. C.2, one can see that

$$\overline{(A \cup B)} = \bar{A} \cap \bar{B} \tag{C.4a}$$

and

$$\overline{(A \cap B)} = \bar{A} \cup \bar{B}. \tag{C.4b}$$

These relationships are useful because they tell us that in any set identity, when we replace unions with intersections, intersections with unions, and sets with their complements, the resulting identity also holds. We shall find use for the De Morgan law as we develop relationships between event probabilities in the sections below.

Partitions. A collection of events A_1, A_2, \dots, A_n is said to partition the sample space S if and only if

$$A_1 \cup A_2 \cup \dots \cup A_n = S \tag{C.5a}$$

and

$$A_i \cap A_j = \emptyset \quad \text{for} \quad i \neq j. \tag{C.5b}$$

Fields We have defined events as collections of outcomes in an event space S . In the sections to follow we shall set the stage for assigning probabilities to events. We shall therefore restrict our attention to certain sets of events that are said to comprise a *field*. A field \mathcal{F} is a set of events such that:

1. If $A_i \in \mathcal{F}$, then $\overline{A_i} \in \mathcal{F}$.
2. If $A_i \in \mathcal{F}$ and $A_j \in \mathcal{F}$, then $A_i \cup A_j \in \mathcal{F}$.

A *Borel field* \mathcal{B} has the property that if the events A_1, A_2, \dots, A_k are contained in \mathcal{B} , then the events $\{A_1 \cap A_2 \cap \dots \cap A_k\}$ and $\{A_1 \cup A_2 \cup \dots \cup A_k\}$ are also contained in the field. One of the important properties of Borel fields is the assurance that whenever one considers set operations such as intersections and unions on the events, the resulting sets are also events for which probabilities can be assigned.

Fig. C.2 A Venn diagram illustrating the De Morgan law. The area with hatching in both directions is the complement of $A \cup B$. The region with hatching in either or both directions is the complement of $A \cap B$.

C.1.3 Definitions of probability

Each event A associated with an experiment has some probability of occurrence, denoted $\Pr(A)$. Much debate has centered on the issue of the assignment and interpretation of probability. As we describe in the Prologue, there are two major schools, known as the frequentists and Bayesians, with ardently defended positions regarding the assignment of probabilities. In the Prologue we discuss in some detail the controversy between these camps and our own philosophy toward the assignment of probabilities for problems in imaging. Here we briefly give several definitions of probability before presenting the axiomatic framework that will guide the rest of the appendix.

Relative frequency A useful definition of probability is based on the relative frequency of an experimental outcome, and a person who adopts this approach is referred to as a *frequentist*. In this school, probability is determined by repeatedly performing an experiment and counting the number of times the outcome actually occurs.

In frequentist parlance, if event A occurs $m(A)$ times in M trials, the relative frequency of the event is the number of occurrences of the event divided by the number of trials, $m(A)/M$. As the number of trials of an experiment approaches infinity, the probability of a particular event is the limit of the relative frequency of that event:

$$\Pr(A) = \lim_{M \rightarrow \infty} \frac{m(A)}{M}. \quad (\text{C.6})$$

Those who propound this definition of probability emphasize its objectivity and the verifiability of the probability of some event A through experimental confirmation.

Ensemble definition In reality it is rarely practical to repeat an experiment a large number of times, and it is often impossible to duplicate the exact experimental conditions. An alternative conceptual approach is to postulate an infinite collection of identical experiments, called an *ensemble*, and to define probability as the frequency of occurrence of an event within the ensemble. Thus (C.6) still applies but with $m(A)$ interpreted as the number of members of the ensemble for which A occurs.

The ensemble definition of probability was first advanced by the physicist J. Willard Gibbs in the context of statistical mechanics. In that application, the ensemble is the set of possible states of a system of indistinguishable particles; an event is one possible set of state variables for the system. The famous Boltzmann-Gibbs distribution describes the equilibrium solution, that is, the distribution of energies for a system in thermal or mechanical equilibrium.

Classical definition The classical definition specifies a probability as the ratio of the number of favorable outcomes to the total number of possible outcomes for an experiment. For example, the roll of a six-sided die has six possible outcomes, three of which are favorable to an even event. The classicist would therefore conclude that the probability of an even event is $3/6 = 1/2$. Classical probability is distinct from the relative-frequency approach in that the favorable outcomes are counted in advance of the performing of an experiment. While classical probability is also considered to be objective, it is limited to situations where the experimental outcomes are equally likely, thereby rendering this definition useful only in situations where a symmetry is present between the various possible outcomes. In addition, the approach is not applicable when the number of outcomes is nondenumerable. Even when the number of outcomes is finite, one can imagine problems in specifying the possible outcomes and assuring their equal likelihood.

Subjective interpretation: Bayesian approach The Bayesian approach is founded on a subjective or personal interpretation of probability. In this approach probability is a measure of the weight of some belief. For example, a student believes he will get an A in a course based on some subjective assessment of his odds. This definition is used routinely by our judicial system when the jury is charged with determining whether or not a defendant is guilty beyond a reasonable doubt. Subjective probabilities can take on numerical values as well. A student can believe his probability of getting an A is 0.75, for example, based on information he has about the teacher and his own effort and ability. Note that while the frequentist interpretation of probability is in terms of real or hypothetical repeated trials of an experiment, a Bayesian's view departs from this picture radically. In the Bayesian world there is

no consideration of a collection of experiments; probability is a statement of belief about a single event. This is an important distinction between these two schools of probabilistic thought.

One might think that the subjective nature of this definition, where probability is based largely on intuition, makes it difficult to codify into a rigorous mathematical framework. (In fact, many authors refer to this definition as the intuitive interpretation of probability.) However, authors such as Savage (1954), De Groot (1970), and de Finetti (1974, 1975) have developed axiomatic systems of probability where the probability functions are interpreted subjectively but are still required to satisfy axioms such as those found in the next section, or some that are very similar.

C.1.4 Axiomatic approach

Regardless of how one chooses to assign probabilities to events, it will be necessary for our purposes that algebraic manipulation of the event probabilities be possible. This requirement is satisfied by requiring the probabilities of events to satisfy a number of axioms. Probabilities that satisfy such a system of axioms are sometimes referred to as *mathematical probabilities*. Mathematical probabilities may stem from any of the definitions of probability given above.

The axiomatic approach to probability begins by defining a function $\Pr(\cdot)$ such that each event A is assigned a number $\Pr(A)$ called the probability of event A . This function must satisfy the following conditions:

- I. $0 \leq \Pr(A) \leq 1$, or $\Pr(A)$ is nonnegative.
- II. The probability of the certain event is 1, that is, $\Pr(S) = 1$.
- III. If $A \cap B = \emptyset$, then $\Pr(A \cup B) = \Pr(A) + \Pr(B)$.

That is, the probability of occurrence of any of a set of mutually exclusive events is found by simply adding their individual probabilities.

The three properties given above are usually referred to as the Kolmogorov Axioms, after Andrei N. Kolmogorov (1903–1959), one of the fathers of modern probability theory. From the Kolmogorov axioms it is straightforward to derive other properties that event probabilities must obey, such as the following:

- IV. $\Pr(\emptyset) = 0$.
- V. $\Pr(\bar{A}) = 1 - \Pr(A)$.
- VI. $\Pr(A \cup B) = \Pr(A) + \Pr(B) - \Pr(A \cap B)$.

These relationships can be useful when calculating the probabilities associated with possible outcomes of more complicated experiments. It is left to the reader as an exercise to show that the relative-frequency definition of probability (C.6) satisfies Kolmogorov's axioms.

C.1.5 Joint probability

We are often interested in the probability that two events A and B both occur. We refer to this event as the joint event $(A \cap B)$. The corresponding probability $\Pr(A \cap B)$, also denoted $\Pr(A, B)$, is the joint probability. The joint probability of two events A and B can be written as either $\Pr(A, B)$ or $\Pr(B, A)$ since the AND operation is commutative as in (C.2a), meaning event order is not important. Joint probabilities must satisfy the same basic axioms as the probabilities of the individual events, $\Pr(A)$ and $\Pr(B)$.

C.1.6 Conditional probability

Often we shall be interested in the following question: Given that event B has occurred, what is the probability that event A has occurred? In other words, we are interested in the probability of the event A *conditioned* on the occurrence of event B . We denote this probability $\Pr(A|B)$, where the vertical bar is read *given* or *conditioned on*. In the Venn diagram of Fig. C.1, we are interested in the probability that an outcome is a member of the set of outcomes defining event A , assuming that it is a member of the sample space defined by event B . When considering conditional probabilities, we are essentially redefining the sample space by restricting it to only those outcomes that are contained in the event hypothesized to have occurred, in this case event B .

The conditional probability $\Pr(A|B)$ is found by dividing the joint probability $\Pr(A, B)$ of events A and B by the probability that event B has occurred:

$$\Pr(A|B) = \frac{\Pr(A, B)}{\Pr(B)}. \quad (\text{C.7})$$

If A and B are mutually exclusive, then

$$\Pr(A|B) = 0. \quad (\text{C.8})$$

On the other hand, if B implies A then

$$\Pr(A|B) = 1. \quad (\text{C.9})$$

Equation (C.7) can be generalized to more than two events as follows:

$$\Pr(A, B, C) = \Pr(A) \Pr(B|A) \Pr(C|A, B) \quad (\text{C.10})$$

and

$$\Pr(A_1, A_2, \dots, A_k) = \Pr(A_1) \Pr(A_2|A_1) \Pr(A_3|A_1, A_2) \cdots \Pr(A_k|A_1, A_2, \dots, A_{k-1}). \quad (\text{C.11})$$

Independent events Suppose that events A and B are defined in a sample space S and both $\Pr(A)$ and $\Pr(B)$ are greater than zero. Events A and B are called *statistically independent* if $\Pr(A|B) = \Pr(A)$. It then follows from (C.7) that

$$\Pr(A, B) = \Pr(A) \Pr(B) \quad (\text{C.12})$$

for statistically independent events.

Total probability If the set of events $\{B_i\}$ partitions the event space S [see (C.5)], and event A is also contained in S , then the total probability of event A can be found by summing the conditional probability of event A over all events $\{B_i\}$:

$$\Pr(A) = \sum_i \Pr(A|B_i) \Pr(B_i). \quad (\text{C.13})$$

C.1.7 Bayes' rule

Once the conditional probability $\Pr(A|B)$ has been defined by (C.7), it follows immediately that we can write the joint probability of events A and B as

$$\Pr(A, B) = \Pr(A|B) \Pr(B). \quad (\text{C.14})$$

We know from the properties of the intersection operation (C.2a) that $\Pr(A, B) = \Pr(B, A)$. Thus we can also express the joint probability in terms of the probability of event B conditioned on event A :

$$\Pr(A, B) = \Pr(B|A) \Pr(A). \quad (\text{C.15})$$

Equating (C.14) and (C.15) yields

$$\Pr(A|B) \Pr(B) = \Pr(B|A) \Pr(A), \quad (\text{C.16})$$

which leads to

$$\Pr(B|A) = \frac{\Pr(A|B) \Pr(B)}{\Pr(A)}. \quad (\text{C.17})$$

More generally, if the set of events $\{B_i\}$ partition S then we can use the total probability rule of (C.13) to show that

$$\Pr(B_j|A) = \frac{\Pr(A|B_j) \Pr(B_j)}{\sum_i \Pr(A|B_i) \Pr(B_i)}. \quad (\text{C.18})$$

Equation (C.18) is known formally as Bayes' rule, after Thomas Bayes (1704–1761), an English mathematician and philosopher. In Sec. C.4.3 below and throughout the text we shall say more about the applicability of Bayes' rule for drawing inferences about the occurrence of events using prior information and measured data.

C.2 SINGLE RANDOM VARIABLES

C.2.1 Definition of a random variable

In many scientific experiments the outcomes are numbers, such as the density of film at some spatial location or the number of photons that arrive at a detector within some time interval. The sample description space in the first example is the set of nonnegative real numbers, while in the second example it is confined to the set of nonnegative integers.

To use a numerical quantity to represent the outcome of an experiment, a mapping is needed from the original sample space S to the set of real numbers.¹ Suppose we have a sample space S with a probability function $\Pr(\cdot)$ defined on events in that sample space. A *random variable* x is a function that maps S onto the set of real numbers. That is, we observe $x = x'$ if and only if the outcome of the experiment is a $\zeta \in S$ such that $x(\zeta) = x'$. Then

$$\Pr(x = x') = \Pr\{\zeta \in S : x(\zeta) = x'\}. \quad (\text{C.19})$$

Equation (C.19) is a formal definition of the probability function for the random variable x . In order for the probability function of (C.19) to satisfy the Kolmogorov Axioms, every event must be *measurable*. This requirement is met provided (Papoulis, 1991)

1. The set $\{x \leq x'\}$ is an event for any real number x' ;
2. The probabilities of the events $\{x = \infty\}$ and $\{x = -\infty\}$ equal 0.

A function that satisfies the above requirements is called measurable in the field \mathcal{B} (see C.1.2).

As an example of a mapping to the set of real numbers, consider the experiment of tossing a coin. In this case there are two possible outcomes on each trial, either a head or a tail. A real-valued random variable can be associated with this experiment by assigning the numerical value 1 to the outcome if a head should result; if the outcome is a tail it is assigned the value 0. In this way the experimental outcomes are mapped to real values. Sometimes the outcome of an experiment is a numerical value that can be used as the random variable with no other mapping required. Such is the case, for example, if we are interested in the voltage across a resistor. The measured voltage V is the random variable of interest.

Notation Many books rigorously indicate random variables by using a special type font or by using capital letters (with the corresponding lower-case letter signifying a sample or a particular realization of the random variable). Though appealing in theory, this device runs into difficulty in practice.

One problem is that equations involving random variables are inherently ambiguous. If, for example, we write $y = ax + b$, where x and y have been identified as random variables and a and b are fixed parameters, the equation can mean that any particular realization of x , say $x = x_0$, is associated with a corresponding realization of y , namely $y = y_0 \equiv ax_0 + b$. Since this functional association holds for all realizations, it can as well be said to hold for the random variables themselves.

Another difficulty arises in imaging, as well as in many other physical applications, where it is not always clear whether a given quantity should be treated as a random variable. For example, an object to be imaged can be regarded either as fixed but unknown, as a spatial random process described by some known or unknown probability law, or as one sample function of such a random process. No matter which of these viewpoints we adopt, the equation describing the imaging

¹We have deliberately restricted our discussion here to real random variables. Complex random variables are addressed in Chap. 8.

system has the same form (and the same ambiguity attaches to the image as to the object). If a particular operator equation relates an object to its image, it does so in the same way no matter whether we think of the object as nonrandom or as one sample function of a random process. And if we think of presenting an entire ensemble of random objects to the imaging system, the same operator can be used to compute the corresponding ensemble of images.²

Since it does not seem worthwhile to incorporate typographic distinctions that have no effect on the mathematical operations involved, we simply denote scalar random variables by italicized upper or lower case characters, just as for any other scalar mathematical variable. Vector random variables (discussed only briefly here but more thoroughly in Chap. 8) will be denoted by boldface lower-case letters, just as for any other vector. When it is necessary to distinguish a particular realization from the general random variable, the realization will be denoted either with a subscript or prime or by using a different case, but such situations will arise infrequently.

Discrete random variables In the coin-tossing example above, the random variable describing the outcome of the experiment took on isolated values, *i.e.*, either 0 or 1. Such a variable is called a *discrete random variable*. Formally, a random variable x is said to be discrete if x takes on only a finite number k of values $\{x_1, x_2, \dots, x_k\}$ or, at most, a countably infinite set $\{x_i, i = 1, \dots, \infty\}$ of such values. For a discrete random variable that can take on the values $\{x_i\}$, the probability of each outcome is denoted by $\Pr(x = x_i)$ or the shorthand $\Pr(x_i)$. It can be shown that

$$\sum_i \Pr(x = x_i) = 1, \quad (\text{C.20})$$

where the sum is over the set of all possible values of i . This normalization is a consequence of the second Kolmogorov axiom.

Continuous random variables In some experiments the random variable of interest can take on a continuum of possible values, as in the example of the voltage across a resistor mentioned above. Variables of this type are known as *continuous random variables*.

A convenient way of describing the statistical properties of a continuous random variable is in terms of the *probability density function* (PDF), denoted $\text{pr}(\cdot)$. This function is defined in terms of the probability that the random variable assumes a value within some specified small range of values. That is,

$$\text{pr}(x_0) \equiv \lim_{\Delta x \rightarrow 0} \frac{1}{\Delta x} \Pr(x_0 - \frac{1}{2}\Delta x \leq x \leq x_0 + \frac{1}{2}\Delta x). \quad (\text{C.21})$$

In other words, for vanishingly small Δx , $\text{pr}(x_0)\Delta x$ gives the probability that the random variable x takes on a value that is within $\pm\frac{1}{2}\Delta x$ of the particular value x_0 .

The PDF can be used to calculate the probability that the random variable x falls in the finite interval (a, b) by dividing the interval into small, mutually exclusive elements of width Δx . Equation (C.21) then leads to

$$\Pr(a \leq x \leq b) = \int_a^b \text{pr}(x') dx'. \quad (\text{C.22})$$

²In this discussion we are not considering either measurement noise or randomness in \mathcal{H} .

Since x is constrained to lie in the interval $(-\infty, \infty)$, it must be true that

$$\int_{-\infty}^{\infty} \text{pr}(x') dx' = 1, \quad (\text{C.23})$$

by Kolmogorov's second axiom.

C.2.2 Probability density functions

Although defined most naturally for continuous random variables, PDFs can be used also for discrete ones if we allow delta functions. Consider a random variable x that takes on the discrete set of values $\{x_i\}$. We can define a PDF for x by:

$$\text{pr}(x) = \sum_i \text{Pr}(x_i) \delta(x - x_i), \quad (\text{C.24})$$

where $\delta(x - x_i)$ is a Dirac delta function and, as before, $\text{Pr}(x_i)$ is the *probability* (not density) that random variable x takes on the specific value x_i . We shall follow this typographic distinction consistently: lower-case $\text{pr}(\cdot)$ will denote a PDF and capital $\text{Pr}(\cdot)$ a probability.

To demonstrate the consistency of the definition in (C.24), we make use of some elementary properties of delta functions (see Chap. 2). Consider first a region $a < x \leq b$ that contains no allowed value of x . The probability that x falls in this region is given by the integral in (C.22). Since a delta function vanishes unless its argument is zero, which never happens over the postulated region, this integral is identically zero, as it must be since the region contains no allowed values.

Next consider a region of width 2ϵ around an allowed value, say x_j , and assume that ϵ is small enough that the region contains no other allowed values. From (C.22) and (C.24), the probability that x lies in this region is

$$\text{Pr}(x_j - \epsilon < x < x_j + \epsilon) = \int_{x_j - \epsilon}^{x_j + \epsilon} dx' \sum_i \text{Pr}(x_i) \delta(x' - x_i) = \text{Pr}(x_j), \quad (\text{C.25})$$

where the last step used the sifting property of the delta function, (2.23). Thus (C.25) shows that the probability that x lies in the small region around x_j , as computed from the density (C.24), is the same as the probability that x is precisely equal to x_j .

Finally, consider a region that contains two allowed values, say x_j and x_k . The sifting property of delta functions now shows that the probability that x lies in this region is $\text{Pr}(x_j) + \text{Pr}(x_k)$, which, according to Kolmogorov Axiom III, is just the probability that x is either x_j or x_k .

Thus the delta-function density defined by (C.24) contains exactly the same information about the discrete random variable x as does the original probability law $\text{Pr}(x_i)$.

C.2.3 Cumulative distribution function

Every measurable random variable x has an associated function called the cumulative distribution function of x , denoted $F(x)$. The cumulative distribution function of the random variable x is defined for any real number c by

$$F(c) = \text{Pr}(x \leq c). \quad (\text{C.26})$$

That is, $F(c)$ is the probability that the random variable x is less than or equal to c . That $F(x)$ exists is a condition for a measurable random variable, according to the properties of such random variables given in Sec. C.2.1. The definition (C.26) holds true for all values of c , even though it encompasses values of c that may not be attainable by the random variable x . For example, the random variable may not be able to take on negative values. Then (C.26) would result in the finding that $F(c) = 0$ for $c < 0$. Or, for a discrete random variable, the value of c may not be one of the values of x_i the variable can assume. Applying (C.26) in that instance would result in the sum of the probabilities $\Pr(x = x_i)$ for all $x_i < c$.

The cumulative distribution has the following properties:

$$F(c_1) \leq F(c_2) \quad \text{if} \quad c_1 < c_2, \tag{C.27a}$$

$$\lim_{c \rightarrow -\infty} F(c) = 0, \tag{C.27b}$$

$$\lim_{c \rightarrow \infty} F(c) = 1. \tag{C.27c}$$

Equation (C.27a) says that the distribution function is a nondecreasing function of c . This property holds since for every $c_1 < c_2$ the event $\{x \leq c_1\}$ is contained in the event $\{x \leq c_2\}$ and so the probability of the event $\{x \leq c_2\}$ must be at least as great. The proofs for (C.27b) and (C.27c) are based on the fact that x must be measurable, so it must take on some finite value [$\Pr(x = -\infty) = \Pr(x = \infty) = 0$], and the probability of the certain event, $\Pr(x < \infty)$, is 1.

The cumulative distribution function is useful for describing the probability that a random variable lies within some interval. It can be shown that

$$\Pr(c_1 < x \leq c_2) = F(c_2) - F(c_1) \quad \text{for all} \quad c_1 < c_2. \tag{C.28}$$

We can distinguish among continuous and discrete random variables depending on the form of the cumulative distribution function, specifically, whether derivatives of $F(x)$ exist for every value of x . A discrete random variable has a distribution function $F(x)$ with a staircase form and discontinuities at the points x_i as shown in Fig. C.3. A continuous random variable has a continuous cumulative distribution function as shown in Fig. C.4.

Fig. C.3 The cumulative distribution function of a discrete random variable.

For continuous random variables we can derive the probability that x takes on some particular value by allowing the interval in (C.28) to become arbitrarily small,

leading to the definition of the PDF in terms of the derivative of the cumulative distribution function:

$$\text{pr}(x) = \frac{dF(x)}{dx}. \quad (\text{C.29})$$

This, in turn, leads to the following result:

$$F(x) = \int_{-\infty}^x \text{pr}(x') dx'. \quad (\text{C.30})$$

For discrete random variables we have an analogous expression for the cumulative distribution function:

$$F(x) = \sum_{x_i \leq x} \text{Pr}(x_i). \quad (\text{C.31})$$

Equations (C.29) and (C.30) also hold for the discrete case if we allow generalized functions. As we indicated below (C.28), the cumulative distribution function for a discrete random variable has a staircase form, which can be expressed as a sequence of step functions. If we make use of the fact that the derivative of a step function is a delta function (see Chap. 2), we see that taking the derivative of $F(x)$ in (C.29) yields the delta functions of (C.24). Similarly, performing the integration operation of (C.30) on a series of delta functions gives back the staircase form for $F(x)$.

From (C.29)–(C.31) we see that the cumulative distribution function contains the same information as the PDF. For continuous random variables, the PDF $\text{pr}(x)$ can be thought of as a mass density along the real x axis. That is, $\text{pr}(x) dx$ represents the mass in the interval $(x, x + \Delta x)$. In the discrete case, the impulses $\text{pr}(x_i) \delta(x - x_i)$ can be thought of as point masses of weight $\text{pr}(x_i)$ at locations x_i . We know from Kolmogorov's axioms that these masses are positive and that the sum of all mass along the real line is 1. The probability that the random variable x takes on a value in the interval (a, b) is the mass in that interval. The mass in the interval $(-\infty, x)$ is the distribution function $F(x)$.

Fig. C.4 The cumulative distribution function of a continuous random variable.

C.2.4 Expectations

The PDF and cumulative distribution function are complete descriptions of the behavior of a random variable, but we are often interested in summary measures

of this behavior. The most important single descriptor of a random variable is its *expected value*, which is also referred to as the *mean* of the random variable. The expected value of the random variable x will be written as $E\{x\}$, $\langle x \rangle$ or \bar{x} ; these notations will be used interchangeably.

A discrete random variable x has an expected value defined by

$$E\{x\} = \sum_i x_i \Pr(x_i), \quad (\text{C.32})$$

where the sum is over all possible values of x_i . We see that the expected value is a weighted average of the possible values of x_i , where the weights are the probabilities that the random variable takes on each of those values. Note that, for a discrete random variable that takes on only integer values, its mean can take on any value in $(0, \infty)$.

A continuous random variable x has an expected value defined by

$$E\{x\} = \int_{-\infty}^{\infty} x \text{pr}(x) dx, \quad (\text{C.33})$$

where $\text{pr}(x)$ is the PDF for x . This definition applies to discrete random variables as well when (C.24) is used to define the PDF for the discrete random variable.

The *median* of a random variable, x_{med} , is defined as the value of x for which the cumulative distribution function $F(x_{med}) = \Pr(x \leq x_{med})$ is equal to 1/2. The value of the random variable is thus equally likely to be either greater than or less than the median.

A *mode* of a random variable, x_{mode} , is a value of x for which $\text{pr}(x)$ takes on a local maximum. A *unimodal* PDF has a single maximum and thus a single mode. When $\text{pr}(x)$ has an absolute maximum but also another local maximum at an equal or lower value, it is said to be *bimodal*. A probability density can have a locally flat region and therefore an infinite number of modes. Certain estimators, called maximum *a posteriori* estimators, make particular use of the mode of a PDF (see Chap. 13).

The mean of a random variable specifies the center of gravity of $\text{pr}(x)$. Another important parameter is the *variance*, which is a measure of the spread of the random variable about its mean. The variance, σ^2 , is defined by

$$\sigma^2 = \text{Var}\{x\} = E\{(x - \bar{x})^2\} = \int_{-\infty}^{\infty} (x - \bar{x})^2 \text{pr}(x) dx. \quad (\text{C.34})$$

Note that

$$\sigma^2 = E\{x^2\} - \bar{x}^2. \quad (\text{C.35})$$

The positive square root σ is referred to as the *standard deviation*.

Chebyshev inequality Let x be an arbitrary random variable with mean \bar{x} and finite variance σ^2 . Then the Chebyshev inequality, given to us by the Russian mathematician P. L. Chebyshev (1821–1894), provides a bound on the probability that

x deviates from its mean by an amount $\delta > 0$. From the definition of variance we have

$$\begin{aligned}\sigma^2 &\equiv \int_{-\infty}^{\infty} (x - \bar{x})^2 \text{pr}(x) dx \geq \int_{|x - \bar{x}| \geq \delta} (x - \bar{x})^2 \text{pr}(x) dx \\ &\geq \delta^2 \int_{|x - \bar{x}| \geq \delta} \text{pr}(x) dx = \delta^2 \Pr(|x - \bar{x}| \geq \delta).\end{aligned}\quad (\text{C.36})$$

Thus

$$\Pr(|x - \bar{x}| \geq \delta) \leq \frac{\sigma^2}{\delta^2}.\quad (\text{C.37})$$

Moments The behavior of a random variable can be further specified in terms of its *moments*, with the k^{th} moment defined by

$$m_k = \text{E}\{x^k\} = \int_{-\infty}^{\infty} x^k \text{pr}(x) dx.\quad (\text{C.38})$$

By the Schwarz inequality, $m_1^2 \leq m_2$ for any probability law.

Central moments The k^{th} *central moment* μ_k of a random variable is defined by

$$\mu_k = \text{E}\{(x - \bar{x})^k\} = \int_{-\infty}^{\infty} (x - \bar{x})^k \text{pr}(x) dx.\quad (\text{C.39})$$

Thus for any random variable $\mu_0 = 1$, $\mu_1 = 0$, and $\mu_2 = \sigma^2$.

The *skewness* of a random variable, given by

$$\text{Skewness} = \frac{\mu_3}{\mu_2^{3/2}},\quad (\text{C.40})$$

measures the lack of symmetry of the PDF. The *kurtosis* (Greek *kurtos*, convex, swelling) of a random variable, given by

$$\text{Kurtosis} = \frac{\mu_4}{\mu_2^2},\quad (\text{C.41})$$

measures the flatness or peakedness of the corresponding PDF. Skewness and kurtosis are sometimes used to describe the shapes of distributions for pattern recognition applications (Pratt, 1991).

Factorial moments Suppose n is a nonnegative, integer-valued random variable. The k^{th} *factorial moment* of n is given by

$$c_k = \text{E}\{n(n-1)\cdots(n-k+1)\} = \sum_{n=0}^{\infty} n(n-1)\cdots(n-k+1) \text{Pr}(n) = \sum_{n=0}^{\infty} \frac{n!}{k!} \text{Pr}(n).\quad (\text{C.42})$$

The first factorial moment c_1 is simply the mean m_1 , and the second factorial moment is related to the mean and variance by

$$c_2 = \sigma^2 + m_1^2 - m_1.\quad (\text{C.43})$$

One example of the applicability of the factorial moments in optics is in the description of the statistics of the number of photoelectrons emitted by a photosensitive surface upon which a light source is incident (Helstrom, 1995). Factorial moments come in when calculating the probability that more than a threshold number of counts are detected in a particular time interval.

Cumulants The *cumulants* (also called the *semi-invariants*) of a random variable are defined by

$$\exp \left[\sum_{k=1}^{\infty} \kappa_k \frac{t^k}{k!} \right] = \sum_{k=0}^{\infty} m_k \frac{t^k}{k!}, \quad (\text{C.44})$$

where the m_k are the ordinary moments defined in (C.38). By expanding the left-hand side, and equating coefficients for equal powers of t , the reader can generate relationships between the cumulants and the ordinary moments. Of most interest, the first-order cumulant is the mean and the second-order cumulant is the variance of the random variable.

The cumulants are given their name because a random variable z formed by summation of a set of independent random variables $\{x_i\}$ will have cumulant κ_k equal to the sum of the cumulants of the underlying random variables for each value of k (Helstrom, 1995). The cumulants of the $\{x_i\}$ can thus be used to derive the PDF of z for cases where the PDFs of the underlying random variables are unknown. First the cumulants of the $\{x_i\}$ are determined (via a fitting algorithm); the sum of the cumulants gives the cumulants of z , which are then used to solve for the PDF of z .

C.3 FUNCTIONS OF A SINGLE RANDOM VARIABLE

We are often interested in a function of the outcome of an experiment, rather than the outcome itself. For example, we might want to know the square of the voltage across a resistor, where the voltage is itself a random variable. Probabilities can also be assigned to random variables derived from functions of random experimental outcomes.

C.3.1 Transformation of PDFs

Suppose x is a random variable with PDF $\text{pr}_x(x)$. Any function $y = f(x)$ results in a new random variable whose probabilistic behavior depends on the form of $f(x)$ and the PDF of x . If the function $f(x)$ is monotonic, then it is one-to-one and onto, so that each x is mapped to only one y and each y can come from at most one x . Such functions are the easiest to work with, for they allow us to use a general formula for transforming the density function describing x to compute a density function for the random variable y . We must put one additional requirement on $f(x)$, and that is that $f^{-1}(y)$ must have a continuous derivative. The PDF for y is then determined by

$$\text{pr}_y(y) dy = \text{pr}_x(x) dx, \quad (\text{C.45a})$$

or

$$\text{pr}_y(y) = \text{pr}_x[f^{-1}(y)] \left| \frac{d}{dy} f^{-1}(y) \right|, \quad (\text{C.45b})$$

for all y in the range of $f(x)$. The absolute value appears in the second line because dx and dy in the first line are defined to be always positive. (We use subscripts on the density functions here to distinguish which function describes the behavior of x and which applies to y . Some books use such subscripts routinely. We shall use

them only when confusion might otherwise arise as to which variable the density function describes.)

Equation (C.45) has applicability even if $f(x)$ is not monotonic, as long as $f(x)$ is monotonic over intervals for which (C.45) can be used. For example, suppose $y = x^2$ and we restrict y to be greater than 0. Then $f^{-1}(y) = \pm\sqrt{y}$, $|df^{-1}(y)/dy| = 1/(2\sqrt{y})$ and

$$\text{pr}_y(y) = \frac{1}{2\sqrt{y}} [\text{pr}_x(\sqrt{y}) + \text{pr}_x(-\sqrt{y})]. \quad (\text{C.46})$$

Thus the PDF of y is a sum representing the two monotonic intervals of $f(x)$. Many more examples on the use of (C.45) for transforming density functions can be found in Frieden (1991), Casella and Berger (1990) and Stark and Woods (1986).

C.3.2 Expected values

If y is a measurable function of the random variable x , the expected value of $y = f(x)$ can be computed from

$$\text{E}\{y\} = \int_{-\infty}^{\infty} f(x) \text{pr}(x) dx. \quad (\text{C.47})$$

As a simple example, suppose $y = ax$. Then $\langle y \rangle = a\langle x \rangle$ and $\langle y^2 \rangle = a^2\langle x^2 \rangle$, so that the variance of y is related to the variance of x according to the relationship $\sigma_y^2 = a^2\sigma_x^2$. This is a specific consequence of the fact that the process of taking expectations is a linear operation. More generally, if $f_1(x)$ and $f_2(x)$ are two functions for which expectations exist, then

$$\text{E}\{af_1(x) + bf_2(x) + c\} = a\text{E}\{f_1(x)\} + b\text{E}\{f_2(x)\} + c \quad (\text{C.48})$$

for any constants a , b , and c .

Jensen's Inequality A function $f(x)$ of a nonrandom variable x is said to be convex in an interval I if, in that interval, $d^2f(x)/dx^2$ is greater than or equal to zero. Jensen's Inequality (Rade and Westergren, 1990) states that for a set of constants λ_i and a convex function $f(x)$,

$$f(x_1\lambda_1 + \cdots + x_n\lambda_n) \leq \lambda_1f(x_1) + \cdots + \lambda_nf(x_n) \quad (\text{C.49})$$

for $\sum_{i=1}^n \lambda_i = 1$ and $\lambda_i \geq 0$.

Now suppose $f(x)$ is a convex function of a random variable x . Given the mean of the random variable, $\bar{x} = \text{E}\{x\}$, Jensen's Inequality allows us to say the following about the mean of the function:

$$f(\text{E}\{x\}) \leq \text{E}\{f(x)\}. \quad (\text{C.50})$$

This expression can be verified by rewriting (C.47) using the elementary definition of integration and recognizing that the resulting factors, $\Delta x \text{pr}(x_i)$, play the role of the λ_i in (C.49).

Taylor series A differentiable function of a random variable x can be expanded in a Taylor series about \bar{x} to give

$$f(x) = \sum_k \frac{f^k(\bar{x})}{k!} (x - \bar{x})^k. \quad (\text{C.51})$$

Taking the expectation of both sides and keeping only terms through second order, we find

$$\langle f(x) \rangle = f(\bar{x}) + \frac{1}{2} \sigma_x^2 f''(\bar{x}). \tag{C.52}$$

C.3.3 Generating functions

Characteristic function The characteristic function of the real-valued random variable x is defined by

$$\psi(\xi) \equiv \mathbb{E} \{ e^{-2\pi i \xi x} \} = \int_{-\infty}^{\infty} dx \operatorname{pr}(x) e^{-2\pi i \xi x}. \tag{C.53}$$

It is evident from (C.53) that the characteristic function and the PDF form a Fourier transform pair. Thus the characteristic function uniquely determines the PDF. This relationship was called *Ein Schönes Theorem der Wahrscheinlichkeitsrechnung* by Gauss (1900). The PDF is written in terms of an inverse Fourier transform of $\psi(\xi)$ as

$$\operatorname{pr}(x) = \int_{-\infty}^{\infty} d\xi \psi(\xi) e^{2\pi i \xi x}. \tag{C.54}$$

Many authors choose to define the characteristic function as the expectation of $\exp(+2\pi i \xi t)$ or $\exp(+i \xi t)$. Since in imaging applications the random variable of interest is often the spatial position or time of an event, our definition (C.53) maintains the convention we use throughout this book: the forward Fourier transform maps the spatial or temporal domain to the spatial or temporal frequency domain.

The definition of $\psi(\xi)$ in terms of the expectation of $\exp(-2\pi i \xi x)$ leads naturally to the realization that moments of the random variable x can be derived through differentiation of $\psi(\xi)$:

$$\mathbb{E} \{ x^k \} = (-2\pi i)^{-k} \left. \frac{\partial^k}{\partial \xi^k} \psi(\xi) \right|_{\xi=0}. \tag{C.55}$$

This is the moment-generating property of the characteristic function. It is often much easier to perform the differentiation required in (C.55) than to do the integration of (C.38) in order to calculate the moments of x . As we shall see in Sec. C.4.5, the characteristic function can also be very useful in determining the PDF for sums of random variables.

Moment-generating function The *moment-generating function* $M(t)$ is related to the characteristic function by a simple change of variables. The moment-generating function of a random variable x is defined by

$$M(t) = \psi \left(-\frac{t}{2\pi i} \right) = \mathbb{E} \{ e^{xt} \} = \int_{-\infty}^{\infty} dx \operatorname{pr}(x) e^{xt}. \tag{C.56}$$

Many authors define the moment-generating function and the characteristic function with the same sign in the exponential. The negative exponential in our definition of $\psi(\xi)$ results from having defined the characteristic function as the forward Fourier transform of the PDF (C.53).

As its name suggests, the moment-generating function can be used to compute moments:

$$\mathbb{E} \{ x^k \} = \left. \frac{\partial^k}{\partial t^k} M(t) \right|_{t=0}. \tag{C.57}$$

Thus the k^{th} derivative of the moment-generating function, when evaluated at zero, allows the determination of the k^{th} moment.

The moment-generating function can also be expressed in terms of a Taylor series in t about the origin:

$$M(t) = \sum_{k=0}^{\infty} \frac{1}{k!} \mathbf{E}\{x^k\} t^k. \quad (\text{C.58})$$

The coefficients in the series can be seen to be proportional to the moments of the random variable x . This Taylor series representation is valid provided the series converges and all derivatives of $M(t)$ exist.

The primary use of the moment-generating function is to characterize PDFs. If the set of moments of a random variable x is unique (in that there is only one PDF with this set of moments) then the moment-generating function may be used to determine the probability density function for x (Helstrom, 1995). In general, however, two distribution functions with the same moments need not be the same. The reader interested in delving into this issue more deeply can find many related theorems and examples in Shiryayev (1984).

The moment-generating function is the two-sided Laplace transform (4.77) of the inverted PDF for x . That is,

$$M(t) = \int_{-\infty}^{\infty} dt \operatorname{pr}(-x) e^{-xt} = \mathcal{L}_{\mathbf{a}_2}\{\operatorname{pr}(-x)\}. \quad (\text{C.59})$$

Thus the inverse Laplace transform given in (4.78) can be used to derive the PDF on x given $M(t)$.

Cumulant-generating function The *cumulant-generating function* for a random variable x is related to the moment-generating function through a logarithm:³

$$S(t) = \ln M(-t) = \ln\langle e^{-xt} \rangle. \quad (\text{C.60})$$

The cumulant-generating-function can be used to obtain the cumulants according to

$$\kappa_k = (-1)^k \left. \frac{\partial^k}{\partial t^k} S(t) \right|_{t=0}. \quad (\text{C.61})$$

Probability-generating function We are often interested in nonnegative integer-valued random variables, for example when we are concerned with photon-counting statistics in detectors. Such variables are described by a set of probabilities $\operatorname{pr}(n)$ for each possible value of n . The characteristic function then takes on the form

$$\psi(\xi) = \langle e^{-2\pi i \xi n} \rangle = \sum_{n=0}^{\infty} \operatorname{Pr}(n) e^{-2\pi i \xi n} = \sum_{n=0}^{\infty} \operatorname{Pr}(n) (e^{-2\pi i \xi})^n. \quad (\text{C.62})$$

We see that the summation is in the form of a power series in $\exp(-2\pi i \xi)$. If we let the complex variable z replace $\exp(-2\pi i \xi)$ we can write

$$\langle z^n \rangle = \sum_{n=0}^{\infty} \operatorname{Pr}(n) z^n = \Phi(z). \quad (\text{C.63})$$

³The minus sign in (C.58) is the result of our definition of the moment-generating function, which differs from Helstrom in the sign in the exponent of (C.53).

This is the defining equation for $\Phi(z)$, the probability-generating function for the integer-valued random variable n . From (C.63) we see that $\Phi(z)$ resembles the z transform (4.88) of $\text{Pr}(n)$, but with z^n in place of z^{-n} . Since (C.62) has the form of a complex Taylor series where the probabilities are the coefficients, comparison with (B.44) shows that

$$\text{Pr}(n) = \frac{1}{n!} \left. \frac{\partial^n}{\partial z^n} \Phi(z) \right|_{z=0}. \tag{C.64}$$

Hence the name probability-generating function.

Generation of factorial moments We again consider a nonnegative, integer-valued random variable n with a probability-generating function $\Phi(z)$. The factorial moments c_k [cf. (C.42)] can be obtained via differentiation of $\Phi(z)$:

$$\begin{aligned} c_k &= E\{n(n-1)(n-2)\cdots(n-k+1)\} = \sum_{n=0}^{\infty} n(n-1)(n-2)\cdots(n-k+1) \text{Pr}(n) \\ &= \left. \frac{\partial^k}{\partial z^k} [\Phi(z)] \right|_{z=1}. \end{aligned} \tag{C.65}$$

Thus $\Phi(z)$ can be used to generate factorial moments rather than probabilities by the simple expedient of evaluating the derivatives at 1 rather than 0. A function that generates factorial moments would logically be called the *factorial-moment-generating function*, but to avoid ugly hyphenation we shall refer to it simply as the FMGF.

C.3.4 Integrals of functions of random variables

The expected value of a random variable $y = f(x)$ is usually computable from a Riemann integral of the form (C.47). There is no difficulty in evaluating this integral when we can divide the range of integration into successively smaller intervals without concern for how the intervals are chosen. The rub comes when the summand is a function such that the value of the integral does in fact depend on how the subdivisions are chosen. For example, suppose $f(x)$ is a mapping of the form

$$f(x) = \begin{cases} 0 & \text{if } x \text{ is rational} \\ 1 & \text{if } x \text{ is irrational} \end{cases}. \tag{C.66}$$

We need to be able to integrate functions of this type in order to find the expectations of such events, but the process of integrating by cutting the x axis into smaller and smaller pieces and doing the sum will not give an answer independent of where the cuts fall. To remedy this difficulty we make use of the concepts of measure spaces and Lebesgue integration, as presented by Papoulis (1965).

The integral (C.47) can be rewritten, with the elementary definition of integration, as

$$\begin{aligned} E\{f(x)\} &= \int_{-\infty}^{\infty} dx f(x) \text{pr}(x) = \lim_{\Delta x \rightarrow 0} \sum_{k=-\infty}^{\infty} \Delta x f(x_k) \text{pr}(x_k) \\ &= \lim_{\Delta x \rightarrow 0} \sum_{k=-\infty}^{\infty} f(x_k) \text{Pr}(x_k - \frac{1}{2}\Delta x \leq x \leq x_k + \frac{1}{2}\Delta x), \end{aligned} \tag{C.67}$$

where $x_k = k\Delta x$, and we have used (C.21) in the last step. Equation (C.67) is a sum in terms of differential events $\{x_k - \frac{1}{2}\Delta x \leq x \leq x_k + \frac{1}{2}\Delta x\}$ that are mutually exclusive; their union is the certain event S . The expectation $E\{f(x)\}$ is obtained by multiplying the probability of each differential event by the value of the function when that event is true, followed by summing over all such events. The resulting limit, obtained when $\Delta x \rightarrow 0$, is the Lebesgue integral in the space S :

$$E\{f(x)\} = \int_S f(x) dF, \quad (\text{C.68})$$

where $F(x)$ is the cumulative distribution function defined in Sec. C.2.3. Only events with nonzero measure in S (those that have finite probability) contribute to the expected value.

Lebesgue integration is one possible solution to the inadequacy of Riemann integration. Another approach is to use the theory of distributions, which is presented in Chap. 2. In that chapter we show that the derivative of a step function is a delta function. Then the definition of the PDF in terms of the derivative of the cumulative distribution function (C.29) holds even for discrete variables in a generalized sense.

C.3.5 Relationship between probability spaces and measure spaces

We have invoked terms from the theory of measure spaces as well as those from the realm of probability. Friedman (1991) presents the following table correlating terms used in the discussion of probability spaces to those of measure spaces:

Sample probability space	Normalized measure space
Elementary event	Element in space
Event	Measure space in A
Certain event	S
Impossible event	\emptyset
Probability of $A = \Pr(A)$	Measure of $A = \mu(A)$
Almost surely	Almost everywhere
Random variable x	Bounded measurable function x
Expected value of x	Lebesgue integral of x
Limit in probability	Limit in measure
Limit almost surely	Limit almost everywhere

C.4 TWO RANDOM VARIABLES

In this section we extend our discussion of random variables to include descriptions of the outcomes of two or more experiments, or two or more repetitions of the same experiment. Random variables considered two at a time can be considered to be two-dimensional random vectors, or bivariate random vectors. Chapter 8 extends the concepts of this section to higher dimensionality.

C.4.1 Joint probability

In Sec. C.1.5 we used the language of set theory to write the joint probability of two events. The concepts developed there require only minor notational changes for use in the description of random variables considered jointly. Suppose we are interested in an experiment involving two continuous random variables denoted x and y . Their joint PDF is written $\text{pr}(x, y)$. This PDF is properly normalized if it satisfies

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \text{pr}(x', y') dx' dy' = 1. \quad (\text{C.69})$$

The two-dimensional cumulative distribution function is written

$$F(x, y) = \int_{-\infty}^x \int_{-\infty}^y \text{pr}(x', y') dx' dy'. \quad (\text{C.70})$$

The joint PDF is related to the two-dimensional cumulative distribution function by

$$\text{pr}(x, y) = \frac{\partial^2}{\partial x \partial y} F(x, y), \quad (\text{C.71})$$

the two-dimensional analogue of (C.29).

Similar expressions result for discrete random variables:

$$\Pr(x_i \text{ and } y_i) = \Pr(x_i, y_i) \quad (\text{C.72})$$

is the joint probability that the discrete random variables x and y take on the values x_i and y_i . Proper normalization requires that

$$\sum_{x_i} \sum_{y_i} \Pr(x_i, y_i) = 1, \quad (\text{C.73})$$

where the sums run over all possible values of x_i and y_i . The cumulative distribution function for a discrete two-dimensional probability is

$$F(x, y) = \Pr(x_i \leq x, y_i \leq y) = \sum_{x_i \leq x} \sum_{y_i \leq y} \Pr(x_i, y_i). \quad (\text{C.74})$$

In the next sections, expressions will be given only for continuous random variables. As we have just seen, as well as earlier in Sec. C.2, expressions for discrete random variables can be obtained from their continuous counterparts by replacing the continuous integrals of (C.70) and (C.69) with sums over the allowed values of the discrete random variables.

C.4.2 Marginal and conditional probability

When an experiment involves two (or more) random variables, we often find ourselves interested in the statistics of one particular random variable, regardless of the behavior of the other. The *marginal probability* of random variable x is found by integrating the joint density of x and y over all possible values for y :

$$\text{pr}(x) = \int_{-\infty}^{\infty} \text{pr}(x, y) dy. \quad (\text{C.75})$$

Marginal probabilities are used to compute probabilities or expectations of a single random variable exactly as discussed in Sec. C.2 and Sec. C.3.

Another important kind of probability is the *conditional probability*, as discussed earlier in Sec. C.1.6. The conditional probability density of x given y , written $\text{pr}(x|y)$, is found by dividing the joint probability density $\text{pr}(x, y)$ by the probability density of y :

$$\text{pr}(x|y) = \frac{\text{pr}(x, y)}{\text{pr}(y)}. \quad (\text{C.76})$$

The total probability of x is found by integrating the joint probability of x and y over all possible values of y :

$$\text{pr}(x) = \int_{-\infty}^{\infty} \text{pr}(x|y) \text{pr}(y) dy. \quad (\text{C.77})$$

Often we are interested in the PDF on a random variable x conditioned on a particular event A , written $\text{pr}(x|A)$. More generally, if a set of events $\{A_i\}$ partitions the event space, then the total probability $\text{pr}(x)$ is a weighted sum of the conditional probabilities:

$$\text{pr}(x) = \sum_i \text{pr}(x|A_i) \Pr(A_i). \quad (\text{C.78})$$

The resulting density function $\text{pr}(x)$ is called a *mixture* PDF because it is a mixture or linear combination of probability densities.

Statistical independence Two random variables are said to be statistically independent if the value of one of them has no influence on the other. When two random variables are independent, it follows that their joint PDF takes the form

$$\text{pr}(x, y) = \text{pr}(x) \text{pr}(y). \quad (\text{C.79})$$

It can be shown that the two-dimensional cumulative distribution function of two independent random variables also factors:

$$F(x, y) = F(x) F(y). \quad (\text{C.80})$$

C.4.3 Bayes' rule

Bayes' rule was introduced in Sec. C.1.7 above. It can be obtained in terms of two continuous random variables by combining (C.76) and (C.77) to give

$$\text{pr}(x|y) = \frac{\text{pr}(y|x) \text{pr}(x)}{\int_{-\infty}^{\infty} \text{pr}(y|x) \text{pr}(x) dx}. \quad (\text{C.81})$$

C.4.4 Expectations, joint moments and covariance

The expected value of x conditioned on a particular value of y is obtained as follows:

$$E\{x|y\} = \int_{-\infty}^{\infty} dx x \text{pr}(x|y). \quad (\text{C.82})$$

The conditional expectation can be averaged over the variable on which it is conditioned to determine the expectation of the other random variable:

$$E\{x\} = \int_{-\infty}^{\infty} dy E\{x|y\} \text{pr}(y). \quad (\text{C.83})$$

The variance of a single variable can be derived from conditional expectations as follows:

$$\begin{aligned} \text{Var}\{x\} &= \left\langle \left\langle (x - \langle x \rangle_{x|y})^2 \right\rangle_{x|y} \right\rangle_y \\ &= \left\langle \left\langle (x - \langle x \rangle_{x|y} + \langle x \rangle_{x|y} - \langle x \rangle_{x|y})^2 \right\rangle_{x|y} \right\rangle_y \\ &= \left\langle \left\langle (x - \langle x \rangle_{x|y})^2 \right\rangle_{x|y} \right\rangle_y + \left\langle \left\langle (\langle x \rangle_{x|y} - \langle x \rangle_{x|y})^2 \right\rangle_{x|y} \right\rangle_y \\ &= E_y\{\text{Var}\{x|y\}\} + \text{Var}_y\{E\{x|y\}\}, \end{aligned} \quad (\text{C.84})$$

where subscripts have been added to the variance and expectation on the last line as a reminder that they apply to the y variable.

The *covariance* of two random variables is defined to be

$$\text{Cov}\{x, y\} \equiv E\{(x - \langle x \rangle)(y - \langle y \rangle)\} = E\{xy\} - \langle x \rangle \langle y \rangle. \quad (\text{C.85})$$

If x and y are independent, their covariance is 0.

The *correlation coefficient* ρ of two random variables is defined by

$$\rho = \frac{\text{Cov}\{x, y\}}{\sqrt{\sigma_x^2 \sigma_y^2}}. \quad (\text{C.86})$$

If x and y are independent, their correlation coefficient is 0 and x and y are said to be *uncorrelated*. However, the converse is not true; a correlation coefficient of 0 does not imply statistical independence.

Let x and y be independent random variables, and consider two functions $g(x)$ and $h(y)$, where $g(x)$ is a function only of x and $h(y)$ is a function only of y . Then

$$E\{g(x)h(y)\} = E\{g(x)\}E\{h(y)\}. \quad (\text{C.87})$$

This relationship can be verified using (C.79):

$$\begin{aligned} E\{g(x)h(y)\} &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \text{pr}(x, y) g(x) h(y) dx dy \\ &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \text{pr}(x) \text{pr}(y) g(x) h(y) dx dy \\ &= \int_{-\infty}^{\infty} \text{pr}(x) g(x) dx \int_{-\infty}^{\infty} \text{pr}(y) h(y) dy = E\{g(x)\}E\{h(y)\}. \end{aligned} \quad (\text{C.88})$$

C.4.5 Functions of two random variables

In Sec. C.3.1 a method was presented for determining the PDF for a function $f(x)$ of the random variable x . We are often interested in functions of the form $z = f(x, y)$ and $h(u, v) = f(x, y)$. In the following sections we describe methods for determining the PDF of functions of two random variables.

One function of two random variables We start by considering a simple function z of two random variables x and y . The cumulative distribution of z , $F_z(z')$, represents the probability that $f(x, y) = z$ is less than or equal to z' . There is some region Ω of the event space for which this condition is satisfied. That is, the event $\{z \leq z'\}$ is equal to the event $\{(x, y) \in \Omega\}$. Integration of the joint probability density function $\text{pr}(x, y)$ over the region Ω gives $F_z(z)$:

$$F_z(z) = \iint_{(x,y) \in \Omega} \text{pr}_{xy}(x, y) \, dx \, dy. \quad (\text{C.89})$$

There will be instances where knowledge of the joint PDF $\text{pr}_{xy}(x, y)$ and the form of $f(x, y)$ are enough to allow determination of $\text{pr}_z(z)$. (In principle this is always true, although in practice cranking through the integral in (C.89) can be quite difficult.) Further on in this section we shall describe a second approach that provides an alternative solution strategy, which is through the use of characteristic functions. We shall first apply (C.89) to two special cases, where z is first the sum and then the product of two random variables. Our treatment follows that of Stark and Woods (1986).

Example 1: Functions of the form $z = x + y$ Suppose two independent random variables x and y are summed to form the random variable z . We next show that the PDF for z in this special case is given by the convolution of the PDFs for x and y .

The cumulative distribution function for z gives the probability that z is less than some value:

$$\begin{aligned} F_z(z) &= \iint_{x+y \leq z} \text{pr}_{xy}(x, y) \, dx \, dy = \int_{-\infty}^{\infty} dy \int_{-\infty}^{z-y} \text{pr}_{xy}(x, y) \, dx \\ &= \int_{-\infty}^{\infty} [I_{xy}(z - y, y) - I_{xy}(-\infty, y)] \, dy, \end{aligned} \quad (\text{C.90})$$

where $I_{xy}(x, y)$ is the indefinite integral

$$I_{xy}(x, y) = \int_{-\infty}^x \text{pr}_{xy}(x', y) \, dx'. \quad (\text{C.91})$$

Differentiation of $F_z(z)$ yields the PDF of z :

$$\text{pr}_z(z) = \frac{dF_z(z)}{dz} = \int_{-\infty}^{\infty} \frac{d}{dz} [I_{xy}(z - y, y)] \, dy = \int_{-\infty}^{\infty} \text{pr}_{xy}(z - y, y) \, dy. \quad (\text{C.92})$$

This is a general result; we have not yet invoked the independence of x and y . The independence of x and y implies that the joint probability factors, giving

$$\text{pr}_z(z) = \int_{-\infty}^{\infty} \text{pr}_x(z - y) \text{pr}_y(y) \, dy. \quad (\text{C.93})$$

Integrals of this form, called convolutions, are discussed in more detail in Chap. 3. Equation (C.93) is expressed by saying that the PDF of a sum of independent random variables is the convolution of the density functions of the underlying random variables.

Whenever a random variable is formed from the sum of two or more random variables, the mean of the result is the sum of the means of the underlying random variables. That is, if $z = x + y$, then $\bar{z} = \bar{x} + \bar{y}$. Moreover, if the underlying variables are independent, the variances of the underlying variables add. Thus, for $z = x + y$ with x and y independent,

$$\sigma_z^2 = \sigma_x^2 + \sigma_y^2. \tag{C.94}$$

Let us now extend the example to that of a weighted sum of random variables. Let $z = ax + by$, where the coefficients a and b are nonrandom and the x and y are random. The expected value of z is given by

$$\begin{aligned} E\{z\} &= E\{ax + by\} = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy (ax + by) \text{pr}(x, y) \\ &= \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy ax \text{pr}(x, y) + \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy by \text{pr}(x, y). \end{aligned} \tag{C.95}$$

Each integral in the last line of (C.95) results in a marginal probability by (C.75):

$$E\{z\} = \int_{-\infty}^{\infty} dx ax \text{pr}_x(x) + \int_{-\infty}^{\infty} dy by \text{pr}_y(y) = a\bar{x} + b\bar{y}. \tag{C.96}$$

Thus for any random variable that is formed as a weighted sum of random variables, the expected value of the sum is given by the weighted sum of the means of the underlying random variables. While (C.94) requires that x and y be independent, (C.96) holds for any correlation relationship between x and y .

The process that allowed us to simplify (C.95) by integrating out all but one of the random variables from the joint probability is called *marginalization*. We will find this technique to be quite useful in the treatment of random processes in Chap. 8 and beyond.

Example 2: Functions of the form $z = xy$ To find the PDF for this case, we start as we did in the previous example by first determining the cumulative distribution function for z . Since $F_z(z)$ represents the probability that z is less than some value, we need to determine the boundaries of the region Ω that defines the event $z = xy \leq z'$. Region Ω is bounded by contours of constant z in x - y space given by hyperbolae of the form $y = z/x$ (see Fig. C.5). The integral of (C.89) becomes

$$F_z(z) = \int_0^{\infty} dy \int_{-\infty}^{z/y} \text{pr}_{xy}(x, y) dx + \int_{-\infty}^0 dy \int_{z/y}^{\infty} \text{pr}_{xy}(x, y) dx \quad \text{for } z \geq 0. \tag{C.97}$$

Let $I_{xy}(x, y)$ again be the indefinite integral defined in (C.91). Equation (C.97) can then be rewritten for $z \geq 0$ as

$$F_z(z) = \int_0^{\infty} dy [I_{xy}(z/y, y) - I_{xy}(-\infty, y)] + \int_{-\infty}^0 dy [I_{xy}(\infty, y) - I_{xy}(z/y, y)]. \tag{C.98}$$

Differentiation of $F_z(z)$ yields the PDF for z :

$$\text{pr}_z(z) = \frac{dF_z(z)}{dz} = \int_{-\infty}^{\infty} \frac{1}{|y|} \text{pr}_{xy}(z/y, y) dy, \quad z \geq 0. \tag{C.99}$$

It can be shown that this expression is also valid for $z < 0$. If x and y are statistically independent, the joint probability in (C.99) factors and the density function for z becomes

$$\text{pr}_z(z) = \int_{-\infty}^{\infty} \frac{1}{|y|} \text{pr}_x(z/y) \text{pr}_y(y) dy, \quad z \geq 0. \quad (\text{C.100})$$

This expression is similar to the convolution result of (C.93), except that the shift $z - y$ is replaced by the ratio z/y . Expressions of this sort are known as Mellin convolutions; Mellin transforms are treated in more detail in Sec. 4.2.2.

Fig. C.5 The boundaries of the region Ω that define the event $z = xy \leq z'$. Region Ω is bounded by contours of constant z in x - y space given by hyperbolae of the form $y = z/x$.

Characteristic functions We return now to the subject of our first example. Consider again two independent random variables x and y with characteristic functions $\psi_x(\xi)$ and $\psi_y(\xi)$. The characteristic function of the random variable $z = x + y$ is given by

$$\psi_z(\xi) = \text{E} \{ e^{-2\pi i \xi z} \} = \text{E} \{ e^{-2\pi i \xi (x+y)} \} = \text{E} \{ e^{-2\pi i \xi x} \} \text{E} \{ e^{-2\pi i \xi y} \} = \psi_x(\xi) \psi_y(\xi), \quad (\text{C.101})$$

where we have made use of (C.87) to factor the expectation into functions of x and y . We found earlier that the density function for z was the convolution of the density functions for x and y . Equation (C.101) demonstrates that the characteristic function for z is the product of the characteristic functions for x and y . This relationship is as we should expect given that the characteristic function and the PDF form a Fourier transform pair (C.53). By virtue of the convolution theorem (3.132) we know that convolutions are transformed to simple products through Fourier transformation.

A similar derivation would show that if x and y are independent, with moment-generating functions $M_x(t)$ and $M_y(t)$, then the moment-generating function of the random variable $z = x + y$ is given by $M_z(t) = M_x(t) M_y(t)$.

Two functions of two random variables Suppose we have two continuous random variables, x and y , and two functions of those random variables $u = f_1(x, y)$ and $v = f_2(x, y)$. We are interested in the joint probability density $\text{pr}_{uv}(u, v)$ of the new bivariate random vector (u, v) . In this section we present a bivariate extension of

the transformation of PDFs presented for functions of single random variables in Sec. C.3.1.

We assume that the functions $f_1(x, y)$ and $f_2(x, y)$ are differentiable and that they are also one-to-one and onto (see Sec. 1.3.4). Then the inverse mappings $x = h_1(u, v)$ and $y = h_2(u, v)$ are known to exist. The role played by the derivative in the univariate case [*cf.* (C.45)] is now played by the *Jacobian* of the transformation. The Jacobian, denoted J , is the determinant of the matrix of partial derivatives:

$$J = \det \begin{pmatrix} \frac{\partial x}{\partial u} & \frac{\partial x}{\partial v} \\ \frac{\partial y}{\partial u} & \frac{\partial y}{\partial v} \end{pmatrix} = \frac{\partial x}{\partial u} \frac{\partial y}{\partial v} - \frac{\partial x}{\partial v} \frac{\partial y}{\partial u}, \quad (\text{C.102})$$

where

$$\frac{\partial x}{\partial u} = \frac{\partial h_1(u, v)}{\partial u} \quad (\text{C.103a})$$

$$\frac{\partial x}{\partial v} = \frac{\partial h_1(u, v)}{\partial v} \quad (\text{C.103b})$$

$$\frac{\partial y}{\partial u} = \frac{\partial h_2(u, v)}{\partial u} \quad (\text{C.103c})$$

$$\frac{\partial y}{\partial v} = \frac{\partial h_2(u, v)}{\partial v}. \quad (\text{C.103d})$$

Then, in direct analogy with (C.45), the joint PDF for (u, v) takes the form

$$\text{pr}_{uv}(u, v) = \text{pr}_{xy}[h_1(u, v), h_2(u, v)] |J|, \quad (\text{C.104})$$

where J is assumed to be nonzero on the event space $\{x, y\}$.

C.5 CONTINUOUS PROBABILITY LAWS

C.5.1 Univariate normal

One of the most commonly encountered probability laws is the normal law, written in standard univariate form as

$$\text{pr}(x) = \left(\frac{1}{2\pi\sigma^2} \right)^{\frac{1}{2}} \exp \left[-\frac{x^2}{2\sigma^2} \right], \quad -\infty < x < \infty. \quad (\text{C.105})$$

This law is also commonly referred to as the Gaussian probability density, after the German mathematician and physicist Carl Friedrich Gauss (1777–1855). We shall use normal and Gaussian interchangeably. The normal law is used to model phenomena in almost all branches of science, including the distributions of height and weight in children, the IQ of a population, and the noise in some kinds of images. Its usefulness stems in part from the ease with which it can be manipulated, as well as its approximation to other distributions, as we shall see in later sections. Furthermore, under very weak assumptions it can be shown that a random variable formed by summing a set of other random variables is approximately normal (Sec. 10.3.5). Figure C.6 shows the familiar bell-shaped appearance of the normal distribution.

Fig. C.6 The standard normal distribution.

We shall first show that (C.105) is properly normalized. For normalization as a PDF we require

$$\left(\frac{1}{2\pi\sigma^2}\right)^{\frac{1}{2}} \int_{-\infty}^{\infty} \exp\left[-\frac{x^2}{2\sigma^2}\right] dx = 1. \quad (\text{C.106})$$

The integral shown above cannot be solved immediately since $\exp(-x^2)$ does not have an antiderivative. There is, however, a simple solution: the normalization integral can be manipulated into the form of a perfect differential by squaring and transforming to polar coordinates. The result is just the integral of an exponential, and we find immediately

$$\int_{-\infty}^{\infty} \exp\left[-\frac{x^2}{2\sigma^2}\right] dx = (2\pi\sigma^2)^{\frac{1}{2}}, \quad (\text{C.107})$$

and so the PDF of (C.105) is indeed properly normalized.

Moments The mean of the PDF of (C.105) is zero because of the even symmetry and strong convergence of the integrand. The mean can be shifted to an arbitrary value \bar{x} by writing

$$\text{pr}(x) = \left(\frac{1}{2\pi\sigma^2}\right)^{\frac{1}{2}} \exp\left[-\frac{(x-\bar{x})^2}{2\sigma^2}\right]. \quad (\text{C.108})$$

The symmetry now shifts to the point \bar{x} , making the first moment about \bar{x} equal to zero. That \bar{x} is indeed the first moment about the origin can be verified by letting $x' = x - \bar{x}$.

We calculate the second moment about the mean as

$$\langle (x - \bar{x})^2 \rangle = \left(\frac{1}{2\pi\sigma^2}\right)^{\frac{1}{2}} \int_{-\infty}^{\infty} dx (x - \bar{x})^2 \exp\left[-\frac{(x - \bar{x})^2}{2\sigma^2}\right]. \quad (\text{C.109})$$

If we let $\beta = 1/2\sigma^2$ the definite integral can be identified as the derivative of the normalization integral; that is,

$$\begin{aligned} \int_{-\infty}^{\infty} dx (x - \bar{x})^2 \exp\left[-\frac{(x - \bar{x})^2}{2\sigma^2}\right] &= -\frac{\partial}{\partial \beta} \int_{-\infty}^{\infty} dx \exp[-\beta(x - \bar{x})^2] \\ &= -\frac{\partial}{\partial \beta} \left(\frac{\pi}{\beta}\right)^{\frac{1}{2}} = \frac{1}{2}\pi^{\frac{1}{2}}\beta^{-\frac{3}{2}} = \frac{1}{2}\pi^{\frac{1}{2}}(2\sigma^2)^{\frac{3}{2}}. \end{aligned} \quad (\text{C.110})$$

Multiplying by the normalization constant in front of the integral in (C.109), namely, $1/\sqrt{2\pi\sigma^2}$, we obtain

$$\langle (x - \bar{x})^2 \rangle = \sigma^2. \tag{C.111}$$

We see therefore that the parameter σ^2 is the second moment of this density about the mean, *i.e.*, the variance. A random variable drawn from a normal distribution with parameters \bar{x} and σ^2 is denoted $x \sim \mathcal{N}(\bar{x}, \sigma^2)$. A standard normal random variable has mean 0 and variance 1 and is denoted $x \sim \mathcal{N}(0, 1)$.

By extending the previous steps we can show that all odd moments of this PDF about the mean are zero, and all even moments can be expressed in terms of σ^2 . In particular, by applying $\partial/\partial\beta$ once more, we immediately find the fourth central moment:

$$\langle (x - \bar{x})^4 \rangle = 3\sigma^4. \tag{C.112}$$

The kurtosis (C.41) of a Gaussian is thus 3. Distributions with kurtosis greater than 3 are more peaked than a Gaussian; they are referred to as *leptokurtic*. Kurtosis less than 3 yields a broader, flatter shape than that of a Gaussian; such distributions are referred to as *platykurtic*.

Cumulative distribution function Suppose we are given a normal random variable $x \sim \mathcal{N}(\bar{x}, \sigma^2)$ and we are interested in the probability that x is less than some value x' . The cumulative distribution contains this information:

$$F(x') = \Pr(x < x') = \left(\frac{1}{2\pi\sigma^2}\right)^{\frac{1}{2}} \int_{-\infty}^{x'} \exp\left[-\frac{(x - \bar{x})^2}{2\sigma^2}\right] dx. \tag{C.113}$$

We convert this expression to one involving a standard normal by a transformation of variables. Let $y = (x - \bar{x})/\sigma$ and $y' = (x' - \bar{x})/\sigma$. Then

$$\begin{aligned} F(x') &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{y'} \exp\left[-\frac{1}{2}y^2\right] dy \\ &= \frac{1}{\sqrt{2\pi}} \int_0^{y'} \exp\left[-\frac{1}{2}y^2\right] dy - \frac{1}{\sqrt{2\pi}} \int_0^{-\infty} \exp\left[-\frac{1}{2}y^2\right] dy = \frac{1}{2} \operatorname{erf}\left(\frac{y'}{\sigma\sqrt{2}}\right) + \frac{1}{2}, \end{aligned} \tag{C.114}$$

where the function

$$\operatorname{erf}(a) \equiv \frac{2}{\sqrt{\pi}} \int_0^a \exp[-t^2] dt \tag{C.115}$$

is called the *error function*. Many probability and statistics books contain tables of error functions to facilitate the evaluation of interval probabilities of the form $\Pr(a < x < b)$ for normal random variables. It should be noted that there is more than one definition in the literature for the error function.

Characteristic function We now derive the characteristic function of a normal random variable with mean equal to 0:

$$\begin{aligned} \psi(\xi) &= \mathbb{E}\{e^{-2\pi i \xi x}\} = \frac{1}{\sqrt{2\pi\sigma^2}} \int_{-\infty}^{\infty} e^{-2\pi i \xi x} \exp\left[-\frac{x^2}{2\sigma^2}\right] dx \\ &= \frac{1}{\sqrt{2\pi\sigma^2}} \mathcal{F}\left\{\operatorname{gaus}\left(\frac{x}{\sqrt{2\pi\sigma^2}}\right)\right\} = \exp(-2\pi^2 \xi^2 \sigma^2), \end{aligned} \tag{C.116}$$

where we have made use of the Fourier relationships for Gaussians given in (3.177)–(3.180). Equation (C.116) can be generalized to a Gaussian random variable with mean \bar{x} using the Fourier shift theorem (3.108).

C.5.2 Uniform distribution

A random variable is uniformly distributed if it has the following PDF:

$$\text{pr}(x) = \begin{cases} 1/(b-a), & a < x \leq b \\ 0, & \text{elsewhere} \end{cases} \quad (\text{C.117})$$

The real parameters a and b define the limits of the possible outcome values of the random variable. This density function is also sometimes called the rectangular distribution. For shorthand, we shall denote a random variable that is drawn from a uniform distribution by $x \sim \mathcal{U}(a, b)$. By symmetry, the mean of the random variable is the midpoint: $\langle x \rangle = (b+a)/2$. It can also be shown that $\sigma^2 = (b-a)^2/12$. One optical application of this PDF is the description of a speckle source with a random phase uniformly distributed over 2π , so that $a = 0$, $b = 2\pi$, and $\text{pr}(\theta) = 1/2\pi$.

C.5.3 Exponential distribution

The exponential probability law has many applications in imaging. It can be used to describe the random distribution of lifetimes of particles undergoing radioactive decay as well as the random intensity of a laser speckle pattern. A random variable x that has an exponential distribution has a PDF given by

$$\text{pr}(x) = \begin{cases} \beta^{-1}e^{-x/\beta}, & x \geq 0 \\ 0, & x < 0 \end{cases} \quad (\text{C.118})$$

This density is properly normalized since

$$\int_0^{\infty} \frac{1}{\beta} e^{-x/\beta} dx = 1. \quad (\text{C.119})$$

It can be shown that the expected value of x is β and its variance is β^2 .

The moment-generating function of an exponential random variable is

$$M(t) = \text{E} \{ e^{xt} \} = \frac{1}{\beta} \int_0^{\infty} e^{xt} e^{-x/\beta} dx = \frac{1}{1 - \beta t}. \quad (\text{C.120})$$

A simple change of variables yields the characteristic function:

$$\psi(\xi) = \text{E} \{ e^{-2\pi i \xi x} \} = \frac{1}{1 + 2\pi i \xi \beta}. \quad (\text{C.121})$$

C.5.4 Gamma and beta distributions

Gamma distribution The general form of the gamma probability density is written

$$\text{pr}(x) = \frac{x^{\alpha-1} e^{-x/\beta}}{\beta^{\alpha} \Gamma(\alpha)}, \quad 0 \leq x < \infty, \quad (\text{C.122})$$

where $\Gamma(\alpha)$ is the usual gamma function; for integer α , $\Gamma(\alpha) = (\alpha - 1)!$, but more generally $\Gamma(\alpha)$ is defined by

$$\Gamma(\alpha) = \int_0^\infty dx x^{\alpha-1} e^{-x}, \tag{C.123}$$

where $\alpha > 0$. A random variable that follows this law is said to be drawn from the $\Gamma(\alpha, \beta)$ law. The parameter α primarily influences the shape of the density function, while β primarily affects the scale of the PDF. It can be shown that the gamma density function is properly normalized since

$$\int_0^\infty x^{\alpha-1} e^{-x/\beta} dx = \beta^\alpha \Gamma(\alpha). \tag{C.124}$$

The mean of a gamma distribution is given by

$$E\{x\} = \frac{1}{\beta^\alpha \Gamma(\alpha)} \int_0^\infty x x^{\alpha-1} e^{-x/\beta} dx = \frac{1}{\beta^\alpha \Gamma(\alpha)} \beta^{\alpha+1} \Gamma(\alpha + 1) = \alpha\beta, \tag{C.125}$$

where we have made use of the normalization of the gamma distribution [cf. (C.123)] and definition (C.122). A similar derivation of $E\{x^2\}$ would involve a $\Gamma(\alpha + 2, \beta)$ distribution, with the final result that the variance of a gamma-distributed random variable is $\alpha\beta^2$.

The moment-generating function of a gamma-distributed random variable is given by

$$M(t) = \frac{1}{\beta^\alpha \Gamma(\alpha)} \int_0^\infty e^{xt} x^{\alpha-1} e^{-x/\beta} dx = \frac{1}{\beta^\alpha \Gamma(\alpha)} \Gamma(\alpha) \left[\frac{\beta}{1 - \beta t} \right]^\alpha = \left[\frac{1}{1 - \beta t} \right]^\alpha, \tag{C.126}$$

where we again have made use of (C.124). The characteristic function is thus given by

$$\psi(\xi) = E\{e^{-2\pi i \xi x}\} = \left[\frac{1}{1 + 2\pi i \xi \beta} \right]^\alpha. \tag{C.127}$$

It is left as an exercise for the reader to show that the gamma probability law describes a random variable formed by summing independent random variables that are each exponentially distributed. (*Hint*: Show that the product of N exponential moment-generating functions, each with exponential parameter β , gives the moment-generating function of a gamma distribution with $\alpha = N$.)

Beta distribution The beta function $B(\alpha, \beta)$, given by

$$B(\alpha, \beta) = \int_0^1 x^{\alpha-1} (1-x)^{\beta-1} dx, \tag{C.128}$$

can be used to form a family of distributions known as the beta family:

$$\text{pr}(x) = \frac{1}{B(\alpha, \beta)} x^{\alpha-1} (1-x)^{\beta-1}, \quad 0 < x < 1, \quad \alpha > 0, \quad \beta > 0. \tag{C.129}$$

From the definition of $B(\alpha, \beta)$ it is simple to show that the beta density function is properly normalized. The beta probability law is useful for describing contin-

uous random variables restricted to lie between 0 and 1. For this reason it is often used to describe proportions. It reduces to the uniform law $\mathcal{U}(0, 1)$ when $\alpha = \beta = 1$.

The beta function is related to the gamma function in the following way:

$$B(\alpha, \beta) = \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha + \beta)}. \quad (\text{C.130})$$

Thus it is often possible to make use of the properties of gamma functions when manipulating beta-distributed random variables.

The form of the beta probability law makes calculation of its moments particularly easy:

$$E\{x^n\} = \frac{1}{B(\alpha, \beta)} \int_0^1 x^n x^{\alpha-1} (1-x)^{\beta-1} dx = \frac{1}{B(\alpha, \beta)} B(\alpha + n, \beta) \quad (\text{C.131})$$

by the definition of the beta function (C.128).

In particular,

$$\langle x \rangle = \frac{\alpha}{\alpha + \beta} \quad \text{and} \quad \text{Var}\{x\} = \frac{\alpha\beta}{(\alpha + \beta)^2(\alpha + \beta + 1)}. \quad (\text{C.132})$$

C.5.5 Chi-squared random variables

Suppose we are given a standard normal random variable x . A new variable y , defined by $y = x^2$, is described by the chi-squared probability law. The form of this PDF for y can be determined using the law of transformation of PDFs of random variables (C.45):

$$\text{pr}_y(y) = \text{pr}_x(y) \left| \frac{dx}{dy} \right| = \frac{1}{\sqrt{2\pi y}} e^{-\frac{1}{2}y}. \quad (\text{C.133})$$

More generally, if a random variable z is given by a sum of independent random variables,

$$z = \sum_{i=1}^n x_i^2, \quad (\text{C.134})$$

where each of the $x_i \sim \mathcal{N}(0, 1)$, then

$$\text{pr}(z) = \frac{z^{(n-2)/2} e^{-z/2}}{2^{n/2} \Gamma(\frac{n}{2})}, \quad (\text{C.135})$$

where we have made use of the fact that $\Gamma(\frac{1}{2}) = \sqrt{\pi}$. This probability density is referred to as *chi-squared*, or χ^2 , with n *degrees of freedom*. We shall denote a random variable that is drawn from a chi-squared distribution of this form by $z \sim \chi_n^2$. It can be seen that the χ^2 distribution is a special case of the gamma distribution, with $\alpha = n/2$ and $\beta = 2$. The mean and variance of the chi-squared distribution can be determined from the results for the gamma distribution:

$$E\{z\} = n \quad \text{and} \quad \text{Var}(z) = 2n. \quad (\text{C.136})$$

Note that in the special case where $n = 2$, or $z = x^2 + y^2$, (C.135) reduces to the exponential law.

To derive the characteristic function, consider again the simple case where $y = x^2$. The characteristic function is the Fourier transform of the PDF for y [cf. (C.133)]:

$$\psi_y(\xi) = \frac{1}{\sqrt{2\pi}} \int_0^\infty \exp(-2\pi i \xi y) \exp\left(-\frac{y}{2}\right) y^{-1/2} dy. \quad (\text{C.137})$$

With the change of variables $x = \sqrt{y}$, this becomes

$$\begin{aligned} \psi_y(\xi) &= \frac{1}{\sqrt{2\pi}} \int_0^\infty \exp(-2\pi i \xi x^2) \exp\left(-\frac{x^2}{2}\right) 2 dx \\ &= \sqrt{\frac{2}{\pi}} \int_0^\infty \exp\left[-\frac{1}{2}x^2(1 + 4\pi i \xi)\right] dx = (1 + 4\pi i \xi)^{-1/2}. \end{aligned} \quad (\text{C.138})$$

The characteristic function of z , where z is again the sum of the squares of n mutually independent standard-normal random variables, is a generalization of (C.138):

$$\psi_z(\xi) = (1 + 4\pi i \xi)^{-n/2}. \quad (\text{C.139})$$

The chi-squared law is used in describing the statistics of the irradiance for coherent imaging systems.

C.5.6 Rayleigh density function

The *generalized Rayleigh* PDF describes the behavior of a random variable $z = \sqrt{\sum_{i=1}^n x_i^2}$, where the $\{x_i\}$ are i.i.d. drawn from a $\mathcal{N}(0, \sigma^2)$ PDF. This density function describes the distribution of Euclidian distances from the origin to the point in an n -dimensional space defined by the $\{x_i\}$.

The *Rayleigh density function* refers to the special 2D case, where $z = \sqrt{x^2 + y^2}$, and x and y are independent, zero-mean Gaussian random variables. The form of the PDF is given by

$$\text{pr}(z) = \frac{z}{\sigma^2} \exp\left(-\frac{z^2}{2\sigma^2}\right), \quad z \geq 0, \quad (\text{C.140})$$

where σ^2 is the variance of both x and y .

The PDF given in (C.140) describes the magnitude of a complex random variable z with real part x and imaginary part y . The Rayleigh PDF is encountered in phase-insensitive detection systems, where x and y are the real and imaginary parts of a random field. Lord Rayleigh (1880) originally derived this PDF while considering the random-walk problem as it relates to scattered fields in acoustics. Johnson *et al.* (1994) give many important developments and applications of the Rayleigh distribution. One use for the Rayleigh law is for describing the statistics of the modulus of the complex field on an observation plane illuminated by light from a coherently illuminated rough surface.

C.5.7 Rician density function

In this case the random variable is formed by $z = \sqrt{x^2 + y^2}$, only now $x \sim \mathcal{N}(A, \sigma^2)$ while $y \sim \mathcal{N}(0, \sigma^2)$. The resulting probability density for z can be shown to be

$$\text{pr}(z) = \frac{z}{\sigma^2} \exp\left[-\frac{1}{2} \frac{A^2 + z^2}{\sigma^2}\right] I_0\left(\frac{zA}{\sigma^2}\right), \quad z \geq 0, \quad (\text{C.141})$$

where $I_0(\cdot)$ is the zero-order modified Bessel function of the first kind. The PDF of (C.141) is called the *Rician* density function or sometimes the Rice-Nakagami density function (Rice, 1944, 1945). Rice derived this PDF in the analysis of a sinusoidal signal current of known amplitude in the presence of a noise current. Irradiance, or the squared modulus of a field, follows an exponential law [see (8.232)]. An imaging application of the Rician law arises in the characterization of the statistics of the modulus of the complex field for coherent systems without complete phase randomization.

C.5.8 K distribution

The K distribution is a generalization of the Rayleigh and Rician laws. Whereas the Rayleigh and Rician distributions result from the summation of Gaussian random variables, the K distribution is the solution when the underlying random variables follow a K distribution. The K distribution is written

$$\text{pr}(z) = \frac{2b}{\Gamma(N)} \left[\frac{bz}{2} \right]^N K_{N-1}(bz), \quad z \geq 0, \quad (\text{C.142})$$

where $b \geq 0$, $N > 0$, and $K_{N-1}(\cdot)$ is a modified Bessel function of the second kind with order $N - 1$. A family of K distributions is shown in Fig. C.7.

In a speckle problem, N is the number of reflectors and b is a scale parameter. As $N \rightarrow \infty$ the K distribution approaches a Rayleigh distribution.

Fig. C.7 A family of K distributions for $b = 5$ in (C.152).

C.5.9 Log-normal probability law

If the logarithm of a random variable obeys a univariate normal law, the variable itself is said to obey a log-normal law. Consider a random variable z defined by

$$z = Ae^x, \quad (\text{C.143})$$

or

$$x = \ln(z/A). \quad (\text{C.144})$$

The variable z is described by a log-normal probability law if x is normal. Note that a log-normal random variable is not the log of a normal one, but rather a random

variable whose log is normal. In fact, this distribution might better be called the *antilognormal* distribution since it describes the behavior of an exponential, that is, antilogarithmic function of a random variable.

To find the density for z , we assume $x \sim \mathcal{N}(\bar{x}, \sigma^2)$ and use the transformation rule (C.45). The result is

$$\text{pr}(z) = \frac{1}{\sqrt{2\pi} \sigma z} \exp \left[-\frac{(\ln z - \ln A - \bar{x})^2}{2\sigma^2} \right], \quad (z > 0). \quad (\text{C.145})$$

This density has three free parameters, A , \bar{x} and σ^2 . In terms of these parameters, the mean and variance of z are given by

$$\bar{z} = A \exp \left[\bar{x} + \frac{1}{2}\sigma^2 \right], \quad \text{Var}\{z\} = A^2 \exp(2\bar{x}) \left[e^{2\sigma^2} - e^{\sigma^2} \right]. \quad (\text{C.146})$$

The log-normal probability law often comes into play when a random variable z is the product of independent random variables:

$$z = \prod_{i=1}^N x_i. \quad (\text{C.147})$$

Thus

$$\ln z = \sum_{i=1}^N \ln x_i. \quad (\text{C.148})$$

Since $\ln x_i$ and $\ln x_j$ are statistically independent if x_i and x_j are, the right-hand side of (C.148) is the sum of N independent random variables. By the central-limit theorem (discussed in Chap. 8), the sum is approximately normal, so z is approximately a log-normal random variable.

The log-normal law can arise in the description of the pixel PDFs of reconstructions from tomographic data.

C.5.10 Distributions with infinite moments

There are probability laws that are important in optics that are not so easily manipulated to determine underlying moments and moment-generating functions. The next subsections describe three such interesting distributions.

1/x distribution The $1/x$ probability law has the form

$$\text{pr}(x) = \frac{K}{x}, \quad 0 < a \leq x \leq b. \quad (\text{C.149})$$

The normalization constant K can easily be determined:

$$K^{-1} = \int_a^b \frac{1}{x} dx = \ln(b) - \ln(a). \quad (\text{C.150})$$

The mean and variance of x are given by

$$\text{E}\{x\} = \int_a^b K dx = K(b - a) \quad (\text{C.151})$$

and

$$\text{Var}\{x\} = E\{x^2\} - [E\{x\}]^2 = \frac{K}{2}(b^2 - a^2) - K^2(b - a)^2. \quad (\text{C.152})$$

Note that the variance $\rightarrow \infty$ if $a \rightarrow 0$ or $b \rightarrow \infty$.

The $1/x$ distribution with $a = 0$ and $b = \infty$ is sometimes used in Bayesian inference problems when it is desirable to have a probability law that is independent of scale or units. Jeffreys (1961) advocated this distribution as a noninformative prior. The fact that the PDF cannot be normalized for $a = 0$ turns out not to be important, and $1/x$ is referred to as an *improper prior*.

Cauchy probability law A Cauchy random variable is described by the following PDF:

$$\text{pr}(x) = \frac{a}{\pi} \frac{1}{a^2 + x^2}, \quad -\infty < x < \infty. \quad (\text{C.153})$$

This probability law is named for Auguste Louis Cauchy (1789–1857), a French mathematician whose writings contributed greatly to many fields, including astronomy, optics, hydrodynamics, and function theory.

It is straightforward to verify that the Cauchy law is properly normalized. However, consider a Cauchy random variable with parameter $a = 1$. The evaluation of the expected value of this random variable leads to the integral

$$E\{x\} = \int_{-\infty}^{\infty} x \frac{1}{\pi} \frac{1}{1 + x^2} dx. \quad (\text{C.154})$$

This integral does not strictly exist since it is not absolutely convergent, but it is reasonable to interpret it as a Cauchy principal value (see Sec. B.3.9). With this interpretation,

$$E\{x\} = \mathcal{P} \int_{-\infty}^{\infty} x \frac{1}{\pi} \frac{1}{1 + x^2} dx = \lim_{c \rightarrow \infty} \left[\int_{-c}^c x \frac{1}{\pi} \frac{1}{1 + x^2} dx \right] = 0. \quad (\text{C.155})$$

Thus, with the principal-value interpretation, the mean is zero as expected from the symmetry of $\text{pr}(x)$.

The variance of a Cauchy random variable does not exist because

$$E\{x^2\} = \int_{-\infty}^{\infty} x^2 \frac{1}{\pi} \frac{1}{1 + x^2} dx \quad (\text{C.156})$$

fails to converge in any sense.

The characteristic function of a Cauchy random variable is given by

$$\psi(\xi) = \exp(-2\pi a|\xi|). \quad (\text{C.157})$$

The Cauchy law is useful for describing the distribution of light incident along a line below a point source. It can also be shown that the ratio of two independent random variables both drawn from standard normal distributions is a Cauchy random variable.

Lévy distributions Paul Lévy (1886–1971), a French mathematician, considered a generalized form of the central-limit theorem when he investigated the conditions under which a random variable $y = \sum_i^N x_i$, where all the x_i have distributions from

the same family, has a distribution from the same family. Distributions for which this occurs are called *Lévy*, *Lévy-stable*, or simply *stable* distributions.

The PDF of a Lévy distribution has no closed form in general. The moment-generating function of a Lévy distribution is given by (Feller, 1971)

$$M(\xi) = \exp(-b|\xi|^q), \quad (\text{C.158})$$

where q is the Lévy index ($0 < q \leq 2$) and b is a width parameter. When $q = 2$, the Lévy PDF is a Gaussian, and when $q = 1$ it is a Cauchy distribution. For $q < 2$ the tails of the density decrease sufficiently slowly that all moments beyond the first are divergent. Nevertheless, the width of the distribution can be described, and the parameter b performs this function. It follows from (C.101) that the sum of two independent Lévy random variables of index q and width b is another Lévy random variable of index q and width $2b$.

The name of the Italian sociologist Vilfredo Pareto is often connected to the Lévy distribution, hence Pareto-Lévy or Paretian distributions, owing to Pareto's investigation of income distributions using stable distributions. Mandelbrot (1960, 1963) made extensive use of stable distributions for analyzing financial time-series data. Lévy distributions have also been used to describe animal foraging paths and weather and earthquake patterns. In imaging, Lévy distributions are used to describe the outputs of bandpass or high-pass filters (see Sec. 8.4). Numerical routines are available for the simulation of Lévy distributions (Mantegna, 1994).

C.6 DISCRETE PROBABILITY LAWS

C.6.1 Bernoulli trials and binomial statistics

Bernoulli random variables In addition to the coin-tossing example given in Sec. C.2.1, there are many other examples of experiments where the outcome can be classified as either a success or failure and mapped to a random variable x accordingly. A success (*e.g.*, a head in the coin-tossing experiment) accords the value 1 to x , while a failure (a tail in the coin-tossing example) results in x being assigned the value 0. A random variable that is mapped to the set $\{0, 1\}$ according to the random outcome of an experiment is said to be a *Bernoulli* random variable. The probability law for a Bernoulli random variable is given by

$$\begin{aligned} \Pr(x = 0) &= 1 - p \\ \Pr(x = 1) &= p, \end{aligned} \quad (\text{C.159})$$

where p , the probability of a success, must be between 0 and 1. The mean and variance of a Bernoulli random variable are given by

$$\langle x \rangle = p \quad \text{and} \quad \sigma^2 = p(1 - p). \quad (\text{C.160})$$

Binomial law Suppose we perform a sequence of experiments, with the outcome of each individual experiment scored as either success or failure. The probability of a success on each trial is p ($0 \leq p \leq 1$) and the probability of a failure on each trial is $q = 1 - p$. That is, the outcome of each trial is a Bernoulli random variable. The

probability of n successes in N trials is then described by the *binomial* law:

$$\Pr(n) = \binom{N}{n} p^n q^{N-n}, \quad (\text{C.161})$$

where the binomial coefficient,

$$\binom{N}{n} \equiv \frac{N!}{n!(N-n)!}, \quad (\text{C.162})$$

is often expressed verbally as N choose n since it gives the number of ways n objects can be chosen from a set of N indistinguishable objects. We shall denote a random variable that is drawn from a binomial probability distribution by $n \sim \mathcal{B}(p, N)$.

The mean and variance of a binomial random variable are given by

$$\langle n \rangle = Np \quad \text{and} \quad \sigma^2 = Np(1-p). \quad (\text{C.163})$$

The binomial law describes selection processes in imaging. For example, the probability that a photon will be absorbed (or not) when it strikes a detector can be modeled by a binomial law.

Multinomial law The binomial law governs the probability of outcomes for a two-alternative Bernoulli trial experiment. When there are M distinct possible outcomes on each trial (for example, the tossing of a six-sided die gives $M = 6$), the statistics of the experiment are given by a multinomial law. Let N be the number of trials in the experiment, and let p_i be the probability of outcome i for each trial, where i runs from 1 to M . The number of times outcome i occurs is denoted n_i . The joint probability of the number of times each possible outcome occurs in N trials is given by:

$$\Pr(n_1, n_2, \dots, n_M) = \frac{N!}{n_1! n_2! \dots n_M!} p_1^{n_1} p_2^{n_2} \dots p_M^{n_M} = N! \prod_{i=1}^M \frac{p_i^{n_i}}{n_i!}, \quad (\text{C.164})$$

where $N = n_1 + n_2 + \dots + n_M$ and $\sum_i p_i = 1$.

C.6.2 Poisson distribution

As we shall see in considerable detail in Chaps. 11 and 12, the Poisson probability law plays a fundamental role in problems where discrete events are counted. In optics and imaging, the events will often be photoelectric absorption processes. The randomness in the number of such processes, loosely referred to as *photon noise* or *shot noise*, is often the dominant noise in practical imaging systems.

Here we present a compendium of some of the important mathematical properties of Poisson random variables. A more complete discussion of these properties and the physical context in which they arise is given in Chap. 11.

Probability law, mean and variance A discrete random variable N with a sample space given by the natural numbers (zero and the positive integers) is said to be Poisson-distributed or to obey the Poisson probability law if

$$\Pr(N = n) = \frac{e^{-\lambda} \lambda^n}{n!}, \quad n = 0, 1, 2, \dots \quad (\text{C.165})$$

Note that this probability law is specified entirely by the single number λ , often called *the parameter* of the Poisson distribution.

As elsewhere in this appendix, we shall use the shorthand $\Pr(n)$ for $\Pr(N = n)$ where no confusion can arise. When it is necessary to indicate the parameter explicitly, we shall write the probability as $\Pr(n|\lambda)$, a notation that will prove advantageous in many applications where λ can be a random variable.

The parameter λ is also the mean value of N . To show this, we write

$$\langle N \rangle = \sum_{n=0}^{\infty} n \Pr(n) = \exp(-\lambda) \sum_{n=1}^{\infty} n \frac{\lambda^n}{n!}. \quad (\text{C.166})$$

The change of limits is valid since $0!$ is defined to be one and hence the $n = 0$ term in the sum is zero. Letting $m = n - 1$ and recognizing that $n/n! = 1/(n-1)! = 1/m!$, we find

$$\langle N \rangle = \lambda \exp(-\lambda) \sum_{m=0}^{\infty} \frac{\lambda^m}{m!} = \lambda. \quad (\text{C.167})$$

Because of this result, we shall often use the symbol \bar{N} instead of λ for the parameter of the Poisson distribution.

Higher moments must necessarily be expressible in terms of \bar{N} (or λ) since that is the only parameter in $\Pr(n)$. By a derivation similar to the one just given for $\langle N \rangle$, we can show that the second moment is given by

$$\langle N^2 \rangle = \bar{N}^2 + \bar{N}. \quad (\text{C.168})$$

This result implies that the variance is equal to the mean, *i.e.*,

$$\text{Var}\{N\} = \langle [N - \bar{N}]^2 \rangle = \bar{N}. \quad (\text{C.169})$$

The equality of the mean and the variance is a hallmark of the Poisson distribution. Only pure numbers (dimensionless quantities) can have this property since otherwise the dimensions of the variance would be the square of those of the mean. The Poisson law applies only to integer-valued random variables, and these integers have no dimensions attached to them.

Characteristic function and moment-generating function The moment-generating function for the Poisson distribution is given by

$$M(t) = \langle \exp(tN) \rangle = \exp(-\bar{N}) \sum_{N=0}^{\infty} \frac{(\bar{N}e^t)^N}{N!} = \exp[\bar{N}(e^t - 1)]. \quad (\text{C.170})$$

By a simple change of variables, the characteristic function is given by

$$\psi(\xi) = \langle \exp(-2\pi i \xi N) \rangle = \exp[\bar{N}(e^{-2\pi i \xi} - 1)]. \quad (\text{C.171})$$

From either of these functions, any desired moment can be computed. The first and second moments have already been given, and the third and fourth are:

$$\langle N^3 \rangle = \bar{N}^3 + 3\bar{N}^2 + \bar{N}; \quad (\text{C.172})$$

$$\langle N^4 \rangle = \bar{N}^4 + 6\bar{N}^3 + 7\bar{N}^2 + \bar{N}. \quad (\text{C.173})$$

This sequence can be continued by use of the recursion relation (Metz, 1969):

$$\langle N^k \rangle = \bar{N} \sum_{n=0}^{k-1} \binom{k-1}{n} \langle N^n \rangle. \quad (\text{C.174})$$

A few of the central moments are:

$$\langle (N - \bar{N})^3 \rangle = \bar{N}; \quad (\text{C.175})$$

$$\langle (N - \bar{N})^4 \rangle = 3\bar{N}^2 + \bar{N}; \quad (\text{C.176})$$

$$\langle (N - \bar{N})^5 \rangle = 10\bar{N}^2 + \bar{N}; \quad (\text{C.177})$$

$$\langle (N - \bar{N})^6 \rangle = 15\bar{N}^3 + 5\bar{N}^2 + \bar{N}. \quad (\text{C.178})$$

The factorial moments of a Poisson are particularly simple. The k^{th} factorial moment is given by (Kotz *et al.*, 1986)

$$c_k = \langle N^{(k)} \rangle = \langle N(N-1) \cdots (N-k+1) \rangle = \bar{N}^k. \quad (\text{C.179})$$

Recursive calculation of Poisson probabilities Because of the factorial, it can be difficult to compute $\text{Pr}(n)$ directly for large n . The following recursive relation provides a solution to this problem:

$$\ln[\text{Pr}(n+1)] = \ln[\text{Pr}(n)] + \ln \bar{N} - \ln(n+1). \quad (\text{C.180})$$

Knowing $\ln[\text{Pr}(n)]$, one can thus find $\ln[\text{Pr}(n+1)]$ by adding a numerically well-behaved correction term $\ln \bar{N} - \ln(n+1)$. An equivalent relation is

$$(n+1)\text{Pr}(n+1) = \bar{N}\text{Pr}(n). \quad (\text{C.181})$$

Linear combinations of Poisson random variables The following theorems are given in Haight (1967) and Kotz *et al.* (1986): If N_1 and N_2 are independent Poisson random variables with means \bar{N}_1 and \bar{N}_2 , respectively, then $N_1 + N_2$ is a Poisson random variable with mean $\bar{N}_1 + \bar{N}_2$. Note, however, that $N_1 - N_2$ is not a Poisson random variable since its variance is not equal to its mean; the variance of $N_1 - N_2$ is $\bar{N}_1 + \bar{N}_2$ if N_1 and N_2 are independent and Poisson, but the mean is $\bar{N}_1 - \bar{N}_2$. A linear combination $\alpha N_1 + \beta N_2$ of two independent Poisson random variables is a Poisson random variable if and only if $\alpha = \beta = 1$.

Conversely, if N_1 and N_2 are independent random variables and $N_1 + N_2$ is a Poisson random variable, then N_1 and N_2 must each be Poisson-distributed.

Approximations to the Poisson law A Poisson random variable takes on only integer values, but it is nevertheless sometimes convenient to approximate $\text{Pr}(n)$ by a continuous function of n . Several such approximations are given in Haight (1967) and Abramowitz and Stegun (1965), but the most useful approach is to approximate a Poisson by a Gaussian. To obtain this approximation, we need only replace x with n , \bar{x} with \bar{N} , and σ_x^2 with \bar{N} in the general univariate normal density (C.105). The result is

$$\text{Pr}(n) \simeq (2\pi\bar{N})^{-1/2} \exp \left[- (n - \bar{N})^2 / 2\bar{N} \right]. \quad (\text{C.182})$$

This expression is an excellent approximation if \bar{N} is greater than about 10, but is often usable even for \bar{N} as small as 3.

C.6.3 Bose-Einstein probability law

The *Bose-Einstein* probability law is important in optics applications involving photocount statistics for thermal radiation. In Chap. 11 the Bose-Einstein law is shown to be the appropriate description for the distribution of photocounts resulting from the process of detecting an incident intensity that obeys an exponential probability law. The Bose-Einstein distribution is written

$$\Pr(n) = \frac{\bar{N}^n}{(1 + \bar{N})^{n+1}}, \quad n = 0, 1, 2, \dots, \quad (\text{C.183})$$

where \bar{N} is the mean of the Bose-Einstein random variable. To verify the normalization of this expression we note that

$$\sum_{n=0}^{\infty} \Pr(n) = \sum_{n=0}^{\infty} \frac{1}{1 + \bar{N}} \left[\frac{\bar{N}}{1 + \bar{N}} \right]^n. \quad (\text{C.184})$$

The well-known relationship for a geometric series,

$$\sum_{k=0}^{\infty} ax^k = \frac{a}{1 - x}, \quad (\text{C.185})$$

can then be used to show that the sum of (C.184) is equal to 1. From this simple derivation it should be no surprise that the Bose-Einstein law is often referred to as the *geometric* distribution.

The Bose-Einstein distribution can be rewritten as

$$\begin{aligned} \Pr(n) &= \exp(n \ln \bar{N}) \exp[-(n+1) \ln(1 + \bar{N})] \\ &= \exp\{n [\ln \bar{N} - \ln(1 + \bar{N})] - \ln(1 + \bar{N})\} \\ &= Ae^{-Cn}, \end{aligned} \quad (\text{C.186})$$

where $A = 1/(1 + \bar{N})$ and $C = \ln(1 + \bar{N}) - \ln \bar{N}$. We see from (C.186) that the probability law for n is an exponential that has been discretely sampled because of the discrete nature of n .

Determination of the mean and variance of the distribution involve similar manipulations of geometric series. The variance of the Bose-Einstein law can be shown to be written in terms of the mean as:

$$\text{Var}\{N\} = \bar{N}(1 + \bar{N}). \quad (\text{C.187})$$

The characteristic function for the Bose-Einstein distribution is given by (Saleh, 1978)

$$\psi(\xi) = (1 + \bar{N} - \bar{N}e^{-2\pi i \xi})^{-1}. \quad (\text{C.188})$$

The factorial moments of this distribution are given by (Goodman, 1985)

$$c_k = E\{n(n-1) \cdots (n-k+1)\} = k! \bar{N}^k. \quad (\text{C.189})$$

C.6.4 Negative binomial law

A random variable that follows the negative binomial law is described by

$$\Pr(n) = \binom{n+N-1}{N-1} p^n (1-p)^N \quad 0 \leq n < \infty, \quad (\text{C.190})$$

where $0 \leq p \leq 1$.

The mean and variance are given by

$$\langle n \rangle = \frac{Np}{1-p} \quad \text{and} \quad \sigma^2 = \frac{Np}{(1-p)^2}. \quad (\text{C.191})$$

The negative binomial law describes the number of failures n that occur before reaching a fixed number of successes N in a set of Bernoulli trials, where there are two possible outcomes, the outcomes are independent across trials, and the probability of failure p on each trial is the same. The negative binomial also can arise in doubly stochastic Poisson processes, where there is a Poisson random variable whose underlying parameter is itself drawn from a Gamma distribution.

C.7 Sampling methods

Above we have introduced a variety of analytical expressions for probabilities and probability density functions. Often we need to draw samples from one of these distributions on a computer, but most digital random-number generators provide only random variables uniformly distributed from 0 to 1. Fortunately there are methods by which such random-number generators can be used to generate random variables with arbitrary densities; we shall describe two of them here.

C.7.1 Rejection method

Suppose first that we wish to generate a sample from a PDF $\text{pr}_u(u)$, where u is a continuous random variable defined on the interval $(0, 1)$; an example would be the beta density defined in (C.128). In the rejection method, we generate a pair of random numbers, x and y , both uniformly distributed on $(0, 1)$, where x is a candidate for the desired random number u . We accept the candidate and assign $u = x$ if $\text{pr}_u(x) < y$. We can think of x and y as defining a point in an x - y plane; we accept only points that lie below the curve given by $y = \text{pr}_u(x)$. Points corresponding to low PDF have a low probability of being accepted.

To see that the accepted variables follow the desired PDF, we note that the probability of an accepted variable x falling in a vanishingly small interval $(u - \frac{1}{2}\Delta u, u + \frac{1}{2}\Delta u)$ is the probability that a variable in this range is proposed in the first place times the probability that it is accepted. Since the proposals have PDF $\text{pr}_x(x) = 1$, the probability of a proposal in $(u - \frac{1}{2}\Delta u, u + \frac{1}{2}\Delta u)$ is simply Δu , and the probability of acceptance is $\text{pr}_u(u)$. Thus the probability of an accepted x being in $(u - \frac{1}{2}\Delta u, u + \frac{1}{2}\Delta u)$ is $\text{pr}_u(u)\Delta u$, so it follows from (C.21) that the accepted variables are distributed according to $\text{pr}_u(u)$.

The rejection method can be extended to any continuous random variable u defined on a finite interval (a, b) by drawing x from the uniform distribution on

$(0, 1)$, defining a new random number $x' = a + (b - 1)x$, and then proceeding as above with x' in place of x .

If the range of u is infinite, the rejection method can be applied only approximately. If $\text{pr}_u(u)$ falls off rapidly as $u \rightarrow \pm\infty$, it may be acceptable to truncate the PDF to a finite range and apply the rejection method. Of course, values outside this range will never be generated, but that may be acceptable in some cases. As the range gets wider, the approximation gets better but more of the proposals are rejected.

C.7.2 Cumulative-distribution method

This method requires knowledge of the cumulative distribution function (CDF) as defined by (C.26) or (C.30). We denote the CDF for a continuous random variable u as $F_u(\cdot)$, and we observe that this function has a unique inverse $F_u^{-1}(\cdot)$ since the CDF is monotonically increasing. We can draw a random variable t from a uniform density on $(0, 1)$ and define a new random variable x by

$$x = F_u^{-1}(t). \quad (\text{C.192})$$

The PDF on x is given from (C.45a) as

$$\text{pr}_x(x) = \text{pr}_t(t) \frac{dt}{dx}. \quad (\text{C.193})$$

(No absolute-value signs are needed since $dt/dx \geq 0$.) Since $\text{pr}_t(t) = 1$, we see that

$$\text{pr}_x(x) = \frac{d}{dx} F_u(x) = \frac{d}{dx} \int_{-\infty}^x du \text{pr}_u(u) = \text{pr}_u(x). \quad (\text{C.194})$$

Thus the variable x generated by this procedure indeed has the desired PDF.
