Preface

Images are ubiquitous in the modern world. We depend on images for news, communication and entertainment as well as for progress in medicine, science and technology. For better or worse, television images are virtually a *sine qua non* of modern life. If we become ill, medical images are of primary importance in our care. Satellite images provide us with weather and crop information, and they provide our military commanders with timely and accurate information on troop movements. Biomedical research and materials science could not proceed without microscopic images of many kinds. The petroleum reserves so essential to our economy are usually found through seismic imaging, and enemy submarines are located with sonic imaging. These examples, and many others that readily come to mind, are ample proof of the importance of imaging systems.

While many of the systems listed above involve the latest in high technology, it is not so obvious that there is an underlying intellectual foundation that ties the technologies together and enables systematic design and optimization of diverse imaging systems. A substantial literature exists for many of the subdisciplines of image science, including quantum optics, ray optics, wave propagation, image processing and image understanding, but these topics are typically treated in separate texts without significant overlap. Moreover, the practitioner's goal is to make better images, in some sense, but little attention is paid to the precise meaning of the word "better." In such circumstances, can imaging be called a science?

There are three elements that must be present for a discipline to be called a science. First, the field should have a common language, an agreed-upon set of definitions. Second, the field should have an accepted set of experimental procedures. And finally, the field should have a theory with predictive value. It is the central theme of this book that there is indeed a science of imaging, with a well-defined theoretical and experimental basis. In particular, we believe that image quality can be defined objectively, measured experimentally and predicted and optimized theoretically.

Our goal in writing this book, therefore, is to present a coherent treatment of the mathematical and physical foundations of image science and to bring image evaluation to the forefront of the imaging community's consciousness.

ORGANIZATION OF THE BOOK

There are a number of major themes that weave their way throughout this book, as well as philosophical stances we have taken, so we recommend that the reader begin with the prologue to get an introduction to these themes and our viewpoint. Once this big picture is absorbed, the reader should be ready to choose where to jump into the main text for more detailed reading.

Mathematical Foundations

The first six chapters of this book represent our estimation of the essential mathematical underpinnings of image science. In our view, anyone wishing to do advanced research in this field should be conversant with all of the main topics presented there.

The first four chapters are devoted to the important tools of linear algebra, generalized functions, Fourier analysis and other linear transformations. Chapter 5 treats a class of mathematical descriptions called mixed representations, that is, descriptions that mix seemingly incompatible variables such as spatial position and spatial frequency. Chapter 6 presents the basic concepts of group theory, the mathematics of symmetry, which will be applied to the description of imaging systems in later chapters.

It was our objective in writing these introductory chapters to present the mathematical foundations of image science at a level that will be accessible to graduate students and well-motivated undergraduates. At the same time, we have attempted to include sufficient advanced material so that the material will be beneficial to established workers in the field. This dual goal requires examining many concepts at different levels of sophistication. We have attempted to do this by providing both elementary explanations of the key points and more detailed mathematical treatments. The reader will find that the level of mathematical rigor is not uniform throughout these chapters or even within a particular chapter. We hope that this approach allows each reader to extract from the book insights appropriate to his or her individual interests and mathematical preparation.

Image Formation: Models and Mechanisms

A quick perusal of the of Contents will reveal that a significant portion of the book is devoted to the subject of image formation. We have strived to present a comprehensive and unified treatment of the mathematical and statistical principles of imaging. We hope this serves the image-science community by giving a common language and framework to our many disciplines. Additionally, a thorough understanding of the image-formation process is a prerequisite for the image-evaluation methodology we advocate.

The deterministic analysis of imaging systems begins in Chap. 7, where we present a wide variety of mathematical descriptions of objects and images and mappings from object to image. We argue in Chap. 7 (and briefly also in the Prologue) that digital imaging systems are best described as a mapping from a function to a discrete set of numbers, so much of the emphasis in that chapter will be on such mappings. More conventional mappings such as convolutions are, however, also treated in a unified way. An important tool in Chap. 7 is singular-value decomposition, which is introduced mathematically in Chap. 1.

The deterministic mappings are not a complete description of image formation. Repeated images of a single object will not be identical because of electronic noise in detectors and amplifiers, as well as photon noise, which arises from the discrete nature of photoelectric interactions. In addition, the object itself can often be usefully regarded as random. Object statistics are important in pattern recognition, image reconstruction and evaluation of image quality. Chapter 8 provides a general mathematical framework for the description of random vectors and processes. Particular emphasis is given to Gaussian random vectors and processes, which often arise as the result of the central-limit theorem.

The next two chapters go more deeply into specific mechanisms of image formation. Chapter 9 develops the theory of wave propagation from first principles and treats diffraction and imaging with waves within this framework. Though the objective of the discussion is to develop deterministic models of wave-optical imag-

ing systems, we cannot avoid discussing random processes when we consider the coherence properties of wave fields, so an understanding of the basics of random processes, as presented in Chap. 8, is needed for a full understanding of Chap. 9. The reader with previous exposure to such topics as autocorrelation functions and complex Gaussian random fields can, however, skip Chap. 8 and move directly to Chap. 9.

Chapter 10 is ostensibly devoted to radiometry and radiative transport, but actually it covers a wide variety of topics ranging from quantum electrodynamics to tomographic imaging. A key mathematical tool developed in that chapter is the Boltzmann equation, a general integro-differential equation that is capable of describing virtually all imaging systems in which interference and diffraction play no significant role. The Boltzmann equation describes a distribution function that can loosely be interpreted as a density of photons in phase space, so it is necessary to discuss in that chapter just what we mean by the ubiquitous word *photon*.

In Chap. 10 we discuss only the mean photon density or the mean rate of photoelectric interactions, but in Chap. 11 we begin to discuss fluctuations about these means. In particular, we present there an extensive discussion of the Poisson probability law and its application to simple counting detectors and imaging arrays. Included is a discussion of photon counting from a quantum-mechanical perspective. Many of the basic principles of random vectors and processes enunciated in Chap. 8 are used in Chap. 11.

Chapter 12 goes into more detail on noise mechanisms in various detectors of electromagnetic radiation. The implications of Poisson statistics are discussed in practical terms, and a number of noise mechanisms that are not well described by the Poisson distribution are introduced. A long section is devoted to x-ray and gamma-ray detectors, not only because of their practical importance in medical imaging, but also because they illustrate some important aspects of the theory developed in Chap. 11.

Inferences from Images

With the background developed in Chaps. 1–12, we can discuss ways of drawing inferences from image data. The central mathematical tool we need for this purpose is statistical decision theory, introduced in Chap. 13. This theory allows a systematic approach to estimation of numerical parameters from image data as well as classifying the object that produced a given image, and it will form the cornerstone of our treatment of image quality. In accordance with this theory, we shall define image quality in terms of how well an observer can extract some desired information from an image.

Chapter 14 is a nuts-and-bolts guide to objective assessment of image quality for both hardware and software. Particular attention is paid to evaluating the performance of human observers, for whom most images are intended.

Chapter 15 provides a general treatment of inverse problems or image reconstruction, defined as inferring properties of an object from data that do not initially appear to be a faithful image of that object. Considerable attention is given to what information one can hope to extract and what aspects of an object are intrinsically inaccessible from data obtained with a specific imaging system. A wide variety of image-reconstruction algorithms will be introduced, and special attention will be given to the statistical properties of the resulting images.

Applications

Chapters 16–19 are intended as detailed case studies of specific imaging systems, with the goal of providing examples of how various mathematical tools developed earlier in the book can be applied. Two of these chapters (16 and 18) cover direct imaging systems in which the image is formed without the need for a processing or reconstruction algorithm, and two of them (17 and 19) cover indirect systems in which the initial data set is not a recognizable image. By a different dichotomy, two of the chapters (16 and 17) relate to imaging with x rays and gamma rays, and two of them (18 and 19) relate to imaging with light. The key physical and pedagogical difference is that x rays and gamma rays have such short wavelengths that interference and diffraction can be neglected, and the Boltzmann transport equation of Chap. 10 is applicable. With light, the diffraction theory developed in Chap. 9 takes a central role.

Appendices

Three appendices are provided: one on matrix algebra, a second on complex variables and a third on the fundamentals of probability theory. The material contained there is expected to have been seen by most readers during their undergraduate training. In writing the appendices, we tried to provide a self-contained treatment of the prerequisite material necessary for the understanding of the material in the main text.

SUGGESTIONS FOR COURSE OUTLINES

Drafts of this book have been used as text material for three different courses that have been taught at the Optical Sciences Center of the University of Arizona. Each course has been taught several times, and there has been some experimentation with the course outlines as the book evolved.

The first six chapters of the book were developed for a one-semester course called Mathematical Methods for Optics. This course was originally intended for first-year graduate students but has proved to be more popular with advanced students. It is basically an introductory course in applied mathematics with emphasis on topics that are useful in image science. Expected preparation includes calculus and differential equations and an elementary understanding of matrix algebra and complex analysis. Appendices A and B were originally used as introductory units in the course but are now considered to define the prerequisites for the course. The current syllabus covers Chaps. 1–6 of the book. Earlier, however, a more optics-oriented course was offered based on Chaps. 1–3, 9 and 10. For this course it was necessary to assume that the students had some elementary understanding of random processes.

For advanced graduate students, especially ones who will pursue dissertation research in image science, there is a two-course sequence: Principles of Image Science, taught in the Fall semester, and Noise in Imaging Systems, taught in the Spring. The Principles course begins with Chap. 1; this is a review for those who have previously taken the Mathematical Methods course, but there have been no complaints about redundancy. Chapters 7, 9, 10 and 15 are then covered sequen-

tially. Occasionally it is necessary to review material from Chaps. 2–5, but basically these chapters are assumed as prerequisites. Appendices A and B are available for reference.

Noise in Imaging Systems covers Chaps. 8 and 11–14. Appendix C defines the prerequisite knowledge of probability and statistics, but a general acquaintance with Chaps. 1–3 is also presumed. Neither Mathematical Methods nor Principles of Image Science is a formal prerequisite for the Noise course.

Alternatively, a one-year advanced sequence could be taught by covering Chap. 1 and then 7–15 in sequence. Prerequisite material in this case would be defined by Chaps. 2 and 3 and the three appendices. Necessary topics in Chaps. 4–6 could be sketched briefly in class and then assigned for reading.

The applications chapters, 16–19, have not been used in teaching, although they have been reviewed by graduate students working in image science. They could form the basis for an advanced seminar course.

Acknowledgments

The seeds of this project can be found in the interactions of the authors with Robert F. Wagner, who more than anyone else founded the field of objective assessment of image quality, especially in regard to radiological imaging. Without his insights and guidance, neither that field nor this book would have been born.

Many people have read parts of this book and provided invaluable feedback, but two in particular must be singled out. Matthew Myers may be the only person other than the authors who has read every word of the book (to date, we hope!), and Eric Clarkson has read large portions. Both have provided continuing guidance on mathematics, physics and pedagogy; our debt to them is enormous.

A bevy of students at the University of Arizona also struggled through many parts of the book, sometimes in early draft form, and their diligence and insightful feedback have been invaluable. It is almost unfair to make a list of those who have helped in this respect, since we will surely leave off many who should not be overlooked, but we thank in particular Rob Parada, Jim George, Elena Goldstein, Angel Pineda, Andre Lehovich, Jack Hoppin, Kit-Iu Cheong, Dana Clarke, Liying Chen and Bill Hunter. Former students, too, have been very helpful, especially Brandon Gallas, Craig Abbey, John Aarsvold and Jannick Rolland. Colleagues who have provided invaluable review and guidance include Rolf Clackdoyle, Jeffrey Fessler, Charles Metz, Keith Wear, Robert Gagne, Xiaochuan Pan, Mike Insana, Roger Zemp, Steve Moore, Adriaan Walther, Jim Holden, Todd Peterson, Elizabeth Krupinski, Jack Denny, Donald Wilson and Matthew Kupinski.

Staff at the Radiology Department of the University of Arizona, especially Debbie Spargur, Lisa Gelia and Jane Lockwood, have been a continuing source of cheerful and highly competent assistance in myriad details associated with this project. We also thank Brian W. Miller and Meredith Whitaker for their assistance with figures and Bo Huang for his assistance in converting parts of the book from another word processor to \LaTeX . The authors have benefited significantly from the help of staff at the Center for Devices and Radiological Health of the FDA as well, especially Phil Quinn and Jonathan Boswell.

Special thanks are owed to Stefanie Obara, also known as $\LaTeX_{\mathcal{T}}$, for her diligence and care in polishing up our \LaTeX and producing the final camera-ready text. $\LaTeX_{\mathcal{T}}$ describes herself as “anal and proud of it,” and we are proud of her

production. She participated very capably in formatting, indexing and preparing the bibliography as well as meticulous editing.

Finally, we thank our loving families, who supported and encouraged us during the many years it took to bring this project to fruition.

Prologue

We shall attempt here to provide the reader with an overview of topics covered in this book as well as some of the interrelationships among them. We begin by surveying and categorizing the myriad imaging systems that might be discussed and then suggest a unifying mathematical perspective based on linear algebra and stochastic theory. Next we introduce a key theme of this book, objective or task-based assessment of image quality. Since this approach is essentially statistical, we are led to ruminate on Bayesian and frequentist interpretations of probability. In discussing image quality, probability and statistics, our personal views, developed as we have worked together on imaging issues for two decades, will be much in evidence. The viewpoints presented here are, we hope, more firmly given mathematical form and physical substance in the chapters to follow.

KINDS OF IMAGING SYSTEMS

There are many kinds of objects to be imaged and many mechanisms of image formation. Consequently, there are many ways in which imaging systems can be classified. One such taxonomy, represented by Table I, classifies systems by the kind of radiation or field used to form an image. The most familiar kind of radiation is electromagnetic, including visible light, infrared and ultraviolet radiation. Also under this category we find long-wavelength radiation such as microwaves and radio waves and short-wavelength radiation in the extreme ultraviolet and soft x-ray portions of the spectrum. Of course, the electromagnetic spectrum extends further in both directions, but very long wavelengths, below radio frequencies, do not find much use in imaging, while electromagnetic waves of very short wavelength, such as hard x rays and gamma rays, behave for imaging purposes as particles. Other particles used for imaging include neutrons, protons and heavy ions.

Other kinds of waves are also used in various imaging systems. Mechanical waves are used in seismology, medical ultrasound and even focusing of ocean waves. The DeBroglie principle tells us that matter has both wave-like and particle-like characteristics. The wave character of things we usually call matter is exploited for imaging in scanning tunneling microscopes and in recent work on diffraction of atoms.

Not only radiation, in the usual sense, but also static or quasistatic fields may be the medium of imaging. Magnetic fields are of interest in geophysics and in biomagnetic imaging, while electric fields are imaged in some new medical imaging modalities.

Table I. CLASSIFICATION BY KIND OF RADIATION OR FIELD

<u>Electromagnetic waves</u>	<u>Other waves</u>	<u>Particles</u>	<u>Quasistatic fields</u>
Radio waves	Seismic waves	Neutrons	Geomagnetic fields
Microwaves	Water waves	Protons	Biomagnetic fields
Infrared	Ultrasound	Heavy ions	Bioelectric fields
Visible light	DeBroglie waves	Hard x rays	Electrical impedance
Ultraviolet		Gamma rays	
Soft x rays			

A second useful taxonomy of imaging systems groups them according to the property of the object that is displayed in the image (see Table II). In other words, what does the final image represent?

<u>Optical reflectance</u> Photography Remote sensing LIDAR	<u>Microwave reflectance</u> Radar	<u>Acoustic reflectance</u> Medical ultrasound Sonar
<u>Source strength</u> Astronomical imaging Fluorescence microscopy	<u>Concentration</u> Nuclear medicine MRI (spin density)	<u>Wave amplitude</u> Interferometry Seismology
<u>Attenuation</u> Film densitometry Transmission x ray	<u>Index of refraction</u> Phase-contrast microscope	<u>Scattering properties</u> Medical ultrasound Weather radar
<u>Field strength</u> Biomagnetic imaging Geomagnetic imaging	<u>Electric, magnetic properties</u> Impedance tomography MRI (magnetization) MRI (spin relaxation)	<u>Surface height</u> Optical profilometry Laser ranging Moiré topography

In an ordinary photographic camera, the snapshot usually represents the light reflected from a scene. More precisely, the image reaching the film is related to the product of the optical reflectance of the object and its illumination. Other imaging techniques that essentially map object reflectance include radar imaging and medical ultrasound.

In some instances, however, a photograph measures not reflectance but the source strength of a self-luminous source; a snapshot of a campfire, an astronomical image and a fluorescence micrograph are all examples of emission images. The source strength, in turn, is often related to some concentration or density of physical interest. For example, in nuclear medicine one is interested ultimately in the concentration of some pharmaceutical; if the pharmaceutical is radioactive, its concentration is directly related to the strength of a gamma-ray-emitting source.

Other optical properties can also be exploited for imaging. The index of refraction is used in phase-contrast microscopy, while attenuation or transmissivity of radiation is used in film densitometry and ordinary x-ray imaging. The complex amplitude of a wave is measured in many kinds of interferometry and some forms of seismology, and scattering properties are used in medical ultrasound and weather radar. Electrical and magnetic properties such as impedance and magnetization are of increasing interest, especially in medicine.

We might also classify systems by the imaging mechanism. In other words, how is the image or data set formed? Included in this list (see Table III) are simple refraction and reflection, along with the important optical effects of interference and diffraction. Some imaging systems, however, make use of less obvious physical mechanisms, including scattering and shadow casting. Perhaps the least obvious mechanism is what we shall designate as modulation imaging. In this technique, the imaging system actively modulates the properties of the object being imaged in

a space-dependent manner. Examples include the important medical modality of magnetic resonance imaging (MRI) and the lesser-known method of photothermal imaging, which originated with Alexander Graham Bell.

Table III. CLASSIFICATION BY IMAGING MECHANISM		
<u>Refraction</u>	<u>Reflection</u>	<u>Diffraction</u>
Eyes	Reflecting telescope	Holographic elements
Microscopes	Wolters x-ray telescope	Kinoforms
Cameras		Binary optics
Refracting telescopes		Fresnel zone plates
Fresnel lenses		
<u>Interference</u>	<u>Scattering</u>	<u>Modulation</u>
Holography	Compton telescope	MRI
Synthetic-aperture radar		Photothermal imaging
Stellar interferometers		
Hanbury Brown/Twiss		
	<u>Shadow casting</u>	
	X-ray computed tomography	
	Pinhole imaging of x rays	
	Collimator for gamma rays	
	Coded apertures	

The next dichotomy to consider is direct vs. indirect imaging. By direct imaging we mean any method where the initial data set is a recognizable image. In indirect imaging, on the other hand, a data-processing or reconstruction step is required to obtain the image. Examples of direct and indirect imaging systems are provided in Table IV.

Direct imaging techniques may be divided into serial-acquisition systems or scanners, in which one small region of the object is interrogated at a time, and parallel-acquisition systems where detector arrays or continuous detectors are used to capture many picture elements or pixels in the object simultaneously. Hybrid serial/parallel systems are also possible.

Table IV. DIRECT VS. INDIRECT IMAGING	
<u>Direct – serial acquisition</u>	<u>Direct – parallel acquisition</u>
Scanning microdensitometer	Human eye
Medical gamma-ray scanner	Photographic camera
Confocal scanning microscope	Electronic camera
Scanning-tip microscopes	Optical microscope with CCD
Image dissector	Scintillation camera
	<u>Indirect</u>
	X-ray CT
	SPECT and PET
	MRI
	Holography
	Synthetic-aperture radar

Perhaps the most common type of indirect imaging is tomography in all its varied forms, including the now-familiar x-ray computed tomography (CT), emission tomography such as single-photon emission computed tomography (SPECT) and positron emission tomography (PET), as well as MRI and certain forms of ultrasonic and optical imaging. In all of these methods, the data consist of a set of line integrals or plane integrals of the object, and a reconstruction step is necessary to obtain the final image.

The indirect method of coded-aperture imaging is a shadow-casting method used in x-ray astronomy and nuclear medicine. The shadows represent integrals of the object but here the path of integration depends on the shape of the aperture. As above, tomographic information can be retrieved from the data set following a reconstruction step.

An earlier example of indirect imaging is holography, in which the initial data include information, in coded form, about the amplitude and phase of a diffraction pattern. As is implicit in the name (*holo* = entire), the holographic data are complete in some sense, but are virtually useless to the human observer; again a reconstruction step is required. The holographic principle finds use in nonoptical techniques such as acoustic holography, microwave holography and synthetic-aperture radar or SAR, all indirect imaging methods.

Another principle that leads to specific indirect imaging systems is embodied in the van Cittert–Zernike theorem, relating the intensity distribution of an incoherent source to the coherence properties of the field it produces. Systems that exploit this theorem include the Michelson stellar interferometer and the Hanbury Brown–Twiss interferometer.

The final dichotomy we shall consider is passive vs. active imaging (see Table V). In passive imaging, measurements are made without interacting with a source. Familiar examples include ordinary photography of self-luminous sources or of a reflecting source with natural illumination as well as astronomical imaging and medical thermography. By contrast, an active imaging system supplies the radiation being imaged. Systems in this category include flash photography, transmission imaging (x rays, microscopy, etc.), radar, active SONAR and medical ultrasound.

Table V. PASSIVE VS. ACTIVE IMAGING

<u>Passive systems</u>	<u>Active systems</u>
Fluorescent microscopy	Conventional transmission microscopy
Nuclear medicine	Diagnostic radiology
Lunar imaging with a telescope	Radar ranging of the moon
IR thermography	Photoacoustic imaging
Seismology	Geophysical imaging with explosives
Natural-light photography	Flash photography
Biomagnetic imaging	Magnetic resonance imaging

OBJECTS AND IMAGES AS VECTORS

As we have just seen, many different physical entities can serve as objects to be imaged. In most cases, these objects are functions of one or more continuous variables. In astronomy, for example, position in the sky can be specified by two angles, so the astronomical object being imaged is a scalar-valued function of two variables, or a

two-dimensional (2D) function for short. In nuclear medicine, on the other hand, the object of interest is the three-dimensional (3D) distribution of some radiopharmaceutical, so mathematically it is described as a 3D function. Moreover, if the distribution varies with time — not an uncommon situation in nuclear medicine — then a 4D function is required (three spatial dimensions plus time).

Even higher dimensionalities may be needed in some situations. For example, multispectral imagers may be used on objects where wavelength is an important variable. An accurate object description might then require five dimensions (three spatial dimensions plus time and wavelength).

Sometimes the function is vector-valued. In magnetic resonance imaging, for example, the object is characterized by the proton density and two relaxation times, so a complete object description consists of a 3D vector function of space and time.

Images, too, are often functions. A good example occurs in an ordinary camera, where the image is the irradiance pattern on a piece of film. Even if this pattern is time varying, usually all we are interested in is its time integral over the exposure time, so the most natural description of the image is as a continuous 2D spatial function. Similar mathematics applies to the developed film. The image might then be taken as the optical density or transmittance of the film, but again it is a 2D function. A color image is a vector-valued function; the image is represented by the density of the three color emulsions on the film.

Sometimes images are not functions but discrete arrays of numbers. In the camera example, suppose the detector is not film but an electronic detector such as a charge-coupled device (CCD). A CCD is a set of, say, M discrete detector elements, each of which performs a spatial and temporal integration of the image irradiance. The spatial integral extends over the area of one detector element, while the temporal integration extends over one frame period, typically $1/30$ sec. As a result of these two integrations, the image output from this detector is simply M numbers per frame. In this example, the object is continuous, but the image is discrete. In fact, any digital data set consists of a finite set of numbers, so a discrete representation is virtually demanded.

Another example that requires a discrete representation of the image is indirect imaging such as computed tomography (CT). This method involves reconstruction of an image of one or more slices of an object from a set of x-ray projection data. Even if the original projection data are recorded by an analog device such as film, a digital computer is usually used to reconstruct the final image. Again, the use of the computer necessitates a discrete representation of the image.

In this book and throughout the imaging literature, mathematical models or representations are used for objects and images, and we need to pay particular attention to the ramifications of our choice of model. Real objects are functions, but the models we use for them are often discrete. Familiar examples are the digital simulation of an imaging system and the digital reconstruction of a tomographic image; in both cases it is necessary to represent the actual continuous object as a discrete set of numbers. A common way to construct a discrete representation of a continuous object is to divide the space into N small, contiguous regions called *pixels* (picture elements) or *voxels* (volume elements). The integral of the continuous function over a single pixel or voxel is then one of N discrete numbers representing the continuous object. As discussed in detail in Chap. 7, many other discrete object representations are also possible, but the pixel representation is widespread.

There are rare circumstances where the object to be imaged is more naturally described by a discrete set of numbers rather than by a continuous function. For example, in some kinds of optical computing systems, data are input by modulating a set of point emitters such as light-emitting diodes. If we regard the optical computer itself as a generalized imaging system, then this array of luminous points is the object being imaged. If there are N emitters in the array, we can consider the object to be defined by a set of N numbers. Even in this case, however, we are free to adopt a continuous viewpoint, treating the point emitters as Dirac delta functions. After all, the object is not a set of discrete numbers but the radiance distribution at the diode array face. In our view, then, any finite, discrete object representation is, at best, an approximation to the real world.

To summarize to this point, both objects and images can be represented as either continuous functions in some number of dimensions or as sets of discrete numbers. Discrete representations for *objects* are not an accurate reflection of the real world and should be used with caution, while discrete representations of *images* may be almost mandatory if a computer is an integral part of the imaging system.

These diverse mathematical descriptions of objects and images can be unified by regarding all of them as *vectors* in some *vector space*. A discrete object model consisting of N pixels can be treated as a vector in an N -dimensional Euclidean space, while a continuous object is a vector in an infinite-dimensional Hilbert space. We shall refer to the space in which the object vector resides as *object space*, denoted \mathbb{U} , and we shall consistently use the designation \mathbf{f} to denote the object vector. Similarly, the space in which the data vector is defined will be called *data space* and denoted \mathbb{V} . This space will also be referred to as *image space* when direct imaging is being discussed.

IMAGING AS A MAPPING OPERATION

A unifying theme of this book is the treatment of the image formation process as a mapping between object space \mathbb{U} and image space \mathbb{V} . If we ignore the statistical nature of the imaging process, this mapping is unique in the sense that a particular object \mathbf{f} maps to a single image \mathbf{g} , though it may well be true that many different \mathbf{f} can produce the same \mathbf{g} . We shall refer to the mapping operator as \mathcal{H} , so that $\mathbf{g} = \mathcal{H}\mathbf{f}$.

The mapping operator \mathcal{H} can be either linear or nonlinear. For many reasons, linear systems are easier to analyze than nonlinear ones, and it is indeed fortunate that we can often get away with the assumption of linearity. One common exception to this statement is that many detectors are nonlinear, or at best only approximately linear over a restricted range of inputs.

Chapter 1 provides the mathematical foundation necessary to describe objects and images as vectors and imaging systems as linear operators. A particular kind of operator will emerge as crucial to the subsequent discussions: *Hermitian operators*, better known in quantum mechanics than in imaging. Study of the eigenvectors and eigenvalues of Hermitian operators will lead to the powerful mathematical technique known as *singular-value decomposition* (SVD). SVD provides a set of basis vectors such that the mapping effect of an arbitrary (not necessarily Hermitian) linear operator reduces to simple multiplication.

If the object and the image are both continuous functions, \mathcal{H} is referred to as a continuous-to-continuous, or CC, operator. If, in addition, \mathcal{H} is linear, the relation

between object and image is an integral. Similarly, if both object and image are discrete vectors, \mathcal{H} is referred to as a discrete-to-discrete, or DD, operator. If this DD operator is linear, the relation between object and image is a matrix-vector multiplication.

While both linear models, CC and DD, are familiar and mathematically tractable, neither is really a good description of real imaging systems. As noted above, real objects are continuous functions while digital images are discrete vectors. The correct description of a digital imaging system is thus a continuous-to-discrete, or CD, operator. While such operators may be unfamiliar, they can nevertheless be analyzed by methods similar to those used for CC and DD operators provided the assumption of linearity is valid.

Choice of basis When we describe objects and images as functions, which are vectors in a Hilbert space, we have many options for the basis vectors in this space. One very important basis set consists of plane waves or complex exponentials, and the resulting theory is known broadly as Fourier analysis. When a discrete sum of complex exponentials is used to represent a function, we call the representation a Fourier series, while a continuous (integral) superposition is called a Fourier transform.

A Fourier basis is a natural way to describe many imaging systems. If a spatial shift of the object produces only a similar shift of the image and no other changes, the system is said to be *shift invariant* or to have *translational symmetry*. The mapping properties of these systems are described by an integral operator known as *convolution*, but when object and image are described in the Fourier basis, this mapping reduces to a simple multiplication. In fact, Fourier analysis is equivalent to SVD for linear, shift-invariant systems.

When we use pixels or some other approximate representation of an object, we shall refrain from calling the expansion functions a basis since they do not form a basis for object space \mathbb{U} . Of course, any set of functions is trivially a basis for *some* space (the space of all linear combinations of functions in the set), but it is too easy to lose sight of the distinction between true basis functions for objects and the approximate models we construct.

DETECTORS AND MEASUREMENT NOISE

Every imaging system must include a detector, either an electronic or a biological one. Most detectors exhibit some degree of nonlinearity in their response to incident radiation. Some detectors, such as photographic film, are intrinsically very nonlinear, while others, such as silicon photodiodes, are quite linear over several orders of magnitude if operated properly. All detectors, however, eventually saturate at high radiation levels or display other nonlinearities.

Nonlinearities may be either *global* or *local*. With respect to imaging detectors, a global nonlinearity is one in which the response at one point in the image depends nonlinearly on the incident radiation at another (perhaps distant) point. An example would be the phenomenon known as blooming in various kinds of TV camera tubes. In a blooming detector, a bright spot of light produces a saturated image, the diameter of which increases as the intensity of the spot increases.

A simpler kind of nonlinearity is one in which the output of the detector for one image point or detector element depends nonlinearly on the radiation level in-

cident on that element but is independent of the level on other detector elements. This kind of nonlinearity is referred to as a local or point nonlinearity. To a reasonable approximation, film nonlinearities are local. A local nonlinearity may be either *invertible* or *noninvertible*, depending on whether the nonlinear input-output characteristic is monotonic. If the characteristic is monotonic and known, then it can be corrected in a computer with a simple algorithm.

Randomness due to noise is an essential limitation in any measurement system. We can include noise in our basic imaging equation by writing $\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}$, where \mathbf{n} is a random perturbation added to the noise-free image $\mathcal{H}\mathbf{f}$. Perhaps surprisingly, this additive form is completely general; we can think of $\mathcal{H}\mathbf{f}$ as the mean value of the random data vector \mathbf{g} , and \mathbf{n} is then just *defined* by $\mathbf{n} = \mathbf{g} - \mathcal{H}\mathbf{f}$. With this definition, \mathbf{n} has zero mean, but its other statistical properties can depend in a complicated way on the object and the imaging system.

In imaging, the two main noise sources are photon noise, which arises from the discrete nature of photoelectric interactions, and electronic noise in detectors or amplifiers. Photon noise usually obeys the Poisson probability law and electronic noise is almost always Gaussian.

IMAGE RECONSTRUCTION AND PROCESSING

The mapping from object to image is called the *forward problem*: given an object and knowledge of the imaging system, find the image. We are often interested also in the *inverse problem*: given an image (or some other data set), learn as much as we can about the object that produced it. Note that we do not say: given the image, find the object. Except in rare and usually highly artificial circumstances, it will not be possible to determine the object exactly.

An inverse problem is fundamental to indirect imaging systems, where an image-reconstruction step is needed in order to produce the final useful image. Even in direct imaging, a post-detection processing step may be used for image enhancement. For example, it may be desirable to smooth the image before display or to manipulate its contrast. We shall refer to all such manipulations, whether for purpose of image reconstruction or enhancement, as *post-processing*.

When we are explicitly discussing post-processing, it will often be necessary to distinguish the detector output from the final, processed image. We shall reserve the notation \mathbf{g} for the detector output. The vector \mathbf{g} may be the final image in a direct imaging system, but in indirect imaging it will refer to a data set to be processed further by an operator which we can call \mathcal{O} . In the latter case, we shall use the notation $\hat{\boldsymbol{\theta}} = \mathcal{O}\mathbf{g}$ to denote the final image, a vector of coefficients in a finite-dimensional (hence approximate) object representation. Since we are virtually never able to find these coefficients exactly, we use the caret to denote an estimate.

With post-processing, we have three vectors to deal with: \mathbf{f} , \mathbf{g} and $\hat{\boldsymbol{\theta}}$. These vectors are defined in, respectively, object space, data space and image or reconstruction space.

OBJECTIVE ASSESSMENT OF IMAGE QUALITY

In scientific or medical applications, the goal of imaging is to obtain information about the object. Aesthetic considerations such as bright colors, high contrast or

pleasing form play no obvious role in conveying this information, and subjective impressions of the quality of an image without consideration of its ability to convey information can be very misleading. We adopt the view, therefore, that any meaningful definition of image quality must answer these key questions:

1. What information is desired from the image?
2. How will that information be extracted?
3. What objects will be imaged?
4. What measure of performance will be used?

We refer to the desired information as the *task* and the means by which it is extracted as the *observer*. For a given task and observer and a given set of objects, it is possible to define quantitative figures of merit for image quality. We call this approach *objective* or *task-based* assessment of image quality.

Tasks Two kinds of information might be desired from an image: labels and numbers. There are many circumstances in which we want merely to label or identify the object. For example, a Landsat image is used to identify crops and a screening mammogram is used to identify a patient's breast as normal or abnormal.

More and more commonly in modern imaging, however, the goal is to extract quantitative information from images. A cardiologist might want to know the volume of blood ejected from a patient's heart on each beat, for example, or a military photointerpreter might want to know the number of planes on an airfield or the area of an encampment.

Different literatures apply different names to these two kinds of task. In medicine, labeling is *diagnosis* and extraction of numbers is *quantitation*. In statistics, the former is *hypothesis testing* and the latter is *parameter estimation*. In radar, detection of a target is equivalent to hypothesis testing (signal present vs. signal absent), but determination of the range to the target is parameter estimation.

We shall use the term *estimation* to refer to any task that results in one or more discrete numbers, while a task that assigns the object to one of two or more categories will be called *classification*. Various parts of the imaging literature discuss pattern recognition, character recognition, automated diagnosis, signal detection and image segmentation, all of which fall under classification, while other parts of the literature discuss metrology, image reconstruction and quantitation of gray levels in regions of interest, all of which are estimation tasks.

This dichotomy is not absolute, however, since often the output of an estimation procedure is used immediately in a classification, for example, when features are extracted from an image and passed to a pattern-recognition algorithm. Also, both aspects may be desired from a single image; radar, for example, is an acronym for Radio Detection and Ranging, implying that we want both to detect a signal (classification) and to determine its range (estimation). Often the very same image-analysis problem may be logically cast as either classification or estimation. In functional magnetic resonance imaging (fMRI), for example, the task can be formulated as detecting a change in signal as a result of some stimulus or estimating the strength of the change.

The conceptual division of tasks into classification and estimation will serve us well when we discuss image quality in Chaps. 13 and 14, but we shall also explore there the interesting cases of hybrid estimation/classification tasks and the implications of performing one kind of task before the other.

Observers We call the means by which the task gets done, or the strategy, the *observer*. In spite of the anthropomorphic connotation of this term, the observer need not be a human being. Often computer algorithms or mathematical formulas serve as the observer.

In many cases the observer for a classification task *is* a human, a physician viewing a radiograph or a photointerpreter studying an aerial photo, for example. In these cases the label results from the judgment and experience of the human, and the output is an oral or written classification.

It is, however, becoming increasingly common in radiology and other fields of imaging to perform classification tasks by a computer. If not fully computerized diagnosis, at least computer-aided diagnosis is poised to make an important contribution to clinical radiology, and computer screening of specimen slides is a great help to overworked pathologists. Satellite images generate such an enormous volume of data that purely human classification is not practical. In these cases, the computer that either supplements or supplants the human observer can be called a *machine observer*.

A special observer known as the *ideal observer* will receive considerable attention in this book. The ideal observer is defined as the observer that utilizes all statistical information available regarding the task to maximize task performance (see below for measures of performance). Thus the performance of the ideal observer is a standard against which all other observers can be compared.

Estimation tasks using images as inputs are most often performed by computer algorithms. These algorithms can run the gamut from very ad hoc procedures to ones based on stated optimality criteria that have to do with the bias and/or variance of the resulting estimates.

Objects The observer's strategy will depend on the source of the signal, that is, the parameters of the objects that distinguish one class from another if the task is classification, or the parameter to be estimated if the task is estimation. Table II lists possible sources of signal for a variety of imaging mechanisms.

Given a particular object, there will be a fixed signal and fixed background, or nonsignal component, at the input to the imaging system. Real imaging systems collect data from multiple objects, though, and there will therefore be a distribution of the signal-carrying component and background component across the full complement of objects in each class. The observer's strategy will depend on these distributions of signal and background in the object space.

The observer must also make use of all available knowledge regarding the image-formation process, including the deterministic mapping from object space to image space described above, and knowledge of any additional sources of variability from measurement noise, to generate as complete a description of the data as possible. The more accurately the observer's knowledge of the properties of the data, the better the observer will be able to design a strategy for performing the task.

Measures of task performance For a classification task such as medical diagnosis, the performance is defined in terms of the average error rate, in some sense, but we must recognize that there are different kinds of errors and different costs attached to them. In a binary classification task such as signal detection, where there are just two alternatives (signal present and signal absent), there are two kinds of error. The observer can assert that the signal is present when it is not, which is a false alarm or false-positive decision; or the assertion can be that the signal is not present when in fact it is, which would be a missed detection or a false-negative decision. The trade-off between these two kinds of error is depicted in the receiver operating characteristic (ROC) curve, a useful concept developed in the radar literature but now widely used in medicine. Various quantitative measures of performance on a binary detection task can be derived from the ROC curve (see Chap. 13).

Another approach to defining a figure of merit for classification tasks is to define costs associated with incorrect decisions and benefits (or negative costs) associated with correct decisions. Then the value of an imaging system can be defined in terms of the average cost associated with the classifications obtained by some observer on the images.

For an estimation task where the output is only a single number, we can define the performance in terms of an average error, but we must again recognize that there are two types of error: random and systematic. In the literature on statistical parameter estimation, the random error is defined by the variance of the estimate, while systematic error is called bias. Usually in that literature, bias is computed on the basis of a particular model of the data-generation process, but an engineer will recognize that systematic error can also arise because the model is wrong or the system is miscalibrated. Both kinds of bias will be discussed in this book.

Often more than one quantitative parameter is desired in an estimation task. An extreme example is image reconstruction where an attempt is made to assign one parameter to each pixel in the image. In this case some very subtle issues arise in attempting even to define bias, much less to minimize it. These issues get considerable attention in Chap. 15.

PROBABILITY AND STATISTICS

The figures of merit for image quality just mentioned are inherently statistical. They involve the random noise in the images and the random collection of objects that might have produced the images. In our view, any reasonable definition of image quality must take into account both of these kinds of randomness, so probability and statistics play a central role in this book.

The conventional distinction is that probability theory deals with the description of random data while statistics refers to drawing inferences from the data. From a more theoretical viewpoint, probability theory is essentially *deductive logic*, where a set of axioms is presented and conclusions are drawn, but these conclusions are, in fact, already inherent in the axioms. Statistics, with this dichotomy, is *inductive logic*, where the conclusions are drawn from the data, not just the axioms. Thus, as we shall see, we use probability theory to describe the randomness in objects and images. Statistical decision theory is the tool we use in the objective assessment of images formed by an imaging system for some predefined task.

Bayesians, frequentists and pragmatists We expect that our readers will have some previous acquaintance with basic definitions of probability and the associated operational calculus. There are, however, many subtleties and points of contention in the philosophy of probability and statistical inference. The divisions between different schools, classified broadly as frequentists and Bayesians, are profound and often bitter. We do not propose to enter seriously into this fray, but we cannot avoid adopting a point of view and an operational approach in this book. In this section we give a short summary of what this point of view is and why we have adopted it for various problems in image science.

Of the various definitions of probability given in App. C, perhaps the most intuitively appealing is the one that defines the probability of an event as its relative frequency of occurrence in a large number of trials under identical conditions. Because of the historical origins of probability theory, the concept of probability as relative frequency is usually illustrated in terms of games of chance; *e.g.*, the probability of a coin showing heads is the relative number of times it does so in a very large number of trials. In an optical context, it is easy to conceive of an experiment where the number of photoelectric events in some detector, say a photomultiplier, is recorded for many successive one-second intervals. The limit of the histogram of these counts as the number of trials gets very large can be regarded as the probability law for the counts.

To a Bayesian, probability is a measure of degree of belief, an element of inductive logic and not a physical property or an observable quantity. To illustrate this concept and its relation to frequency, we let some well-known Bayesians speak for themselves:

We ... regard probability as a mathematical expression of our degree of belief in a certain proposition. In this context the concept of verification of probabilities by repeated experimental trials is regarded as *merely* [emphasis added] a means of calibrating a subjective attitude. (Box and Tiao, 1992)

... long-run frequency remains a useful notion for some applications, as long as we remain prepared to recognize that the notion must be abandoned if it contradicts our degree of belief (Press, 1989)

The essence of the present theory is that no probability, direct, prior, or posterior, is simply a frequency. (Jeffreys, 1939)

The interpretation we shall intend in this book when we use the word *probability* will depend somewhat on context. We are pragmatists—many times a relative-frequency interpretation will serve our needs well, but we shall not hesitate to use Bayesian methods and a subjective interpretation of probability when it is useful to do so. In particular, we can often present certain conditional probabilities of the data that we can be “reasonably certain” (a measure of belief, to be sure) would be verified by repeated experiments. Other times, as we shall argue below, there is no conceivable way to experimentally verify a postulated probability law, and in those cases we must be content to regard the probabilities in a Bayesian manner.

Our way of resolving this ambivalence will be presented below after we have seen in more detail how some probabilities of interest in imaging can be interpreted as frequencies and others cannot.

Conditional probability of the image data A statistical entity that plays a major role in the description of the randomness in an image is the conditional probability (or

probability density) of an image data set obtained from a particular object. Since we usually refer to a data set as \mathbf{g} and an object as \mathbf{f} , this conditional probability is denoted $\text{pr}(\mathbf{g}|\mathbf{f})$. Here each component of the image vector \mathbf{g} refers to a particular measurement; for example, the component g_m could be the measured gray level in the m^{th} pixel on an image sensor. The object \mathbf{f} , on the other hand, is best conceptualized as a vector (or function) in an infinite Hilbert space.

The conditional probability $\text{pr}(\mathbf{g}|\mathbf{f})$ is the basic description of the randomness in the data, and it is paramount to compute it if we want to give a full mathematical description of the imaging system. Moreover, all inferences we wish to draw about the object \mathbf{f} , whether obtained by frequentist or Bayesian methods, require knowledge of $\text{pr}(\mathbf{g}|\mathbf{f})$.

Fortunately, $\text{pr}(\mathbf{g}|\mathbf{f})$ is usually quite simple mathematically. For example, with so-called photon-counting imaging systems, it follows from a few simple axioms (enumerated in Chap. 11) that each component of \mathbf{g} is a Poisson random variable and that different components are statistically independent. As a second example, if there are many independent sources of noise in a problem, the central-limit theorem (derived in Chap. 8) allows us to assert that each component of \mathbf{g} is a normal or Gaussian random variable, and often the statistical independence of the different components (conditional on a fixed \mathbf{f}) can be justified as well. In these circumstances, we see no difficulty in regarding $\text{pr}(\mathbf{g}|\mathbf{f})$ as a relative frequency of occurrence. We could easily repeat the image acquisition many times with the same object and accumulate a histogram of data values g_m for each sensor element m . If we have chosen the correct model for the imaging system and all experimental conditions (including the object) are held constant, each of these histograms should approach the corresponding marginal probability $\text{pr}(g_m|\mathbf{f})$ computed on the basis of that model. If we can also experimentally verify the independence of the different values of g_m , we will have shown that the histogram, in the limit of a large number of data sets, is well described by the probability law $\text{pr}(\mathbf{g}|\mathbf{f})$, which in this case is just the product of the individual $\text{pr}(g_m|\mathbf{f})$. Of course, this limiting frequency histogram will depend on the nature of the object and properties of the imaging system, but the mathematical form should agree with our calculation.

The conditional probability $\text{pr}(\mathbf{g}|\mathbf{f})$ is naturally interpreted as a relative frequency since it describes the random variation of the image for repeated observations on the same object. This conditional probability is as much a part of our mathematical description of an imaging system as the system operator \mathcal{H} . The distinction is that \mathcal{H} specifies the average or deterministic characteristics of the system, while $\text{pr}(\mathbf{g}|\mathbf{f})$ specifies the randomness in the image, in a relative-frequency sense. Both are needed for a full description.

Priors When we go beyond the statistical description of the data to the task of drawing inferences from the data, we quickly find that the relative-frequency interpretation of probability is quite limiting. The frequentist approach is to disavow all prior knowledge of the object and form inferences using only the data \mathbf{g} . A little experience with this approach, however, soon convinces one that prior knowledge is essential. If we have only the data, a parameter estimate would logically have to be chosen to be maximally consistent with the data. But the data are often very noisy, so the resulting estimate must be noisy as well. Presented with an image reconstructed by any method that enforces strict agreement with the data, and which incorporates no prior object information, almost everyone would reject it as virtu-

ally useless because of the enormous noise amplification that results. This subjective judgment is really an assertion that we have not incorporated prior knowledge of the objects being imaged.

Bayesian methodology allows us to use prior knowledge about the object being imaged in a logically consistent manner in forming a reconstruction or drawing other inferences. In the image-reconstruction problem, incorporation of prior information results in a smoother image that most observers would assess as more in keeping with prior beliefs about the object.

The difficulty is that the Bayesian method requires a specific functional form for the prior object probability. For hypothesis testing, a conditional probability $\text{pr}(\mathbf{f}|H_j)$ is required, where H_j is the j^{th} hypothesis. For estimation of a parameter $\theta(\mathbf{f})$ related to the object, we need $\text{pr}[\theta(\mathbf{f})]$, which might be calculated from $\text{pr}(\mathbf{f})$. But how do we get such prior object information and what does it mean?

The Bayesian would argue that it is illogical to even try to think of $\text{pr}(\mathbf{f})$ in frequency terms. His contention would be that there is but a single object of interest at any one time, so $\text{pr}(\mathbf{f})$ cannot represent a frequency. Rather, it is a logical element representing our state of knowledge about the (unvarying) object. But in fact this knowledge, like all human knowledge, must have been acquired by experience and observation. We can have no conception of what a liver image should look like without seeing at least a few liver images. Different livers, belonging to different patients, *do* vary, so there should be no objection to using this known variation as an element of an inference. Often the crucial determinant in a diagnosis of liver disease will be whether the observed shape represents a normal anatomical variant or a pathological condition, and this question can be addressed only with frequency information about normal livers.

Because of the sheer dimensionality of the problem, however, the full prior $\text{pr}(\mathbf{f})$ cannot be defined *ab initio* in relative-frequency terms. Even for a relatively coarse discrete model, the number of possible vectors \mathbf{f} is astronomical. For example, if we sample \mathbf{f} on a 64×64 grid and allot 256 gray levels (8 bits) to each sample, there are 256^{4096} or some $10^{10,000}$ possible vectors \mathbf{f} . No amount of experimentation would give an estimate of the relative frequency of occurrence of these vectors. Moreover, in contrast to the situation with $\text{pr}(\mathbf{g}|\mathbf{f})$, there is no simple mathematical model for $\text{pr}(\mathbf{f})$.

Thus, our view coincides with the Bayesian one at this point: the role of the prior $\text{pr}(\mathbf{f})$ in imaging problems is to incorporate what knowledge we do have about \mathbf{f} , not to devise a density from which a sample would resemble the object. A prior on \mathbf{f} must be interpreted as a statement about our knowledge of \mathbf{f} , not a relative frequency. Our strongest argument for this conclusion is, however, one of complexity and dimensionality; it does not stem from a belief that it is somehow inappropriate to consider other objects when making inferences about a particular one.

On the other hand, many priors *can* be interpreted as frequencies. Suppose we want to estimate a single scalar parameter such as a cardiac ejection fraction. It is not at all unreasonable to collect data on the frequency of occurrence of different values of this parameter in some population of interest, and it is quite appropriate to regard these data as a prior probability when estimating the parameter for a particular patient (Mr. Jones, say). If we are “confident” (again, a statement of belief) that Mr. Jones has many characteristics in common with the population used to construct the prior, then we can improve the estimate of ejection fraction for Mr. Jones by considering the population data.

Similarly, in hypothesis testing there may well be useful information available about the frequency with which each hypothesis is true. In medical terms, this information is called disease prevalence, and it should certainly be incorporated into any diagnosis. Of course, there may also be information about a particular patient, say history or clinical indications, which would lead the Bayesian diagnostician to alter the prior probability of disease for that particular patient. In this case, subjective and objective (frequency) information can be combined in a single inference.

Our overall attitude to priors is that they should be justified as relative frequencies when they can, but that Bayesian methods should not be avoided when they cannot. The best priors are the most realistic ones, in the sense that they best predict measurable sampling distributions, but less detailed prior information requires a more broadly construed prior probability law.

Image quality revisited Let us now return to the subject of objective, task-based assessment of image quality. Our basic premise is that image quality must be defined in terms of the *average* performance of some observer on some task of practical interest, but there is considerable room for discussion on the choice of task and observer as well as on the meaning of the word “average.”

The fact that measures of image quality depend on task and observer is simply a fact of life. We cannot expect one system to be better than another for all possible applications. One system might be superior in terms of quantitative accuracy and another in presenting subtle signals to a human for optimal detection. A diligent reader of this book will learn how to compute figures of merit under a wide variety of conditions for many different tasks and observers.

The meaning of the word average is more subtle. An average is always computed with respect to some probability law, and in imaging every probability law rests on statistical knowledge of the object. As we saw above, that knowledge can be partially frequentist but will always have a significant subjective or Bayesian component.

Even so, the philosophy we have espoused for many years, and adopted for this book, is applicable. Image quality must be assessed on the basis of average performance of some task of interest by some observer or decision maker. Whether we are considering a classification or an estimation task, the performance measures are long-run averages, taking into account both conditional randomness of the data, as specified by $\text{pr}(\mathbf{g}|\mathbf{f})$, and randomness, in the sampling sense, of the object. These averages are unabashedly frequentist concepts, but they seem to us to be unavoidable. An image might be reconstructed or a diagnosis made by a Bayesian method, but ultimately we must keep score. How well does the method perform in the long run? We want to know not only our doctor’s personal certainty about our diagnosis, but also his batting average on similar cases. And if the batting averages for some diagnostic task are higher with imaging system A than with system B, we feel justified in claiming that system A is superior to system B for this task.

This is the point at which our approach differs from the strict Bayesian approach. We allow the use of prior information, and even subjective priors, in situations where sampling priors are unavailable or unreliable, but we compute the final performance of the procedure by averaging in a frequentist sense. This pragmatic approach, which will probably earn us the scorn of both camps, strikes us as a sensible middle ground. To a Bayesian who challenges this approach, we pose a question: How else would you compare two priors, two reconstruction algorithms

or two imaging systems? The frequentist, on the other hand, can hardly object to our allowance of subjective priors; they are, after all, justified in a frequentist sense if they give improved long-run performance.

Accounting for the object randomness in performance assessment could be done analytically if we had the full probability density function $\text{pr}(\mathbf{f})$, but we have already seen that this is difficult, if not impossible, even for the Bayesian. In practice, we must estimate the performance rather than compute it analytically. This estimate can be arrived at by using actual or simulated images, *i.e.*, samples drawn from $\text{pr}(\mathbf{f})$. The theoretical expressions for various diagnostic performance measures will be expressed as integrals over an object space of huge dimensionality, but in practice the integrals can be accurately estimated with an amazingly small number of samples. Procedures for carrying out this performance estimate for hypothesis-testing tasks will be detailed in Chap. 14.

Similarly, for an estimation task, we can compute the conditional estimation performance, for example the bias and variance of the estimate for some assumed object, then average the result over possible objects by sampling. In this procedure, any prior whatsoever can be used to find the parameter estimate in the first place, but the performance of that estimate is itself estimated with respect to a realistic sampling prior.

To return to a point raised in the Preface, we believe (however subjectively) that this approach is essential if imaging is to qualify as a science. One of the required elements of a science is that its theories have predictive value. For decades, centuries even, imaging has had its predictive theories for the propagation of light and the formation of images, but only much more recently has it been possible to predict the usefulness of those images. There is now a science of image evaluation that completes the picture by providing a formal, predictive theory of imaging and image quality. We hope after reading this book that you will be able to apply this theory toward the objective evaluation of the imaging systems that are of interest to you.

Vectors and Operators

As discussed in the Prologue, an imaging system is a transformation or mapping from an object to an image. It facilitates the analysis of imaging systems to regard the object as a vector in some space and the image as a vector in some other space, so that the system is an operator mapping from one space to another. To do this, we need a concept of a vector that is more general than the familiar one of conventional 3D vector analysis. For digital images, the extension is easy: we simply define a vector with the number of components equal to the number of pixels in the image and presume that the usual rules of conventional vector analysis still apply. It is often necessary, however, to regard the object, image or both as a function of one or more continuous¹ variables. To preserve the notion of an imaging system as an operator mapping between an object space and an image space in these cases, we must have a more general notion of a vector and the space in which it is defined.

Several different branches of mathematics, including linear algebra, functional analysis and integral transforms, relate to description of these general spaces and mappings between them. Linear algebra, at least as taught at an elementary level, deals with matrices, which can be viewed as mappings from one finite-dimensional space to another: an $M \times N$ matrix maps or transforms an N -dimensional vector to an M -dimensional one (Smith, 1984). A function is another kind of mapping. A scalar-valued function of a real variable x maps one point on the real line to another, thus transforming a scalar to another scalar. A *functional*, on the other hand, maps a function to a scalar; a simple example is a definite integral of the function. An integral transform is a functional that depends on a continuous parameter, so that

¹The word *continuous* has many meanings in mathematics and engineering. The reader should be careful to distinguish a *continuous variable* from a *continuous function*. A scalar that can assume any value over some segment of the real line is called a continuous variable to distinguish it from a discrete index. The elementary meaning of *continuous* for functions is presumed to be known to reader, and the extension of this concept to other mappings is discussed in Sec. 1.3.2.

the result can be thought of as a function itself. In other words, integral transforms, such as the Fourier transform, map a function to a function.

These different kinds of mappings are often treated separately in elementary courses, but there is an essential unity among them. In all cases we are dealing with vectors in some generalized sense and with operators that map one vector to another. Our approach in this chapter is to build a generalized theory on the foundation of ordinary 3D vector analysis with which the reader is presumably familiar.

At a few places in this chapter, we anticipate some simple properties of Dirac delta functions and Fourier transforms, discussed in more detail in Chaps. 2 and 3, respectively. The reader who is unfamiliar with these topics may wish to read at least Secs. 2.2.1, 2.2.4, 3.2.1 and 3.3.1 as background for this chapter.

1.1 LINEAR VECTOR SPACES

1.1.1 Vector addition and scalar multiplication

The simplest definition of vectors is that they are objects that can be added to each other and multiplied by numbers (Gel'fand, 1961). The familiar vectors from 3D vector analysis obviously satisfy this definition. We know that the multiplication of a vector \mathbf{f} , with Cartesian components (f_x, f_y, f_z) , by the scalar λ yields a new vector $\lambda\mathbf{f}$, the components of which are $(\lambda f_x, \lambda f_y, \lambda f_z)$. Similarly, addition of two vectors \mathbf{f}_1 and \mathbf{f}_2 is defined as the operation that yields the new vector $\mathbf{f}_1 + \mathbf{f}_2$, with components given by the sum of the corresponding components of \mathbf{f}_1 and \mathbf{f}_2 .

These definitions extend easily to many other kinds of vectors. Any ordered set of N numbers, called an N -tuple, can be thought of as an N -dimensional vector, with rules for scalar multiplication and addition analogous to the ones above. The individual numbers in the N -tuple are called the components of the vector, and the collection of all such vectors is called a *linear vector space*. If each component is a real number in the range $(-\infty, \infty)$, the space is designated \mathbb{R}^N . Hence the usual 3D space of vector analysis is \mathbb{R}^3 , and each vector in that space is a 3-tuple or triplet of real numbers. Similarly, if each vector is an N -tuple of complex numbers, and each component can assume any value in the complex plane, the space is denoted \mathbb{C}^N .

As a less familiar example, consider a quadratic function $f_1(x)$ defined by

$$f_1(x) = a_1x^2 + b_1x + c_1. \quad (1.1)$$

Multiplication of this function by the scalar λ gives a new quadratic $\lambda f_1(x) = \lambda a_1x^2 + \lambda b_1x + \lambda c_1$. Addition of $f_1(x)$ to a similar quadratic $f_2(x) = a_2x^2 + b_2x + c_2$ yields a third quadratic $f_3(x)$ with coefficients $a_3 = a_1 + a_2$, etc. The collection of all quadratics of the form of (1.1) thus constitutes a vector space, and the functions themselves are the vectors.

An easy extension of this argument shows that any polynomial qualifies as a vector, and the collection of all polynomials is another vector space. The space of polynomials of degree N or less is formally \mathbb{R}^N or \mathbb{C}^N , depending on whether the coefficients are real or complex. Other vector spaces where the vectors are functions will be defined below. Throughout this book, we shall designate vectors by boldface type, even when they are also functions, so $f(x)$ will also be written as \mathbf{f} .

A formal definition of a linear vector space is that it is a set of elements, called vectors, in which the operations of addition and multiplication by a scalar are defined and satisfy the following conditions (Gellert *et al.*, 1977; Stakgold, 1979):

- (a) Commutative property of scalar multiplication: $\mu(\lambda\mathbf{f}) = \lambda(\mu\mathbf{f})$, where λ and μ are arbitrary real or complex numbers.
- (b) Distributive property of scalar multiplication: $(\lambda + \mu)\mathbf{f} = \lambda\mathbf{f} + \mu\mathbf{f}$.
- (c) Existence of identity operator for scalar multiplication: $1\mathbf{f} = \mathbf{f}$.
- (d) Commutative property of addition: $\mathbf{f}_1 + \mathbf{f}_2 = \mathbf{f}_2 + \mathbf{f}_1$.
- (e) Associative property of addition: $(\mathbf{f}_1 + \mathbf{f}_2) + \mathbf{f}_3 = \mathbf{f}_1 + (\mathbf{f}_2 + \mathbf{f}_3)$.
- (f) Distributive property of scalar multiplication with respect to addition:
 $\lambda(\mathbf{f}_1 + \mathbf{f}_2) = \lambda\mathbf{f}_1 + \lambda\mathbf{f}_2$.
- (g) Existence of the zero vector, denoted $\mathbf{0}$ and defined such that $0\mathbf{f} = \mathbf{0}$ and $\mathbf{0} + \mathbf{f} = \mathbf{f}$ for all \mathbf{f} , where 0 (without boldface) is the ordinary scalar zero.
- (h) Continuity of addition: If $\lim_{n \rightarrow \infty} \mathbf{f}_n = \mathbf{f}$ and $\lim_{n \rightarrow \infty} \mathbf{g}_n = \mathbf{g}$, then
 $\lim_{n \rightarrow \infty} (\mathbf{f}_n + \mathbf{g}_n) = \mathbf{f} + \mathbf{g}$.
- (i) Continuity of multiplication: If $\lim_{n \rightarrow \infty} \mathbf{f}_n = \mathbf{f}$ and $\lim_{n \rightarrow \infty} \lambda_n = \lambda$, then
 $\lim_{n \rightarrow \infty} \lambda_n \mathbf{f}_n = \lambda\mathbf{f}$.

1.1.2 Metric spaces and norms

A familiar concept from 3D vector analysis is that of a distance or metric. The 3D vector \mathbf{f}_1 defines a point with Cartesian coordinates² (f_{1x}, f_{1y}, f_{1z}) in the 3D space, while \mathbf{f}_2 defines the point (f_{2x}, f_{2y}, f_{2z}) . One common way of defining the distance $d(\mathbf{f}_1, \mathbf{f}_2)$ between \mathbf{f}_1 and \mathbf{f}_2 is

$$d(\mathbf{f}_1, \mathbf{f}_2) = [(f_{1x} - f_{2x})^2 + (f_{1y} - f_{2y})^2 + (f_{1z} - f_{2z})^2]^{\frac{1}{2}}. \quad (1.2)$$

It is easy to show that this definition satisfies the following conditions:

- (a) $d(\mathbf{f}_1, \mathbf{f}_2) = d(\mathbf{f}_2, \mathbf{f}_1)$;
- (b) $d(\mathbf{f}_1, \mathbf{f}_2) \geq 0$;
- (c) $d(\mathbf{f}_1, \mathbf{f}_2) = 0$ if and only if $\mathbf{f}_1 = \mathbf{f}_2$;
- (d) $d(\mathbf{f}_1, \mathbf{f}_3) \leq d(\mathbf{f}_1, \mathbf{f}_2) + d(\mathbf{f}_2, \mathbf{f}_3)$ (triangle inequality).

In more general settings, we accept as a possible distance or metric any quantity that satisfies these four relations. A linear vector space for which the distance

²Do not confuse the notations \mathbf{f}_n and f_n . The boldface \mathbf{f}_n denotes the n^{th} vector in a set, while f_n denotes the n^{th} component of the vector \mathbf{f} . Thus, by this notation, the j^{th} component of the vector \mathbf{f}_n is denoted f_{nj} .

between any two vectors is defined, in a way consistent with these four conditions, is called a *metric space*. Different metric spaces are distinguished by the definition of distance employed.

Closely related to distance is the concept of a *norm*. In ordinary vector analysis, the norm or length of a vector is the distance between the vector and the origin (or the zero vector). In general, we denote the norm of \mathbf{f} as $\|\mathbf{f}\|$ and require that it satisfy

- (a) $\|\mathbf{f}\| \geq 0$, with equality if and only if $\mathbf{f} = \mathbf{0}$;
- (b) $\|\lambda\mathbf{f}\| = |\lambda| \cdot \|\mathbf{f}\|$, λ an arbitrary real or complex number;
- (c) $\|\mathbf{f}_1 + \mathbf{f}_2\| \leq \|\mathbf{f}_1\| + \|\mathbf{f}_2\|$ (triangle inequality).

Again, it is easy to show that these requirements are met by the conventional definition of length in vector analysis, but many other definitions are also consistent with them.

If we have any definition of norm, it leads immediately to a corresponding definition of distance. The distance $d(\mathbf{f}_1, \mathbf{f}_2)$ between \mathbf{f}_1 and \mathbf{f}_2 can be taken as the norm of $\mathbf{f}_1 - \mathbf{f}_2$.

In an N -dimensional vector space \mathbb{R}^N or \mathbb{C}^N , where a vector \mathbf{f} is an ordered set of N numbers $\{f_n\}$, some possible definitions of the norm are:

$$\|\mathbf{f}\|_2 = \left[\sum_{n=1}^N |f_n|^2 \right]^{\frac{1}{2}} \quad (\mathbb{L}_2 \text{ norm}), \quad (1.3)$$

$$\|\mathbf{f}\|_1 = \sum_{n=1}^N |f_n| \quad (\mathbb{L}_1 \text{ norm}), \quad (1.4)$$

$$\|\mathbf{f}\|_p = \left[\sum_{n=1}^N |f_n|^p \right]^{\frac{1}{p}} \quad (\mathbb{L}_p \text{ norm}), \quad (1.5)$$

$$\|\mathbf{f}\|_\infty = \lim_{p \rightarrow \infty} \|\mathbf{f}\|_p = \max_{n=1, \dots, N} |f_n| \quad (\mathbb{L}_\infty \text{ norm}). \quad (1.6)$$

In the \mathbb{L}_p norm, p can be any positive, real number, not necessarily an integer. The \mathbb{L}_∞ norm is also called the *sup norm* (for *supremum*).

If the \mathbb{L}_2 norm is adopted in a N -dimensional space, we refer to the space as *Euclidean* and denote it as \mathbb{E}^N , regardless of whether the components are real or complex.

1.1.3 Sequences of vectors and complete metric spaces

Another important concept in a vector space is the notion of the limit of a sequence of vectors, written as

$$\lim_{j \rightarrow \infty} \mathbf{f}_j = \mathbf{a}. \quad (1.7)$$

Several interpretations of this limit can be given. As a simple example, consider a sequence of ordinary 3D vectors \mathbf{f}_j with components (f_{jx}, f_{jy}, f_{jz}) . We can say that $\mathbf{f}_j \rightarrow \mathbf{a}$ as $j \rightarrow \infty$, provided each of the three components f_{jn} ($n = x, y, z$) approaches the corresponding component a_n of \mathbf{a} . Similarly, a sequence of vectors

in either \mathbb{R}^N or \mathbb{C}^N approaches a limiting vector \mathbf{a} if each component of the vectors in the sequence limits to the corresponding component of \mathbf{a} , *i.e.*, if $f_{jn} \rightarrow a_n$ as $j \rightarrow \infty$ for $n = 1, \dots, N$.

There is another way to interpret (1.7) if we have a distance measure in our space. A sequence of vectors \mathbf{f}_j in a metric space converges to the fixed vector \mathbf{a} if the distance from \mathbf{f}_j to \mathbf{a} , *i.e.*, $\|\mathbf{f}_j - \mathbf{a}\|$, tends to zero. The precise interpretation of the limit then depends on the metric chosen.

If the distance from one vector in the sequence, \mathbf{f}_j , to another, \mathbf{f}_k , approaches zero as j and k both go to infinity, the sequence is called a *Cauchy sequence*. Every convergent sequence is a Cauchy sequence, but the converse is not true in general because the limit vector may not be in the space (Stakgold, 1967).

If the limit vector \mathbf{a} is an element of the same space in which the \mathbf{f}_j are defined, for every Cauchy sequence, then the space is said to be *complete*. Several examples of complete and incomplete metric spaces are given by Kreysig (1978). For example, the real line and the complex plane are complete, but they become incomplete if even a single isolated point is omitted, or if only rational numbers are considered. The N -dimensional Euclidean space is complete for any finite N . The space of all polynomials of degree M or less is complete when the \mathbb{L}_2 norm is used, but not with \mathbb{L}_∞ . The space of all continuous, absolutely integrable functions on $[0, 1]$ is not complete, but the space of all absolutely integrable functions on that interval is complete.

A complete normed linear space is called a *Banach space*. The appellation honors Stefan Banach (1892–1945), a founder of functional analysis and member of the illustrious group of mathematicians who met at the Scottish Cafe in Lvov (now Lviv, Ukraine) in the 1930s (Kaluza, 1996).

1.1.4 Scalar products and Hilbert space

The space of most use to us in this book is Hilbert space, after David Hilbert (1862–1943). Hilbert launched the twentieth century (for mathematicians, at least) with a talk entitled “Mathematical Problems,” delivered to the Second International Congress of Mathematicians in Paris in 1900. In it, he listed 23 unsolved problems that would occupy the best mathematical minds far into the future. Problem no. 6, in which Hilbert himself took the lead, called for a rigorous mathematical treatment of the axioms of physics. In the first decade of the century, Hilbert and his student Erhard Schmidt developed a theory of integral equations and functions of infinitely many variables. Hilbert showed that many obscure analytic relations in this field become almost intuitively obvious when stated in geometric terms (Reed, 1996). This work, which Hilbert called “spectral theory,” can be regarded as the birth of modern linear algebra, while Hilbert space is the mathematical underpinning of quantum mechanics and hence all of modern physics (Boyer and Merzbach, 1989).

A Hilbert space, an important special case of a normed linear space, is a Banach space in which a scalar product is defined. Again we introduce the subject by appeal to ordinary vector analysis, where the scalar or dot product of two 3D vectors \mathbf{a} and \mathbf{b} is defined as

$$(\mathbf{a}, \mathbf{b}) = a_x b_x + a_y b_y + a_z b_z = \|\mathbf{a}\| \cdot \|\mathbf{b}\| \cos[\theta(\mathbf{a}, \mathbf{b})], \quad (1.8)$$

where $\theta(\mathbf{a}, \mathbf{b})$ is the angle between \mathbf{a} and \mathbf{b} . Thus, for ordinary 3D vectors, both norm and scalar product are defined. The norm expresses the length of a vector,

while the scalar product of two vectors depends not only on their lengths, but also on the angle between them. Since we have already noted that the 3D Euclidean space is complete, the existence of a scalar product as defined above makes it a Hilbert space.

Scalar products In a general Hilbert space, the scalar or inner product $(\mathbf{f}_1, \mathbf{f}_2)$ is a complex-valued functional of the vectors \mathbf{f}_1 and \mathbf{f}_2 with the following properties:

- (a) $(\mathbf{f}_1, \mathbf{f}_2) = (\mathbf{f}_2, \mathbf{f}_1)^*$;
- (b) $(\mathbf{f}_1, \lambda \mathbf{f}_2) = \lambda (\mathbf{f}_1, \mathbf{f}_2)$;
- (c) $(\lambda \mathbf{f}_1, \mathbf{f}_2) = \lambda^* (\mathbf{f}_1, \mathbf{f}_2)$;
- (d) $(\mathbf{f}_1 + \mathbf{f}_2, \mathbf{f}_3) = (\mathbf{f}_1, \mathbf{f}_3) + (\mathbf{f}_2, \mathbf{f}_3)$;
- (e) $(\mathbf{f}_1, \mathbf{f}_1) \geq 0$, with equality if and only if \mathbf{f}_1 is the zero vector.

Property (c) follows from (a) and (b) but is listed separately since it is an important operational rule. Slightly different versions of (b) and (c) are often used; many authors, especially in the mathematics literature, require that $(\mathbf{f}_1, \lambda \mathbf{f}_2) = \lambda^* (\mathbf{f}_1, \mathbf{f}_2)$. The convention given above, however, is common in the physics literature and is the one used throughout this book.

A Hilbert space is always normed, with the norm $\|\mathbf{f}\|$ defined as $\sqrt{(\mathbf{f}, \mathbf{f})}$, so all Hilbert spaces are Banach spaces. The converse, however, does not hold; not all norms are compatible with the required properties of scalar products. For example, the \mathbb{L}_p norm with $p \neq 2$, defined in (1.5), cannot be generated from a scalar product (Stakgold, 1979). If we choose to work with \mathbb{L}_2 , we can therefore take advantage of many useful properties of Hilbert spaces, but the choice of \mathbb{L}_p with $p \neq 2$ confines us to the more general Banach space. Since many of the results in the remainder of this chapter are derived for Hilbert spaces, this is a powerful incentive to choose the \mathbb{L}_2 norm.

Euclidean and \mathbb{L}_2 spaces An important example of a Hilbert space is the N -dimensional Euclidean space \mathbb{E}^N , where each vector \mathbf{f} is an ordered set of complex numbers $\{f_n, n = 1, \dots, N\}$, and the scalar product is defined as

$$(\mathbf{f}_1, \mathbf{f}_2) = \sum_{n=1}^N f_{1n}^* f_{2n}. \quad (1.9)$$

It is straightforward to show that this definition satisfies properties (a)–(e) above, and the \mathbb{L}_2 norm of (1.3) follows at once by setting $\mathbf{f}_1 = \mathbf{f}_2$ and using $\|\mathbf{f}\| = \sqrt{(\mathbf{f}, \mathbf{f})}$.

Another important example of a Hilbert space, usually denoted $\mathbb{L}_2(\alpha, \beta)$, or just \mathbb{L}_2 for short, is the space of complex-valued functions $f(x)$ with a scalar product defined by

$$(\mathbf{f}_1, \mathbf{f}_2) = \int_{\alpha}^{\beta} dx f_1^*(x) f_2(x). \quad (1.10)$$

In this space, the norm is defined by

$$\|\mathbf{f}\| = \sqrt{(\mathbf{f}, \mathbf{f})} = \left[\int_{\alpha}^{\beta} dx |f(x)|^2 \right]^{\frac{1}{2}}. \quad (1.11)$$

For this norm to exist, the integral of the squared modulus of the function over the range (α, β) must exist, so $\mathbb{L}_2(\alpha, \beta)$ is frequently referred to as the space of square-integrable functions. The integral may have to be interpreted in the Lebesgue sense in some cases, but we do not need to go into that detail here. For a concise introduction to Lebesgue integration, see Champeney (1987) or Friedman (1991).

Comparison of (1.9) and (1.10) shows the analogy between the discrete N -dimensional Euclidean space and the space $\mathbb{L}_2(\alpha, \beta)$. In the latter, scalar products and norms have the same structure as in the former, but the discrete sums are replaced with continuous integrals. In a sense, each x specifies a component of \mathbf{f} . Thus we may loosely view $\mathbb{L}_2(\alpha, \beta)$ as a Euclidean space with infinitely many dimensions.

Often we shall have occasion to consider functions of the form $f(\mathbf{r})$, where \mathbf{r} is itself a vector. If \mathbf{r} is defined in two spatial dimensions, it is a vector in \mathbb{R}^2 . The function $f(\mathbf{r})$, on the other hand, if it is square-integrable, is a vector in a Hilbert space in which norms and scalar products are defined by 2D integrals. If the range of integration in each dimension is $(-\infty, \infty)$, we denote the Hilbert space of $f(\mathbf{r})$ as $\mathbb{L}_2[(-\infty, \infty) \times (-\infty, \infty)]$ or $\mathbb{L}_2(\mathbb{R}^2)$. In the same spirit, $f(\mathbf{r})$ may be a square-integrable function defined on the unit disc, *i.e.*, the 2D region interior to the unit circle, which we shall denote as \mathbb{D} . In this case, the function $f(\mathbf{r})$ is said to be a vector in $\mathbb{L}_2(\mathbb{D})$. Where no confusion is likely to result, we shall just use \mathbb{L}_2 to denote the Hilbert space of square-integrable functions $f(\mathbf{r})$, regardless of the space in which \mathbf{r} is defined.

Weighted scalar products Sometimes it is useful to define scalar products with a weighting function in the integrand. For example, we might define

$$(\mathbf{f}_1, \mathbf{f}_2)_w = \int_{\alpha}^{\beta} dx w(x) f_1^*(x) f_2(x), \quad (1.12)$$

where we must require $w(x)$ to be real and ≥ 0 to avoid negative or imaginary norms. In this space, denoted $\mathbb{L}_2(\alpha, \beta; w(x))$, the norm is defined by

$$\|\mathbf{f}\|_w = \left[\int_{\alpha}^{\beta} dx w(x) |f(x)|^2 \right]^{\frac{1}{2}}. \quad (1.13)$$

The advantage of this space is that we can deal with functions that are not, by themselves, square-integrable. For example, $\cos x$ is not in $\mathbb{L}_2(-\infty, \infty)$ but it is in $\mathbb{L}_2(-\infty, \infty; \exp(-x^2))$.

Sobolev space *Sobolev space* is the general term for a function space (not necessarily a Hilbert space) where the norm involves derivatives. The *Sobolev-Hilbert space of order N* , denoted \mathbb{W}_N , consists of functions $f(x)$ such that $f(x)$ and all of its derivatives up to order $N - 1$ are absolutely continuous, while the N^{th} derivative lies in \mathbb{L}_2 (Wahba, 1990).

Schwarz inequality It follows from the definitions of scalar products and norms that the Schwarz inequality holds in every Hilbert space. This important inequality states that

$$|(\mathbf{f}_1, \mathbf{f}_2)|^2 \leq \|\mathbf{f}_1\|^2 \cdot \|\mathbf{f}_2\|^2, \quad (1.14)$$

where the equality holds if and only if $\mathbf{f}_2 = \gamma\mathbf{f}_1$, with γ a constant. Once again, this result is familiar from ordinary 3D vector analysis, where it merely states that the cosine of the angle between two vectors is less than or equal to unity. For real functions, it is reasonable to interpret $(\mathbf{f}_1, \mathbf{f}_2)/(\|\mathbf{f}_1\| \cdot \|\mathbf{f}_2\|)$ as the cosine of the angle between \mathbf{f}_1 and \mathbf{f}_2 in spaces of any dimensionality.

1.1.5 Basis vectors

In conventional vector analysis, we are familiar with the concept of basis vectors or unit vectors along the coordinate axes. Essentially the same concept is applicable to the more general vectors we are discussing here.

If \mathbf{f} is a vector in an N -dimensional space, it is possible to find a set of N vectors $\{\mathbf{u}_n, n = 1, \dots, N\}$ such that \mathbf{f} can be represented as

$$\mathbf{f} = \sum_{n=1}^N \alpha_n \mathbf{u}_n, \quad (1.15)$$

where the $\{\alpha_n\}$ are a set of scalar coefficients particular to the vector \mathbf{f} being represented. If all vectors in the space can be represented in terms of the set $\{\mathbf{u}_n\}$ in this way, the set is said to be *complete* or to form a basis, and the space is said to be spanned by $\{\mathbf{u}_n\}$. (Do not confuse this meaning of the word complete with its meaning in complete metric spaces; unfortunately, both usages are common.) Conversely, if it is possible to find a set of N linearly independent vectors such that any \mathbf{f} in the space can be represented as in (1.15), then we say that the space is N -dimensional.

The choice of a basis is not unique; infinitely many different sets $\{\mathbf{u}_n\}$ can be found to represent \mathbf{f} in the form of (1.15). When a particular set has been chosen, however, the set of components $\{\alpha_n\}$ is a representation of the vector in the given basis. For finite-dimensional spaces, it is conventional to write these numbers in a column and refer to them as a column vector. It must be remembered, however, that this set of numbers will be different for different choices of the basis vectors, while the vector \mathbf{f} has a meaning and algebraic properties quite independent of the basis.

The minimum requirement to impose on a set of basis vectors is that they be linearly independent, so that it is not possible to write one of them as a linear combination of the others. It is very convenient to require further that they be *orthonormal*, which means that they are *orthogonal* and *normalized*. Two vectors \mathbf{u}_m and \mathbf{u}_n ($m \neq n$) are said to be orthogonal if their scalar product vanishes. If every vector in the set is orthogonal to every other, the set is linearly independent. A vector \mathbf{u}_n is normalized if its norm $\|\mathbf{u}_n\| = 1$. Since $\|\mathbf{u}_n\|^2 = (\mathbf{u}_n, \mathbf{u}_n)$, these two requirements can be combined into a single orthonormality condition, written as

$$(\mathbf{u}_m, \mathbf{u}_n) = \delta_{mn}. \quad (1.16)$$

Here the symbol δ_{mn} , with value 1 when $m = n$ and 0 if $m \neq n$, is known as the *Kronecker delta*, after Leopold Kronecker (1823–1891), a number theorist who amassed a fortune in Bismarck's Germany. It was Kronecker who said, "God made the integers; all the rest is the work of man" (Bell, 1937).

If the basis vectors satisfy the orthonormality condition, we can easily determine the expansion coefficients $\{\alpha_n\}$. Taking the scalar product of both sides of

(1.15) with \mathbf{u}_m , we find

$$(\mathbf{u}_m, \mathbf{f}) = \sum_{n=1}^N \alpha_n (\mathbf{u}_m, \mathbf{u}_n) = \sum_{n=1}^N \alpha_n \delta_{mn} = \alpha_m. \quad (1.17)$$

So the expansion coefficient α_m is just the scalar product of the basis vector \mathbf{u}_m with the vector \mathbf{f} being expanded, provided, of course, that a scalar product is defined and the orthonormality condition holds.

For functions (vectors) in an infinite-dimensional Hilbert space, the situation is more delicate. It is not possible to represent an arbitrary vector in such a space by a finite sum such as (1.15), and it is not obvious that it is possible to salvage the formalism by considering an infinite sum.

Fortunately, for a wide class of Hilbert spaces with infinite dimensionality, it is possible to expand an arbitrary vector in terms of a countably infinite set of basis vectors, so that the expansion of (1.15) is valid with the simple modification of setting the upper summation limit to ∞ . Hilbert spaces for which such a countable basis exists are called *separable*. Almost all Hilbert spaces used in analysis are separable, including $\mathbb{L}_2(\alpha, \beta)$ for α and β finite or infinite (Stakgold, 1979). For basis functions on these spaces, orthonormality is still specified by (1.16), and the expansion coefficients are still given by (1.17), though the indices run from 1 to ∞ .

1.1.6 Continuous bases

While it is always possible to use a denumerable basis set for any of the Hilbert spaces considered here, it may nevertheless be convenient or desirable to use a nondenumerably infinite set, especially for $\mathbb{L}_2(-\infty, \infty)$. In that case, the basis function is designated $u_\nu(x)$, where ν is a continuous index, and we refer to the set $\{u_\nu(x)\}$ for all ν in some range as a *continuous basis*.

To demonstrate the utility of continuous bases, we anticipate a few results from Chap. 3 on Fourier analysis. A function $f(x)$ defined on $\mathbb{L}_2(-\frac{1}{2}a, \frac{1}{2}a)$ can be expanded in a Fourier series of the form

$$f(x) = \frac{1}{\sqrt{a}} \sum_{n=-\infty}^{\infty} F_n \exp\left(\frac{2\pi inx}{a}\right), \quad (1.18)$$

where the expansion coefficient F_n is given by

$$F_n = \frac{1}{\sqrt{a}} \int_{-a/2}^{a/2} dx f(x) \exp\left(-\frac{2\pi inx}{a}\right). \quad (1.19)$$

These equations have the same structure as (1.15) and (1.17) if we take $u_n(x) = [1/\sqrt{a}] \exp(2\pi inx/a)$, so these functions comprise a countable orthonormal basis on $\mathbb{L}_2(-\frac{1}{2}a, \frac{1}{2}a)$. But what happens if we let $a \rightarrow \infty$? We cannot continue to define $u_n(x)$ with the factor of $1/\sqrt{a}$ since then $u_n(x)$ would tend to zero for all x . From the theory of Fourier *transforms*, however, we know that we can use as a basis the functions $u_\nu(x) = \exp(2\pi i\nu x)$, where the label ν ranges continuously from $-\infty$ to ∞ . The expansion of $f(x)$ is then given by

$$f(x) = \int_{-\infty}^{\infty} d\nu F(\nu) u_\nu(x). \quad (1.20)$$

The function $F(\nu)$ is known as the Fourier transform of $f(x)$, but in this discussion it plays the role of a set of expansion coefficients, analogous to F_n except that $F(\nu)$ depends on the continuous variable ν . To find the expansion coefficients, we follow a prescription similar to (1.17) and take the scalar product of both sides of (1.20) with $u_{\nu'}(x)$. The result is

$$F(\nu) = \int_{-\infty}^{\infty} dx u_{\nu}^*(x) f(x), \quad (1.21)$$

provided

$$(\mathbf{u}_{\nu}, \mathbf{u}_{\nu'}) = \int_{-\infty}^{\infty} dx u_{\nu}^*(x) u_{\nu'}(x) = \delta(\nu - \nu'), \quad (1.22)$$

where $\delta(\nu - \nu')$ is the Dirac delta function defined in Chap. 2. Equation (1.22) is in fact valid for $u_{\nu}(x) = \exp(2\pi i\nu x)$, but it also holds for many other sets of functions. It can be regarded as the generalization of the orthonormality relation, (1.16), when the functions are indexed by a continuous variable ν rather than a discrete index n .

Though developed in the context of Fourier analysis, (1.20)–(1.22) have much wider applicability. If all functions $f(x)$ in our space can be expanded in terms of some set of functions $u_{\nu}(x)$ satisfying (1.22), we say that the functions form a complete, continuous, orthonormal basis for the space. The expansion coefficients are found by (1.21), which looks very much like the scalar product $(\mathbf{u}_{\nu}, \mathbf{f})$ except that \mathbf{u}_{ν} is not a vector in the same space as \mathbf{f} . In the Fourier example, $\exp(2\pi i\nu x)$ is not square-integrable and hence not contained in $\mathbb{L}_2(-\infty, \infty)$.

1.2 TYPES OF OPERATORS

1.2.1 Functions and functionals

A function $f(x)$ is a transformation or mapping from one linear vector space to another. For simplicity, we assume throughout this section that $f(x)$ is a real, scalar-valued function, defined on $(-\infty, \infty)$. Therefore it associates each value x on the real line with another value on the real line. It maps \mathbb{R}^1 to \mathbb{R}^1 since the particular value $f(x_0)$ for some specific value x_0 of the variable x is a single real number. The complete function $f(x)$ is a vector in \mathbb{L}_2 but the particular value $f(x_0)$ is a vector or point in \mathbb{R}^1 . A scalar-valued function can thus be thought of as an algorithm in which one number, x_0 , is the input and another number, $f(x_0)$, is the output. The space in which the input is defined is referred to as the *domain* of the function, and the space of possible outputs is its *range*. For example, if $f(x) = x^2$, the domain is $\mathbb{R}^1(-\infty, \infty)$ and the range is $\mathbb{R}^1[0, \infty)$.

By contrast, a functional is a mapping from a function space to a scalar (or more generally, from a vector space to a scalar). Like a function, a functional can be regarded as an algorithm; its input is the function $f(x)$ and the output is the functional, a scalar denoted $\Phi[f(x)]$. The complete function $f(x)$ is required for the computation, even though the output is a single number. If $f(x)$ is square-integrable and $\Phi[f(x)]$ is real, the mapping is from \mathbb{L}_2 to \mathbb{R}^1 . As with functions, we can refer to the input space (here \mathbb{L}_2) as the domain of the functional. The range of the functional is the output space \mathbb{R}^1 (or some subset of it if not all real numbers can be generated by the functional).

The functional $\Phi[f(x)]$ is said to be linear if it satisfies

$$\Phi[f_1(x) + cf_2(x)] = \Phi[f_1(x)] + c\Phi[f_2(x)], \quad (1.23)$$

where c is an arbitrary scalar.

According to the *Riesz Representation Theorem* (Stakgold, 1979), the most general form of a linear functional on a Hilbert space is a scalar product of the form³

$$\Phi[f(x)] = (\mathbf{a}, \mathbf{f}) = \int_{-\infty}^{\infty} dx a^*(x) f(x). \quad (1.24)$$

In this case the domain of the functional is \mathbb{L}_2 but the range can be \mathbb{C}^1 or a subset of it if $a(x)$ is complex.

A simple example of a nonlinear functional is the norm, as defined, for example, by (1.11). Any definite integral in which $f(x)$ appears nonlinearly in the integrand is a nonlinear functional.

1.2.2 Integral transforms

Just as a function maps a scalar to a scalar and a functional maps a function to a scalar, an integral transform maps a function to a function. Once again we regard the mapping as an algorithm, but now both input and output are functions. Examples important in image science include the convolution and the Fourier transform.

The general form of a linear integral transform connecting 1D functions is

$$g(x') = \int_{\alpha}^{\beta} dx h(x', x) f(x), \quad (1.25)$$

where $h(x', x)$ is called the kernel of the transform. If both $f(x)$ and $g(x')$ are square-integrable over (α, β) , this integral transform maps $\mathbb{L}_2(\alpha, \beta)$ to the same space, $\mathbb{L}_2(\alpha, \beta)$. Note that the integral transform can be considered as a nondenumerably infinite set of functionals, one for each value of x' .

An example of a nonlinear integral transform from $\mathbb{L}_2(\alpha, \beta)$ to itself is

$$g(x') = \int_{\alpha}^{\beta} dx h(x', x) |f(x)|^2. \quad (1.26)$$

Integral transforms may also involve functions of several variables. For example, the 2D Fourier transform has the structure

$$F(\xi, \eta) = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy f(x, y) \exp[-2\pi i(\xi x + \eta y)]. \quad (1.27)$$

It is thus a linear integral transform from $\mathbb{L}_2(\mathbb{R}^2)$ to $\mathbb{L}_2(\mathbb{R}^2)$ if both $f(x, y)$ and $F(\xi, \eta)$ are square-integrable (a condition we frequently violate!).

As yet another example of a linear integral transform, consider the integral

$$g(x) = \int_{-\infty}^{\infty} dy f(x, y). \quad (1.28)$$

³Strictly speaking, this equation gives the general form of a *bounded, continuous* linear functional, where these terms are defined below.

This transform maps from $\mathbb{L}_2(\mathbb{R}^2)$ to $\mathbb{L}_2(\mathbb{R}^1)$ if $g(x)$ and $f(x, y)$ are square-integrable in their respective spaces.

We shall often use the term *continuous-to-continuous mapping*, (or *CC mapping*) to describe integral transforms. The reason for this term is that an integral transform maps a function of a continuous variable (as opposed to a discrete index) to another function of a continuous variable. There is no implication that either function is itself continuous or even that the mapping itself is continuous in the technical sense discussed in Sec. 1.3.2.

1.2.3 Matrix operators

An $M \times N$ real matrix \mathbf{H} has M rows and N columns. This matrix acting on a real N -dimensional vector \mathbf{f} yields a real M -dimensional vector \mathbf{g} . It therefore maps \mathbb{R}^N to \mathbb{R}^M . If we think of both vectors as elements of a Hilbert space with \mathbb{L}_2 norm, the mapping is from \mathbb{E}^N to \mathbb{E}^M . The mapping rule is the usual rule of matrix multiplication,

$$g_m = \sum_{n=1}^N H_{mn} f_n, \quad (1.29)$$

or in matrix form, $\mathbf{g} = \mathbf{H}\mathbf{f}$. This mapping is linear since $\mathbf{H}(\mathbf{f}_1 + \alpha\mathbf{f}_2) = \mathbf{H}\mathbf{f}_1 + \alpha\mathbf{H}\mathbf{f}_2$.

In many applications of this equation, \mathbf{g} represents a vector of physical measurements (such as a digital image) and \mathbf{f} is a vector of unknown parameters characteristic of some physical object, and the objective is to find or estimate \mathbf{f} . Success in this endeavor depends critically on the number of independent measurements. This number is not necessarily M since it may be possible to express some of the measurements as linear combinations of the others. The number of linearly independent measurements is the same as the number of linearly independent rows of \mathbf{H} . This number is called the *rank* of \mathbf{H} and denoted $R(\mathbf{H})$, or simply R if only one matrix is under discussion. It is not an obvious point, but it can be shown that the number of linearly independent columns is also R . An important rule is that the rank is less than or equal to the smaller of M and N , *i.e.*, $R \leq \min(M, N)$.

1.2.4 Continuous-to-discrete mappings

In Sec. 1.2.1 we saw that functionals map a function, for example in $\mathbb{L}_2(\alpha, \beta)$, to a scalar in \mathbb{R}^1 or \mathbb{C}^1 . Many physical measurement systems yield not one but a finite set of scalars. If the object being measured by such systems is a function in $\mathbb{L}_2(\alpha, \beta)$ and M real measurements are obtained, the system is a mapping from $\mathbb{L}_2(\alpha, \beta)$ to \mathbb{R}^M . If this mapping is linear, its most general form is

$$g_m = \int_{\alpha}^{\beta} dx f(x) h_m(x), \quad (1.30)$$

where g_m is the m^{th} component of the measurement vector \mathbf{g} . The kernel $h_m(x)$ can be called a *sensitivity function* since it describes the sensitivity of the m^{th} measurement to the value of the function $f(x)$ at point x . In an imaging context, $h_m(x)$ is also called the *point response function*.

We refer to the mapping of (1.30) as a *continuous-to-discrete* mapping since it maps a function of a continuous variable x to a discrete set of numbers. The function $f(x)$ itself need not be continuous, however, so long as it is square-integrable.

As noted in the Prologue, continuous-to-discrete mappings are the appropriate descriptions of digital imaging systems viewing real-world objects.

1.2.5 Differential operators

For completeness we mention that differential operators also fit into the general framework of this section. The operator d/dx , for example, is a linear operator whose domain is the set of all differentiable functions. The range is not the same as the domain since the derivative of a differentiable function may not be itself differentiable.

In physical applications, it is often desirable to consider functions that are square-integrable but not differentiable. For example, we might want to consider a function with an abrupt discontinuity, perhaps representing the edge of an object to be imaged. Such a function is in $\mathbb{L}_2(-\infty, \infty)$ since the discontinuity does not prohibit it from being square-integrable. The derivative across the discontinuity does not exist in an elementary sense but can be defined in terms of a generalized function, the delta function (see Chap. 2). By allowing generalized functions, we can thus consider discontinuous, square-integrable functions to be in the domain of d/dx . Note, however, that the derivative (a delta function) is not square-integrable, so again the range is not the same as the domain.

The use of generalized functions may also allow us to treat differential operators as integral operators. For example, the differential operator d/dx has the same effect on functions in $\mathbb{L}_2(-\infty, \infty)$ as the integral operator with kernel $h(x', x) = \delta'(x' - x)$, where $\delta'(x)$ denotes the derivative of a delta function as defined in Chap. 2.

Partial differential operators are of considerable importance in physics and image science. Virtually all of modern physics is based on linear, second-order partial differential operators. The Schrödinger equation, the Poisson equation, the time-dependent wave equation and the time-independent wave equation all fit into this category. An example of prime importance in optics and imaging is the Helmholtz operator, $\nabla^2 + k^2$, where ∇^2 is the 3D Laplacian. This operator appears in the time-independent wave equation, which describes the propagation of monochromatic light, so it is fundamental in the mathematical description of many kinds of imaging systems (see Chap. 9)

1.3 HILBERT-SPACE OPERATORS

1.3.1 Range and domain

Consider a linear operator \mathcal{H} that maps a vector \mathbf{f} in the Hilbert space \mathbb{U} to a vector \mathbf{g} in the Hilbert space \mathbb{V} (see Fig. 1.1). In operator form we write

$$\mathbf{g} = \mathcal{H}\mathbf{f}. \quad (1.31)$$

The space \mathbb{U} is the set of vectors on which \mathcal{H} can act, referred to as the domain of \mathcal{H} . The vector \mathbf{g} will be referred to as the *image* of \mathbf{f} , a term that is used in both mathematics and image science. Though \mathbf{g} is in \mathbb{V} , not all vectors in \mathbb{V} are necessarily images through \mathcal{H} . Thus the range of \mathcal{H} might be a subspace of \mathbb{V} .

Scalar products in \mathbb{U} and \mathbb{V} are denoted $(\cdot, \cdot)_{\mathbb{U}}$ and $(\cdot, \cdot)_{\mathbb{V}}$, respectively. The norms of \mathbf{f} and \mathbf{g} are, respectively, $\|\mathbf{f}\| = \sqrt{(\mathbf{f}, \mathbf{f})_{\mathbb{U}}}$ and $\|\mathbf{g}\| = \sqrt{(\mathbf{g}, \mathbf{g})_{\mathbb{V}}}$.

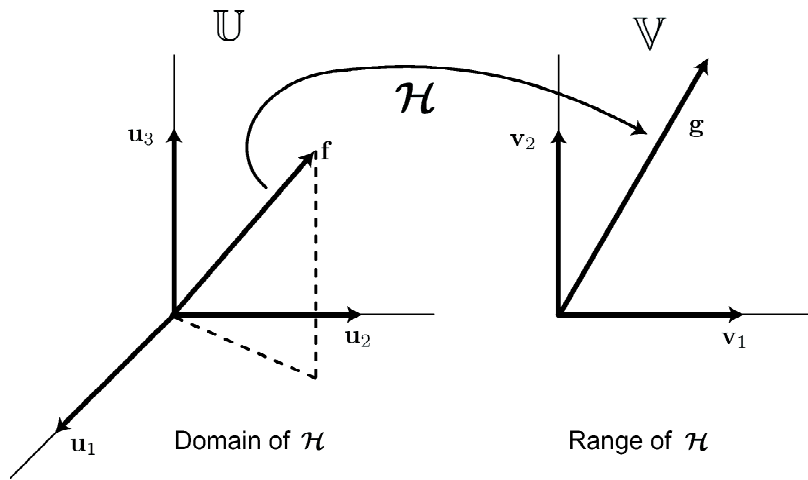

Fig. 1.1 Illustration of the mapping by an operator \mathcal{H} from a Hilbert space \mathbb{U} to a Hilbert space \mathbb{V} . For this illustration, \mathbb{U} is \mathbb{E}^3 and \mathbb{V} is \mathbb{E}^2 . The basis vectors $\{\mathbf{u}_n\}$ and $\{\mathbf{v}_n\}$ in \mathbb{U} and \mathbb{V} , respectively, are also shown.

1.3.2 Linearity, boundedness and continuity

The operator \mathcal{H} is linear if

$$\mathcal{H}[\mathbf{f}_1 + c\mathbf{f}_2] = \mathcal{H}\mathbf{f}_1 + c\mathcal{H}\mathbf{f}_2 \quad (1.32)$$

for all scalars c and all vectors in the domain of \mathcal{H} .

A linear operator \mathcal{H} is bounded if there exists a positive number Q such that $\|\mathcal{H}\mathbf{f}\| < Q\|\mathbf{f}\|$ for all \mathbf{f} in \mathbb{U} . In other words, a bounded operator cannot produce an image of infinite norm when operating on a vector of finite norm. The smallest constant Q for which this inequality holds for all \mathbf{f} in \mathbb{U} , called the norm of \mathcal{H} , is sometimes denoted $\|\mathcal{H}\|$.

A simple example of an unbounded operator on $\mathbb{L}_2(-\infty, \infty)$ is the differential operator d/dx . A discontinuous function $f(x)$ might have finite norm, but its derivative has infinite norm.

The operator \mathcal{H} is continuous if infinitesimal perturbations in \mathbf{f} lead to infinitesimal perturbations in \mathbf{g} . More formally, for each $\epsilon > 0$ there exists a $\delta > 0$ such that $\|\mathcal{H}\mathbf{f}_2 - \mathcal{H}\mathbf{f}_1\| < \epsilon$ whenever $\|\mathbf{f}_2 - \mathbf{f}_1\| < \delta$. Equivalently, if a sequence $\{\mathbf{f}_n\}$ converges to \mathbf{f} as $n \rightarrow \infty$, then $\{\mathcal{H}\mathbf{f}_n\}$ converges to $\mathcal{H}\mathbf{f}$ if and only if \mathcal{H} is continuous. For linear operators, boundedness implies continuity and vice versa. If the range and domain are both finite-dimensional Euclidean spaces, all linear operators are bounded.

1.3.3 Compactness

Another concept related to continuity is *compactness* of an operator. The importance of compactness will become evident in Sec. 1.4 when we discuss eigenvalue spectra, but in this section we discuss the meaning of compactness and conditions under which an operator is compact.

To define a compact operator, we return to the notion of an infinite sequence of input vectors $\{\mathbf{f}_j\}$. We presume the sequence is bounded, so that $\|\mathbf{f}_j\| < C$ for all j and some finite number C . Note that this sequence need not have a limit. It may, however, contain a subsequence that does have a limit. To illustrate, consider a sequence of vectors in the 2D plane (\mathbb{R}^2) where \mathbf{f}_{j+1} is obtained from \mathbf{f}_j by a rotation $\Delta\theta$. For simplicity, assume that $\|\mathbf{f}_j\| = 1$ for all j . As $j \rightarrow \infty$, the vector continues to rotate around the unit circle *ad infinitum*, and there is no limit to the sequence. If $2\pi/\Delta\theta$ is an integer k , then every k^{th} vector forms a convergent subsequence; since $\mathbf{f}_{j+k} = \mathbf{f}_j$, this subsequence has a limit. If $2\pi/\Delta\theta$ is not an integer, one can make any desired vector on the unit circle the limit point simply by choosing from the sequence vectors that lie successively closer to the chosen limit vector. In both cases, therefore, a convergent subsequence exists.

In a finite-dimensional space, such as the 2D space in the example above, every bounded infinite sequence contains a convergent subsequence, but in infinite-dimensional spaces that is not necessarily so, as a simple counterexample will show. Consider a separable Hilbert space spanned by the countably infinite orthonormal basis $\{\mathbf{u}_n\}$. This basis set can be thought of as a sequence, which is bounded since $\|\mathbf{u}_n\| = 1$ for all n . Since the \mathbf{u}_n are distinct (in fact, orthogonal), no subset of them will form a convergent subsequence.

We are now in a position to define compactness: A compact operator is one that maps a bounded sequence into one having a convergent subsequence. More precisely, whenever $\{\mathbf{f}_j\}$ is a sequence in \mathbb{U} with $\|\mathbf{f}_j\| < C$, then $\{\mathcal{H}\mathbf{f}_j\}$ contains a convergent subsequence if \mathcal{H} is compact. Compact operators are also called *completely continuous*. It is easy to show that all compact operators are bounded. It is also true that all bounded operators with a finite-dimensional range are compact. The interesting situation thus arises with operators such as integral transforms that have a range of infinite dimensionality.

The Hilbert-Schmidt theorem (Stakgold, 1979) provides an important way of determining if an integral transform is compact. A linear integral operator of the form of (1.25) is compact if its kernel satisfies the condition

$$\int_{\alpha}^{\beta} dx \int_{\alpha}^{\beta} dx' |h(x', x)|^2 < \infty. \tag{1.33}$$

Integral operators for which this condition is satisfied are called *Hilbert-Schmidt operators*. Though all Hilbert-Schmidt operators are compact, not all linear, compact integral operators are Hilbert-Schmidt.

If $\beta - \alpha$ is finite, the Hilbert-Schmidt condition is satisfied whenever $h(x', x)$ is bounded. If, on the other hand, (α, β) is $(-\infty, \infty)$, it is not sufficient that the kernel be bounded. Consider, for example, the convolution operator, where the kernel $h(x', x)$ is a function only of the difference $x' - x$ and (α, β) is $(-\infty, \infty)$. We can rewrite $h(x', x)$ as $h(x' - x)$ and, through a change of variables, perform the inner integral in (1.33) if $h(x)$ is square-integrable. The result is some finite positive number, but the outer integral still remains. Since the integral of a constant over an infinite range is infinite, the Hilbert-Schmidt condition is not satisfied.

A class of integral operators for which we can establish compactness, even when (α, β) is $(-\infty, \infty)$, consists of operators with kernels that can be written as a

finite sum of products of the form

$$h(x', x) = \sum_{j=1}^J p_j(x') q_j(x), \quad (1.34)$$

where J is finite and $p_j(x')$ and $q_j(x)$ are square-integrable for all j (Stakgold, 1979). Such kernels are referred to as *degenerate*. With this form of the kernel, the double integral in (1.33) becomes a sum of terms, each of which factors into a product of two convergent single integrals, and the Hilbert-Schmidt condition is satisfied. Thus all linear operators with kernels of the form of (1.34) are compact. For example, the operator with kernel $h(x', x) = \exp(-x^2 - x'^2)$ is compact, but one with kernel $h(x', x) = \exp[-(x - x')^2]$ is not.

1.3.4 Inverse operators

The operator \mathcal{H} is said to be *one-to-one* (or *injective*, in the older literature) if each vector \mathbf{g} in the range of \mathcal{H} is the image of exactly one vector \mathbf{f} in \mathbb{U} . Conversely, if \mathcal{H} is not one-to-one, two or more vectors in \mathbb{U} may produce the same image \mathbf{g} . Let \mathbf{f}_1 and \mathbf{f}_2 both have the same image, so that $\mathcal{H}\mathbf{f}_1 = \mathbf{g}$ and $\mathcal{H}\mathbf{f}_2 = \mathbf{g}$. It follows that $\mathcal{H}\{\mathbf{f}_2 - \mathbf{f}_1\} = \mathbf{0}$, where $\mathbf{0}$ is the zero vector. We say that $\mathbf{f}_2 - \mathbf{f}_1$ is a *null vector* of \mathcal{H} or a vector in the *null space* of \mathcal{H} . Only one-to-one operators have no (nontrivial) null space.⁴

If \mathcal{H} is one-to-one, we can define an inverse operator \mathcal{H}_L^{-1} such that

$$\mathcal{H}_L^{-1}\mathcal{H}\mathbf{f} = \mathbf{f} \quad (1.35)$$

for all \mathbf{f} in \mathbb{U} . That it is possible to define such an operator follows because $\mathcal{H}\mathbf{f}$ is, by definition, in the range of \mathcal{H} , and since \mathcal{H} is one-to-one, only a single \mathbf{f} can have this image. The subscript L on \mathcal{H}_L^{-1} indicates that it appears to the *left* of \mathcal{H} in (1.35), and \mathcal{H}_L^{-1} is referred to as the *left inverse* of \mathcal{H} . One-to-one operators always possess a left inverse.

Equation (1.35) can also be written in pure operator form without a specific operand as

$$\mathcal{H}_L^{-1}\mathcal{H} = \mathcal{I}_{\mathbb{U}}, \quad (1.36)$$

where $\mathcal{I}_{\mathbb{U}}$ is the unit operator in \mathbb{U} , mapping any vector \mathbf{f} into itself. Equation (1.35) follows from (1.36) by operating with both sides of the latter equation on an arbitrary \mathbf{f} in \mathbb{U} .

If all vectors in \mathbb{V} are in the range of \mathcal{H} , the mapping of \mathcal{H} is said to be *onto* \mathbb{V} , or simply *onto*. (The term *surjective* is also used.) We can, of course, simply define \mathbb{V} as the range of \mathcal{H} , in which case \mathcal{H} is automatically onto, but that is not always convenient. We might, for example, want to use some general Hilbert space such as \mathbb{L}_2 for the space \mathbb{V} , but there is no guarantee that \mathcal{H} can produce every vector in this space as an image.

If \mathcal{H} is onto (but not necessarily one-to-one), any \mathbf{g} in \mathbb{V} is the image of one or more vectors in \mathbb{U} . It is therefore possible to find an inverse operator that maps

⁴Do not confuse the terms *zero vector* and *null vector*. A zero vector has zero norm, while a null vector for some operator has finite norm itself, but its image through that operator has zero norm. The zero vector is, of course, a null vector of any linear operator, but it is a trivial one.

an arbitrary \mathbf{g} back to one of the vectors in \mathbb{U} that could have produced it as an image. If we operate on this \mathbf{f} with \mathcal{H} , we must get back to our original \mathbf{g} . We can thus define a *right inverse* \mathcal{H}_R^{-1} such that

$$\mathcal{H}\mathcal{H}_R^{-1}\mathbf{g} = \mathbf{g}, \quad (1.37)$$

or, in operator form,

$$\mathcal{H}\mathcal{H}_R^{-1} = \mathcal{I}_V, \quad (1.38)$$

where \mathcal{I}_V is the unit operator in \mathbb{V} .

In summary, a one-to-one operator always possesses a left inverse satisfying (1.36), while an operator that is onto always possesses a right inverse satisfying (1.38). We shall use the term *inverse*, without further qualification, only when (1.36) and (1.38) are both satisfied. If an inverse in this stricter sense exists, the operator is both one-to-one and onto, or *invertible* for short. The more mathematical literature uses the term *bijective* (injective plus surjective) for invertible. An invertible operator has no null space (except the trivial one containing only the zero vector). An operator that is not invertible is said to be *singular*. Thus, nonsingular, invertible and bijective are synonymous.

In an imaging context, real-world imaging operators (as opposed to computer simulations) are *always* singular.

1.3.5 Adjoint operators

Another operator that maps from \mathbb{V} to \mathbb{U} is the adjoint of \mathcal{H} , denoted \mathcal{H}^\dagger . The adjoint of a bounded operator is defined in terms of scalar products. Consider a particular vector in \mathbb{U} and call it \mathbf{f}_1 . The image of \mathbf{f}_1 is $\mathbf{g}_1 = \mathcal{H}\mathbf{f}_1$. The scalar product between \mathbf{g}_1 and some other vector \mathbf{g}_2 in \mathbb{V} , denoted $(\mathbf{g}_2, \mathcal{H}\mathbf{f}_1)_V$, is easily expressed as a sum or integral, as appropriate, over the space \mathbb{V} . It is often useful, however, to express the *same* scalar product as a sum or integral in the original space \mathbb{U} . We can do so by defining \mathcal{H}^\dagger such that

$$(\mathbf{g}_2, \mathcal{H}\mathbf{f}_1)_V = (\mathcal{H}^\dagger\mathbf{g}_2, \mathbf{f}_1)_U \quad (1.39)$$

for all \mathbf{g}_2 and \mathbf{f}_1 . We are thus free, by definition, to shift an operator \mathcal{H} from the right-hand side of a scalar product to the left so long as we replace the operator by its adjoint. This definition can be used to find explicit forms for adjoints, as demonstrated by several examples below.

The following properties of adjoints follow easily from the definition and properties of scalar products (Messiah, 1961):

- (a) $(c\mathcal{H})^\dagger = c^*\mathcal{H}^\dagger$;
- (b) $(\mathcal{H}_1 + \mathcal{H}_2)^\dagger = \mathcal{H}_1^\dagger + \mathcal{H}_2^\dagger$;
- (c) $(\mathcal{H}_1\mathcal{H}_2)^\dagger = \mathcal{H}_2^\dagger\mathcal{H}_1^\dagger$;
- (d) $(\mathcal{H}^\dagger)^\dagger = \mathcal{H}$,

where c is a scalar and \mathcal{H}_1 and \mathcal{H}_2 are two different operators mapping \mathbb{U} to \mathbb{V} .

If $\mathcal{H} = \mathcal{H}^\dagger$, which is possible only if $\mathbb{U} = \mathbb{V}$, the operator is said to be self-adjoint or *Hermitian*. If $\mathcal{H}^\dagger = \mathcal{H}^{-1}$, again possible only if $\mathbb{U} = \mathbb{V}$, the operator is said to be *unitary*.

Adjoint of a matrix operator To understand how to compute adjoints, we begin with the simple case of a matrix operator. If \mathcal{H} maps \mathbb{E}^N to \mathbb{E}^M , it is represented by an $M \times N$ matrix \mathbf{H} . Hence \mathcal{H}^\dagger maps \mathbb{E}^M to \mathbb{E}^N and is represented by an $N \times M$ matrix \mathbf{H}^\dagger . To determine the explicit form of the matrix elements of \mathbf{H}^\dagger , we use the definition of scalar products in Euclidean space, (1.9), in the definition of the adjoint, (1.39). From the left-hand side of (1.39), we obtain

$$(\mathbf{g}_2, \mathcal{H}\mathbf{f}_1)_\mathbb{V} = \sum_{m=1}^M g_{2m}^* \sum_{n=1}^N H_{mn} f_{1n} = \sum_{n=1}^N \sum_{m=1}^M g_{2m}^* H_{mn} f_{1n}. \quad (1.40)$$

Similarly, the right-hand side of (1.39) yields

$$(\mathcal{H}^\dagger \mathbf{g}_2, \mathbf{f}_1)_\mathbb{U} = \sum_{n=1}^N \left[\sum_{m=1}^M [\mathbf{H}^\dagger]_{nm} g_{2m} \right]^* f_{1n} = \sum_{n=1}^N \sum_{m=1}^M [\mathbf{H}^\dagger]_{nm}^* g_{2m}^* f_{1n}. \quad (1.41)$$

Comparison of the final forms of (1.40) and (1.41) shows that $[\mathbf{H}^\dagger]_{nm} = H_{mn}^*$, so the adjoint of \mathbf{H} is obtained by transposing it (interchanging rows and columns) and taking the complex conjugate of each element. For real matrices, adjoint and transpose are synonymous, and we can write $\mathbf{H}^\dagger = \mathbf{H}^t$, where the superscript t denotes transpose.

Adjoint of an integral operator Similar results hold for integral operators. Let \mathcal{H} now represent a linear integral operator as in (1.25). Then a scalar product $(\mathbf{g}_2, \mathcal{H}\mathbf{f}_1)$ can be written as

$$(\mathbf{g}_2, \mathcal{H}\mathbf{f}_1) = \int_\alpha^\beta dx f_1(x) \int_\alpha^\beta dx' g_2^*(x') h(x', x). \quad (1.42)$$

By the definition of the adjoint, this expression must also equal

$$(\mathcal{H}^\dagger \mathbf{g}_2, \mathbf{f}_1) = \int_\alpha^\beta dx \left[\int_\alpha^\beta dx' h^{(\dagger)}(x, x') g_2(x') \right]^* f_1(x), \quad (1.43)$$

where $h^{(\dagger)}(x, x')$ is the kernel of the adjoint operator. Comparison of (1.42) and (1.43) shows that

$$h^{(\dagger)}(x, x') = h^*(x', x). \quad (1.44)$$

Thus the kernel for \mathcal{H}^\dagger is obtained from the kernel for \mathcal{H} by interchanging x and x' and taking the complex conjugate. This result is the continuous generalization of the adjoint of a matrix.

In using (1.44), it is important to pay attention to which of the two arguments of the kernel is the variable of integration. By (1.25), we know that $g(x') = [\mathcal{H}\mathbf{f}](x') = \int dx h(x', x) f(x)$, so the integral is over the second argument of $h(x', x)$. Similarly, $[\mathcal{H}^\dagger \mathbf{g}](x)$ would be written as $\int dx' h^{(\dagger)}(x, x') g(x')$; again, the integral is over the second argument of the kernel, which here is $h^{(\dagger)}(x, x')$. With (1.44), however, we can also write $[\mathcal{H}^\dagger \mathbf{g}](x) = \int dx' h^*(x', x) g(x')$. The integral is now over the *first* argument of $h^*(x', x)$, which is just the conjugate of the kernel needed to compute $[\mathcal{H}\mathbf{f}](x')$; no explicit interchange is needed in moving from \mathcal{H} to \mathcal{H}^\dagger if we are careful to associate x with space \mathbb{U} and x' with \mathbb{V} consistently. The

situation is exactly the same as in the DD case, where we can write $[\mathbf{H}^\dagger \mathbf{g}]_n$ as either $\sum_m [\mathbf{H}^\dagger]_{nm} g_m$ or $\sum_m [\mathbf{H}]_{mn}^* g_m$.

The integral operator \mathcal{H} is Hermitian or self-adjoint if $h(x, x') = h^*(x', x)$. Integral operators with real kernels are Hermitian if the kernel is symmetric in interchange of the arguments.

Adjoint of a continuous-to-discrete mapping If the operator \mathcal{H} is the continuous-to-discrete mapping of (1.30), then its adjoint is a discrete-to-continuous mapping. This mapping yields a function of x denoted $[\mathcal{H}^\dagger \mathbf{g}](x)$, where \mathbf{g} is the vector with m^{th} component given by (1.30). An argument similar to the ones given for matrix and integral operators shows that

$$[\mathcal{H}^\dagger \mathbf{g}](x) = \sum_{m=1}^M g_m h_m^*(x). \quad (1.45)$$

Thus the adjoint operator in this case consists of a superposition of the complex conjugates of the sensitivity functions $h_m(\mathbf{r})$ with weights g_m .

1.3.6 Projection operators

An important class of operators is known in the linear-algebra literature as *projection operators*, though the reader is cautioned that this same term is used in other arenas (even elsewhere in this book!) with different meanings.

Projection operators have a property known as *idempotency*. An operator \mathcal{P} is said to be idempotent if

$$\mathcal{P}^2 = \mathcal{P}. \quad (1.46)$$

In other words, acting a second time with the same operator produces no further effect.

An idempotent operator that is also Hermitian is called a projection operator or *projector*.⁵ To see the reason for this designation, we consider a simple example in \mathbb{E}^N . Suppose that the vector \mathbf{f} is expanded in the orthonormal basis $\{\mathbf{u}_n, n = 1, \dots, N\}$ as in (1.15). The projection operator \mathcal{P}_n is defined so that

$$\mathcal{P}_n \mathbf{f} = \alpha_n \mathbf{u}_n, \quad (1.47)$$

for all \mathbf{f} , where α_n is the component of \mathbf{f} along direction \mathbf{u}_n . Thus the operator \mathcal{P} singles out one component of \mathbf{f} and produces a vector in the direction of the corresponding basis vector; all other components of \mathbf{f} are set to zero by \mathcal{P}_n . Once the components are set to zero, a second application of the operator has no further effect, so its idempotency is obvious. The resulting vector $\mathcal{P}_n \mathbf{f}$ is said to be the projection of \mathbf{f} along \mathbf{u}_n or onto the 1D subspace spanned by \mathbf{u}_n .

As a second example, consider the operator \mathcal{P}_{nm} defined so that

$$\mathcal{P}_{nm} \mathbf{f} = \alpha_n \mathbf{u}_n + \alpha_m \mathbf{u}_m, \quad (1.48)$$

⁵Some books use the term projector for any idempotent operator. The more specific term *orthogonal projector* is then used for an idempotent Hermitian operator. Our usage implies that a projector is both Hermitian and idempotent.

where \mathbf{f} is expressed by (1.15). In this case, the resulting vector lies in the 2D subspace spanned by \mathbf{u}_n and \mathbf{u}_m , and the operator \mathcal{P}_{nm} is said to project \mathbf{f} onto the nm -plane (see Fig. 1.2).

Fig. 1.2 Illustration of the meaning of the projection operators $\mathcal{P}_{\mathbb{S}}$ and $\mathcal{P}_{\mathbb{S}_{\perp}}$. The Hilbert space \mathbb{U} is \mathbb{E}^3 as in Fig. 1.1, subspace \mathbb{S} is the 1-2 plane, and subspace \mathbb{S}_{\perp} is the 3-axis.

More generally, if \mathbf{f} is defined in a Hilbert space \mathbb{U} , we can consider two subspaces \mathbb{S} and \mathbb{S}_{\perp} that together comprise the entire space \mathbb{U} . The subspaces are said to be orthogonal if any vector in \mathbb{S} is orthogonal to any vector in \mathbb{S}_{\perp} . The subspace \mathbb{S}_{\perp} is said to be the *orthogonal complement* of \mathbb{S} if any vector \mathbf{f} in \mathbb{U} can be written uniquely as a sum of two vectors, one in \mathbb{S} and one in \mathbb{S}_{\perp} . The required decomposition is

$$\mathbf{f} = \mathcal{P}_{\mathbb{S}} \mathbf{f} + \mathcal{P}_{\mathbb{S}_{\perp}} \mathbf{f}, \quad (1.49)$$

where $\mathcal{P}_{\mathbb{S}}$ is the projector onto \mathbb{S} and $\mathcal{P}_{\mathbb{S}_{\perp}}$ is the projector onto \mathbb{S}_{\perp} . Since $\mathbf{f} = \mathcal{I}\mathbf{f}$, where \mathcal{I} is the identity operator, it follows that

$$\mathcal{P}_{\mathbb{S}_{\perp}} = \mathcal{I} - \mathcal{P}_{\mathbb{S}}, \quad (1.50)$$

provided \mathbb{S}_{\perp} is the orthogonal complement of \mathbb{S} .

Explicit forms for these projectors can be given in terms of basis vectors for the two subspaces. Assume that \mathbb{S} is spanned by the orthonormal basis set $\{\phi_k, k = 1, \dots, K\}$ while \mathbb{S}_{\perp} is spanned by the orthonormal set $\{\psi_m, m = 1, \dots, M\}$. If the original space is \mathbb{E}^N , we must have $K + M = N$, but in general K or M or both can be infinite. One possible choice of bases would be for $\{\phi_k\}$ and $\{\psi_m\}$ to be disjoint subsets of $\{\mathbf{u}_n\}$, but any other bases would suffice as well.

In terms of the subspace basis vectors, the projections of \mathbf{f} are

$$\mathcal{P}_{\mathbb{S}} \mathbf{f} = \sum_{k=1}^K (\phi_k, \mathbf{f}) \phi_k, \quad (1.51)$$

$$\mathcal{P}_{\mathbb{S}_{\perp}} \mathbf{f} = \sum_{m=1}^M (\psi_m, \mathbf{f}) \psi_m. \quad (1.52)$$

1.3.7 Outer products

A convenient way of writing the projection operators of the last section, without reference to a particular vector \mathbf{f} , is in terms of *outer products* (also known as *tensor products*). Like the inner or scalar product, the outer product involves two vectors. Unlike the scalar product, however, an outer product is not a scalar but instead an operator. This concept will be explained first in terms of vectors in finite-dimensional Euclidean spaces.

Consider an M -dimensional vector \mathbf{b} and an N -dimensional vector \mathbf{a} . The outer product of these two vectors is the $M \times N$ matrix \mathbf{ba}^\dagger with components given by

$$[\mathbf{ba}^\dagger]_{mn} = b_m a_n^*. \quad (1.53)$$

One way to view this definition is to regard \mathbf{b} as an $M \times 1$ matrix (or column vector) and \mathbf{a} as an $N \times 1$ matrix. Then \mathbf{a}^\dagger is the $1 \times N$ matrix (row vector) obtained from \mathbf{a} by the rule derived above for forming the adjoint of a matrix operator: interchange rows and columns and take the complex conjugate. With this view, (1.53) follows from the usual rule for matrix-matrix multiplication (see Fig. 1.3).

$$\begin{array}{ccc} \mathbf{b} = \begin{pmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \end{pmatrix} & \mathbf{a} = \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix} \\ 4 \times 1 & 3 \times 1 \\ \mathbf{ba}^\dagger = \begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \end{bmatrix} \begin{bmatrix} a_1^* & a_2^* & a_3^* \end{bmatrix} = \begin{bmatrix} b_1 a_1^* & b_1 a_2^* & b_1 a_3^* \\ b_2 a_1^* & b_2 a_2^* & b_2 a_3^* \\ b_3 a_1^* & b_3 a_2^* & b_3 a_3^* \\ b_4 a_1^* & b_4 a_2^* & b_4 a_3^* \end{bmatrix} \\ & 4 \times 3 \end{array}$$

Fig. 1.3 Illustration of the outer product of two vectors \mathbf{b} and \mathbf{a} , where \mathbf{b} has 4 elements and is represented as a 4×1 column vector, while \mathbf{a} has 3 elements and is represented as a 3×1 column vector. The outer product \mathbf{ba}^\dagger is a 4×3 matrix or an operator that can map from \mathbb{E}^3 to \mathbb{E}^4 .

Another view of \mathbf{ba}^\dagger is to regard it as an operator mapping an $N \times 1$ vector to an $M \times 1$ vector. Consider the action of this operator on some $N \times 1$ vector \mathbf{c} . The result is an $M \times 1$ vector, the m^{th} element of which is

$$[\mathbf{ba}^\dagger \mathbf{c}]_m = \sum_{n=1}^N [\mathbf{ba}^\dagger]_{mn} c_n = \sum_{n=1}^N b_m a_n^* c_n = b_m \sum_{n=1}^N a_n^* c_n = (\mathbf{a}, \mathbf{c}) b_m, \quad (1.54)$$

or, in vector form,

$$\mathbf{ba}^\dagger \mathbf{c} = (\mathbf{a}, \mathbf{c}) \mathbf{b}. \quad (1.55)$$

Thus the result of this operator acting on \mathbf{c} is the vector \mathbf{b} times the scalar (\mathbf{a}, \mathbf{c}) . The notation makes this result evident⁶ when we realize that $\mathbf{a}^\dagger \mathbf{c}$ is just another

⁶Readers familiar with quantum mechanics will recognize that \mathbf{ba}^\dagger in Dirac notation is $|\mathbf{b}\rangle\langle\mathbf{a}|$ and $\mathbf{a}^\dagger \mathbf{c}$ is $\langle\mathbf{a}|\mathbf{c}\rangle$.

way of writing the scalar product,

$$\mathbf{a}^\dagger \mathbf{c} = (\mathbf{a}, \mathbf{c}) = \sum_{n=1}^N a_n^* c_n. \quad (1.56)$$

Thus (1.55) can be viewed as $(\mathbf{b}\mathbf{a}^\dagger)\mathbf{c} = \mathbf{b}\mathbf{a}^\dagger\mathbf{c} = \mathbf{b}(\mathbf{a}^\dagger\mathbf{c}) = (\mathbf{a}^\dagger\mathbf{c})\mathbf{b}$, where the last step is valid since $(\mathbf{a}^\dagger\mathbf{c})$ is just a scalar, and there is no problem with rewriting it on the other side of the vector \mathbf{b} .

We can readily generalize the concept of outer product to include continuous functions. We simply regard (1.55) as *defining* the operator $\mathbf{b}\mathbf{a}^\dagger$, with whatever form of the scalar product is appropriate. Thus either \mathbf{a} or \mathbf{b} can be either discrete or continuous, though of course \mathbf{a} and \mathbf{c} must be in the same space so that the scalar product can be defined.

In this new notation, one specific form of projection operator is

$$\mathcal{P} = \mathbf{p}\mathbf{p}^\dagger, \quad (1.57)$$

where \mathbf{p} is some vector with unit norm. The actions of this projector and its square on an arbitrary \mathbf{f} are

$$\mathcal{P}\mathbf{f} = \mathbf{p}\mathbf{p}^\dagger\mathbf{f} = (\mathbf{p}, \mathbf{f})\mathbf{p} \quad (1.58)$$

$$\mathcal{P}^2\mathbf{f} = \mathbf{p}\mathbf{p}^\dagger\mathcal{P}\mathbf{f} = (\mathbf{p}, \mathbf{f})(\mathbf{p}, \mathbf{p})\mathbf{p} = (\mathbf{p}, \mathbf{f})\mathbf{p} = \mathcal{P}\mathbf{f}, \quad (1.59)$$

where the last line follows since $(\mathbf{p}, \mathbf{p}) = \|\mathbf{p}\|^2 = 1$.

If $\mathbf{p} = \mathbf{u}_n$, then $\mathbf{p}\mathbf{p}^\dagger$ is the same as the simple projector defined in (1.47). The general form of a projector is

$$\mathcal{P} = \sum_n \mathbf{p}_n \mathbf{p}_n^\dagger, \quad (1.60)$$

where $\{\mathbf{p}_n\}$ is any set of mutually orthogonal vectors with unit norm. The idempotency follows since

$$\mathcal{P}^2\mathbf{f} = \sum_n \mathbf{p}_n \mathbf{p}_n^\dagger \mathcal{P}\mathbf{f} = \sum_n \sum_m (\mathbf{p}_m, \mathbf{f})(\mathbf{p}_n, \mathbf{p}_m)\mathbf{p}_n = \sum_n (\mathbf{p}_n, \mathbf{f})\mathbf{p}_n = \mathcal{P}\mathbf{f}, \quad (1.61)$$

and we have used the orthonormality of the \mathbf{p}_n .

We can also use this notation to express the completeness of a set of orthonormal basis vectors $\{\mathbf{u}_n, n = 1, \dots, N\}$. We have defined this set to be complete for representation of the space \mathbb{U} if any vector \mathbf{f} in the space can be expanded in terms of the \mathbf{u}_n . In terms of outer products, this requires that

$$\sum_{n=1}^N \mathbf{u}_n \mathbf{u}_n^\dagger = \mathcal{I}_{\mathbb{U}}, \quad (1.62)$$

where $\mathcal{I}_{\mathbb{U}}$ is the identity operator in \mathbb{U} . This completeness condition, illustrated in Fig. 1.4, is referred to as *closure* of the set $\{\mathbf{u}_k\}$ or the decomposition of the unit operator. If it is satisfied, the component expansion is

$$\mathbf{f} = \sum_{n=1}^N \mathbf{u}_n \mathbf{u}_n^\dagger \mathbf{f} = \sum_{n=1}^N (\mathbf{u}_n^\dagger \mathbf{f}) \mathbf{u}_n, \quad (1.63)$$

so that the expansion coefficients are given by $\alpha_n = \mathbf{u}_n^\dagger \mathbf{f}$, which is just another notation for the scalar product $(\mathbf{u}_n, \mathbf{f})$.

A similar closure relation can also be given for a continuous basis. If the set of functions $\{u_\nu(x)\}$, where ν is a continuous index, forms a basis for some Hilbert space \mathbb{U} , then any function in \mathbb{U} can be expanded as in (1.20). For this to be possible, we must have

$$\int_{-\infty}^{\infty} d\nu u_\nu^*(x') u_\nu(x) = \delta(x - x'), \quad (1.64)$$

which is the continuous closure relation analogous to (1.62). One way to interpret this equation is that it represents the expansion of the function $\delta(x - x')$ as a continuous superposition of the basis functions $u_\nu(x)$. Since x' is arbitrary, a delta function at any location can be synthesized in this way. Since, as we shall see in Chap. 2, any function in \mathbb{L}_2 can be expanded in terms of delta functions, (1.64) guarantees that any function in \mathbb{L}_2 can be expanded in terms of the full set of $u_\nu(x)$.

$$\begin{aligned} \mathbf{u}_1 &= \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} & \mathbf{u}_2 &= \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix} & \mathbf{u}_3 &= \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \\ \mathbf{u}_1 \mathbf{u}_1^\dagger &= \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} & \mathbf{u}_2 \mathbf{u}_2^\dagger &= \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix} & \mathbf{u}_3 \mathbf{u}_3^\dagger &= \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} \\ \sum_{j=1}^3 \mathbf{u}_j \mathbf{u}_j^\dagger &= \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} = \mathbf{I} \end{aligned}$$

Fig. 1.4 Illustration of the completeness of the three basis vectors in \mathbb{E}^3 . The sum of the 3 outer products is the identity operator.

1.4 EIGENANALYSIS

1.4.1 Eigenvectors and eigenvalue spectra

If the range and domain of a linear operator \mathcal{A} are the same space, it may be possible to find vectors ψ such that $\mathcal{A}\psi$ is the same as ψ except for a multiplicative constant. In other words, the length of the vector is changed but its angle is not. Since most vectors are changed into another vector in a different direction by action of the operator, these vectors are special ones characteristic of the operator. They are called *eigenvectors*, from the German for characteristic vectors, and the constant λ is an *eigenvalue*. A central theme running throughout this book is that eigenvectors and eigenvalues are essential tools for analyzing imaging systems and solving inverse problems.

The eigenvectors and eigenvalues satisfy an *eigenvalue equation* of the form

$$\mathcal{A}\psi = \lambda\psi, \quad (1.65)$$

or

$$[\mathcal{A} - \lambda\mathcal{I}]\psi = \mathbf{0}, \quad (1.66)$$

where $\mathbf{0}$ is the zero vector and \mathcal{I} is the unit operator.⁷

If the operator $\mathcal{A} - \lambda\mathcal{I}$ is invertible, (1.66) has only trivial solutions, $[\mathcal{A} - \lambda\mathcal{I}]^{-1}\mathbf{0} = \mathbf{0}$. Nontrivial solutions exist only if $\mathcal{A} - \lambda\mathcal{I}$ is singular. This conclusion leads to another interpretation of the eigenvalues: $\lambda\mathcal{I}$ is a particular shift of the operator \mathcal{A} that makes it singular. If \mathcal{A} itself is singular, $\lambda = 0$ is an eigenvalue, and conversely.

Depending on the operator, the eigenvalues may form a discrete set, or there might be some continuous range of possible values. In the former case we can use a discrete index n to label different eigenvalues and their associated eigenvectors. We say that \mathcal{A} has a *discrete spectrum* of eigenvalues, and (1.65) becomes

$$\mathcal{A}\psi_n = \lambda_n\psi_n. \quad (1.67)$$

If the eigenvalues fall in some continuous range, we need a continuous label ν to distinguish them, so the eigenvalue equation is written

$$\mathcal{A}\psi_\nu = \lambda_\nu\psi_\nu. \quad (1.68)$$

Such operators are said to have a *continuous spectrum*. Some operators have spectra with both continuous and discrete components.

Compact operators have only discrete spectra. In a finite-dimensional space, all linear operators are compact, so continuous spectra occur only for operators in infinite-dimensional spaces such as \mathbb{L}_2 . This class of operators includes both integral and differential operators, but we shall be concerned mainly with the former in this book.

In Sec. 1.3.3 we noted that a linear integral operator in $\mathbb{L}_2(\alpha, \beta)$ is compact if the Hilbert-Schmidt condition, (1.33), is satisfied. If α and β are finite, this condition requires only that the kernel be bounded. If, however, $(\alpha, \beta) = (-\infty, \infty)$, the only general rule we have is that the Hilbert-Schmidt condition is valid if the kernel is degenerate in the sense expressed by (1.34). Since even so common an operator as the convolution violates the Hilbert-Schmidt condition, we shall frequently have to account for continuous spectra.

1.4.2 Similarity transformations

We can operate on the eigenvalue equation (1.67) with some invertible operator \mathcal{W} and obtain a new eigenvalue equation:

$$\mathcal{W}\mathcal{A}\psi_n = \lambda_n\mathcal{W}\psi_n. \quad (1.69)$$

Since \mathcal{W} is invertible, we can insert the unit operator $\mathcal{W}^{-1}\mathcal{W}$, obtaining

$$\mathcal{W}\mathcal{A}\mathcal{W}^{-1}\mathcal{W}\psi_n = \lambda_n\mathcal{W}\psi_n. \quad (1.70)$$

This equation shows that the new operator $\mathcal{W}\mathcal{A}\mathcal{W}^{-1}$ has the same eigenvalue spectrum as the original operator \mathcal{A} , but with the new eigenvectors $\mathcal{W}\psi_n$. A

⁷A slightly different definition of eigenvalue is often used in treatises on integral equations. There it is common to write the eigenvalue equation as $\lambda\mathcal{A}\psi = \psi$. This convention yields eigenvalues that are the reciprocals of the ones used here.

transformation of operators and eigenvectors in this way by means of an invertible operator is called a *similarity transformation*, and \mathcal{A} and $\mathcal{W}\mathcal{A}\mathcal{W}^{-1}$ are said to be *similar operators*. Equation (1.70) shows that a discrete eigenvalue spectrum is invariant under a similarity transformation, and the same result for a continuous spectrum follows from an analogous derivation. In summary, similar operators have the same eigenvalue spectrum.

A particular form of similarity transformation is the *unitary transformation*. If \mathcal{W} is a unitary operator, its inverse equals its adjoint. From the defining property of the adjoint, (1.39), it is easy to show that the unitary transformation preserves the norm of a vector, *i.e.*, $\|\mathcal{W}\psi\| = \|\psi\|$. A unitary transformation is thus a generalized rotation of a vector, changing its direction but not its length.

Similarity transformations, basis vectors and coordinate systems It is evident from (1.70) that the transformed operator $\mathcal{W}\mathcal{A}\mathcal{W}^{-1}$ has the same effect when acting on $\mathcal{W}\psi_n$ that \mathcal{A} does when acting on ψ_n . Since this is true for any vector in the domain of \mathcal{A} , it means we can always replace any operator equation of the form $\mathcal{A}\mathbf{f} = \mathbf{g}$ with an equivalent relation $\mathcal{A}'\mathbf{f}' = \mathbf{g}'$, where $\mathcal{A}' = \mathcal{W}\mathcal{A}\mathcal{W}^{-1}$, $\mathbf{f}' = \mathcal{W}\mathbf{f}$, and $\mathbf{g}' = \mathcal{W}\mathbf{g}$ (provided \mathbf{f} and \mathbf{g} are both in the domain of \mathcal{W}). The two equations $\mathcal{A}'\mathbf{f}' = \mathbf{g}'$ and $\mathcal{A}\mathbf{f} = \mathbf{g}$ represent the same mathematical relation expressed in terms of different basis vectors; the new basis vectors are related to the old ones by $\mathbf{u}'_n = \mathcal{W}\mathbf{u}_n$. A similarity transformation can be regarded as a change of the coordinate axes in terms of which a vector or operator is expressed. If \mathcal{A} is a matrix, then the specific matrix elements are changed, $A_{mn} \neq A'_{mn}$, but the effect of the matrix as an operator is unchanged if the relevant vectors are also changed appropriately. Thus a matrix is dependent on choice of basis, while the underlying operator is not. Similarly, for integral operators like (1.25), a change of variables will change the functional forms of the functions and the kernel, but not the meaning of the underlying operator equation.

1.4.3 Eigenanalysis in finite-dimensional spaces

In this section we restrict attention to operators for which the range and domain are both \mathbb{E}^N . Then, with respect to some basis, the operator \mathcal{A} is the $N \times N$ matrix \mathbf{A} , and the eigenvector ψ_n is an $N \times 1$ column vector. In that case, \mathbf{A} is necessarily bounded, continuous and compact, and we can make some general statements about the eigenvalues and eigenvectors.

The eigenvectors are the solution of the set of N simultaneous, homogeneous equations, one for each component of the following vector equation:

$$[\mathbf{A} - \lambda\mathbf{I}]\psi = \mathbf{0}, \quad (1.71)$$

where \mathbf{I} is the $N \times N$ unit matrix. This set of equations has no nontrivial solutions unless $\mathbf{A} - \lambda\mathbf{I}$ is singular, or equivalently, its determinant vanishes (see App. A). This determinant, called the characteristic determinant for \mathbf{A} , is an N^{th} -order polynomial of the form (Eves, 1966)

$$\chi(\lambda) = \det[\mathbf{A} - \lambda\mathbf{I}] = (-1)^N [\lambda^N + a_1\lambda^{N-1} + a_2\lambda^{N-2} + \dots + (-1)^N a_N], \quad (1.72)$$

where $\det(\cdot)$ denotes determinant. By the Fundamental Theorem of Algebra (Gellert *et al.*, 1977), this polynomial has N roots, at least one of which is nonzero if a_N is

nonzero. It is only when λ is equal to one of these roots that (1.71) has a nontrivial solution. The roots of $\chi(\lambda)$ are thus the eigenvalues of \mathbf{A} for which a solution of the eigenvalue equation exists. The eigenvalues are not necessarily distinct, and if a particular eigenvalue occurs k times, it is said to be an eigenvalue of *multiplicity* k . In the physics literature, the term *degeneracy* is used for multiplicity.

One consequence of multiplicity of eigenvalues is that the eigenvectors are not unique. Any linear combination of two eigenvectors with the same eigenvalue is still an eigenvector associated with that same eigenvalue. Suppose $\mathbf{A}\psi_1 = \lambda\psi_1$ and $\mathbf{A}\psi_2 = \lambda\psi_2$ (same λ). It follows that $\mathbf{A}(\alpha\psi_1 + \beta\psi_2) = \lambda(\alpha\psi_1 + \beta\psi_2)$, with α and β arbitrary scalars, so $(\alpha\psi_1 + \beta\psi_2)$ is also an eigenvector with eigenvalue λ .

In principle (and in practice for very small matrices), one can find the eigenvalues by solving the characteristic equation $\chi(\lambda) = 0$. These eigenvalues can then be plugged back into (1.71) to find the corresponding eigenvectors. As a practical matter, however, the characteristic polynomial is of no use in finding eigenvalues of matrices with $N > 4$, since there are no formulas for factoring polynomials of order 5 or higher. Actual calculation of the $\{\lambda_n\}$ and the corresponding $\{\psi_n\}$ is an enterprise best left to the computer. Many computer packages exist for this purpose. An invaluable resource for anyone wanting to write new code or understand the packages is Numerical Recipes (Press *et al.*, 1992).

Both the sum and the product of the eigenvalues can be related back to properties of the matrix (Strang, 1980). Let λ_n ($n = 1, \dots, N$) denote the (not necessarily distinct) eigenvalues of \mathbf{A} . The sum of these eigenvalues is the *trace* (sum of the diagonal elements) of \mathbf{A} :

$$\sum_{n=1}^N \lambda_n = \sum_{n=1}^N A_{nn} \equiv \text{tr}(\mathbf{A}), \quad (1.73)$$

where $\text{tr}(\cdot)$ stands for trace. The product of the eigenvalues is the determinant of the matrix:

$$\prod_{n=1}^N \lambda_n = \det(\mathbf{A}). \quad (1.74)$$

This result shows that \mathbf{A} is singular if any eigenvalue is zero, since then $\det(\mathbf{A}) = 0$. Since the eigenvalues are unchanged by a similarity transformation, the trace and determinant are also unchanged.

As we noted in Sec. 1.2.3, the rank of a general (not necessarily square) matrix is defined as the number of linearly independent rows or columns. For a square matrix, it can be shown that the rank is also the number of nonzero eigenvalues (counting multiplicity). Thus the multiplicity of the zero eigenvalue is $N - R$, where R is the rank and N is the dimension. If the matrix is nonsingular, no eigenvalues are zero, so $R = N$. A nonsingular matrix is sometimes referred to as a *full-rank* matrix.

There is one form of matrix for which it is possible to determine the eigenvalues without any computation at all. If the matrix is diagonal, then the diagonal elements are just the eigenvalues. For matrices in this form, (1.73) and (1.74) are easily verified. In fact, a somewhat broader statement can also be made. If the matrix is in upper (or lower) triangular form, where all elements below (above) the diagonal are zero, then the diagonal elements are the eigenvalues (Strang, 1980).

In some cases it is possible to find a similarity transformation that will reduce a matrix to diagonal form. This process is known as *diagonalization*. We noted above that a similarity transformation preserves the eigenvalue spectrum, so diagonalization is one way of solving the eigenvalue problem. Unfortunately, not all square matrices are diagonalizable (Strang, 1980; Smith, 1984).

1.4.4 Eigenanalysis of Hermitian operators

In this section we consider Hermitian operators in some Hilbert space \mathbb{U} . This space may have either finite or infinite dimensionality, and in the latter case the spectrum may be either discrete or continuous. The goal of the section is to see what additional properties of the eigenvalues and eigenvectors follow from the Hermiticity. An excellent reference for this section is Messiah (1961).

One key point is that the eigenvalues of a Hermitian operator are real. To show this, let \mathcal{A} be a Hermitian operator satisfying the eigenvalue equation (1.65). Taking the scalar product of this equation with ψ and making use of properties of the scalar product (see Sec. 1.1.4), we find

$$(\psi, \mathcal{A}\psi) = (\psi, \lambda\psi) = \lambda(\psi, \psi) = \lambda\|\psi\|^2. \quad (1.75)$$

With the definition of the adjoint, we also have

$$(\psi, \mathcal{A}\psi) = (\mathcal{A}^\dagger\psi, \psi) = (\lambda\psi, \psi) = \lambda^*(\psi, \psi) = \lambda^*\|\psi\|^2. \quad (1.76)$$

Since $\|\psi\|$ is nonzero, comparison of (1.75) and (1.76) shows that $\lambda^* = \lambda$ if \mathcal{A} is Hermitian.

An interesting special case of this result holds for operators of the form $\mathcal{B}^\dagger\mathcal{B}$. Any operator of this form is Hermitian since $(\mathbf{u}, \mathcal{B}^\dagger\mathcal{B}\mathbf{v}) = (\mathcal{B}\mathbf{u}, \mathcal{B}\mathbf{v}) = (\mathcal{B}^\dagger\mathcal{B}\mathbf{u}, \mathbf{v})$ for arbitrary \mathbf{u} and \mathbf{v} . As we shall see in the next section, this result is very useful since it allows us to construct a Hermitian operator $\mathcal{B}^\dagger\mathcal{B}$ from any arbitrary operator \mathcal{B} . Moreover, for operators of this form, the eigenvalues are real and nonnegative. To show this, let $\mathcal{B}^\dagger\mathcal{B}\phi = \mu\phi$ and again take the scalar product with ϕ . The calculation proceeds as in (1.75) and (1.76):

$$(\phi, \mathcal{B}^\dagger\mathcal{B}\phi) = \mu\|\phi\|^2 = (\mathcal{B}\phi, \mathcal{B}\phi) = \|\mathcal{B}\phi\|^2, \quad (1.77)$$

from which we find that $\mu = \|\mathcal{B}\phi\|^2/\|\phi\|^2$. The denominator in this expression is always a positive, real number, while the numerator is either zero or positive and real. Thus μ cannot be negative and is zero only if $\mathcal{B}\phi = \mathbf{0}$. We say that an operator of the form $\mathcal{B}^\dagger\mathcal{B}$ is *nonnegative-definite* or *positive-semidefinite*. If it has no null space, all eigenvalues are strictly greater than zero, and the operator is *positive-definite*.

Next we show that eigenvectors corresponding to different eigenvalues are orthogonal. Suppose $\mathcal{A}\psi_1 = \lambda_1\psi_1$ and $\mathcal{A}\psi_2 = \lambda_2\psi_2$, where \mathcal{A} is Hermitian and $\lambda_1 \neq \lambda_2$. Then

$$(\psi_1, \mathcal{A}\psi_2) = \lambda_2(\psi_1, \psi_2) = (\mathcal{A}\psi_1, \psi_2) = \lambda_1(\psi_1, \psi_2), \quad (1.78)$$

where we have used the facts that \mathcal{A} is Hermitian and the eigenvalues are real. Subtracting the second and fourth forms of (1.78) yields

$$(\lambda_2 - \lambda_1)(\psi_1, \psi_2) = 0. \quad (1.79)$$

Hence,

$$(\psi_1, \psi_2) = 0 \quad \text{if } \lambda_2 \neq \lambda_1. \quad (1.80)$$

Since we can always normalize the eigenvectors to unit norm without changing the eigenvalues, (1.80) says that ψ_1 and ψ_2 are orthonormal, just the property we desire in a set of basis vectors.

If two or more eigenvectors share the same eigenvalue, we cannot be guaranteed that they are orthonormal, but we can always construct orthonormal linear combinations of them. As noted in Sec. 1.4.3, any linear combination of eigenvectors with the same eigenvalue is still an eigenvector associated with that same eigenvalue, and the coefficients in the linear combinations can be chosen to ensure orthonormality. This procedure, known as *Gram-Schmidt orthogonalization*, is detailed in App. A.

Consider a Hermitian operator in \mathbb{E}^N . It has exactly N eigenvectors (some of which may be null vectors), and with Gram-Schmidt orthogonalization, they form an orthonormal set. Since *any* set of N orthonormal vectors constitutes a complete basis for the N -dimensional space, we can be assured that the full set of eigenvectors forms a basis.

In infinite-dimensional spaces, as usual, we cannot make such broad statements. If we restrict attention to separable Hilbert spaces and compact, Hermitian operators, it can be shown that the denumerably infinite set of eigenvectors does indeed form a basis (Stakgold, 1979). As far as the authors know, no general statements are possible for noncompact operators or nonseparable Hilbert spaces. Fortunately, nonseparable spaces are seldom encountered, but noncompact operators are common.

A noncompact Hermitian operator may have a continuous spectrum; if it does, the eigenvectors will not be in the Hilbert space (Messiah, 1961). Nevertheless, the eigenvectors may form a continuous basis for the space. An important example is the Fourier basis discussed previously. It will be shown in Chap. 7 that the basis functions $\exp(2\pi i\nu x)$ are eigenfunctions of convolution operators, which we know to be noncompact. The main result of Fourier theory is that this continuous set of eigenfunctions can be used to expand any function in the separable Hilbert space $\mathbb{L}_2(-\infty, \infty)$.

Except for the Fourier example and one or two others, it is difficult to make precise mathematical statements about completeness of the eigenvectors of a noncompact Hermitian operator. This difficulty is apparent in the literature on quantum mechanics, where it is essential to deal with noncompact Hermitian operators. A central tenet of quantum mechanics is that all physically measurable quantities are represented by Hermitian operators in a Hilbert space. Many of these operators, including the important position and momentum operators, are noncompact. Messiah (1961) comments that it is a difficult mathematical problem to prove that the eigenfunctions of any particular operator form a basis for the space, but he says it has been done for the position and momentum operators.⁸ He goes on to say, "In fact, the completeness property is so closely related to the physical interpretation (of quantum mechanics) that the whole theory would have to be profoundly revised

⁸The eigenfunctions of the momentum operator are the Fourier basis functions, and the eigenfunctions of the position operator are the delta functions, both of which can be used as a basis for $\mathbb{L}_2(-\infty, \infty)$.

if it did not hold true.” Messiah and other books (*e.g.*, Cohen-Tannoudji *et al.*, 1977) duck this problem by defining an *observable* as a Hermitian operator whose eigenvectors form a basis in the Hilbert space and simply postulating that all physically measurable quantities are observables in this sense. Mathematical research into this important question is actively continuing (Dubin and Hennings, 1990).

1.4.5 Diagonalization of a Hermitian operator

From Sec. 1.4.2, we know that the eigenvalue spectrum of an operator is unchanged by a similarity transformation, a special case of which is a unitary transformation. We noted also in Sec. 1.4.3 that one way of finding the eigenvalues is to diagonalize the operator by means of a similarity transformation. In this section we pursue this approach for Hermitian operators, beginning with Hermitian matrices.

Hermitian matrices An important property of any Hermitian matrix is that it can be diagonalized by a suitable unitary transformation (Strang, 1980). This property is a direct consequence of the fact that the eigenvectors $\{\psi_n\}$ of an $N \times N$ Hermitian matrix \mathbf{A} can be chosen (using the Gram-Schmidt procedure if needed) to form an orthonormal basis in \mathbb{E}^N . From these eigenvectors we can construct an $N \times N$ matrix Ψ , the mn^{th} element of which is defined to be the m^{th} component of ψ_n , or

$$\Psi_{mn} = \psi_{nm}. \quad (1.81)$$

The reversal of indices may look peculiar, but it has an easy interpretation. Since Ψ_{mn} is the element in the m^{th} row and n^{th} column of Ψ , the entire n^{th} column is just the column vector ψ_n . In other words, we form the matrix Ψ by arraying the column vectors ψ_n side by side.

It follows from the completeness and orthonormality of the eigenvectors that Ψ is unitary. In particular, $\Psi^\dagger \Psi = \mathbf{I}$ is a statement of the orthonormality condition, (1.16), since

$$\begin{aligned} [\Psi^\dagger \Psi]_{nn'} &= \sum_{k=1}^N [\Psi^\dagger]_{nk} \Psi_{kn'} = \sum_{k=1}^N \Psi_{kn}^* \Psi_{kn'} \\ &= \sum_{k=1}^N \psi_{nk}^* \psi_{n'k} = (\psi_n, \psi_{n'}) = \delta_{nn'}. \end{aligned} \quad (1.82)$$

A similar analysis shows that $\Psi \Psi^\dagger = \mathbf{I}$ is a statement of the completeness or closure condition, (1.62). Hence $\Psi^\dagger = \Psi^{-1}$.

Since ψ_n is an eigenvector of \mathbf{A} , Ψ is precisely the unitary matrix that diagonalizes \mathbf{A} :

$$[\Psi^\dagger \mathbf{A} \Psi]_{nn'} = \sum_{j=1}^N \sum_{k=1}^N \psi_{nj}^* A_{jk} \psi_{n'k} = \lambda_{n'} \sum_{j=1}^N \psi_{nj}^* \psi_{n'j} = \lambda_n \delta_{nn'}. \quad (1.83)$$

This result can be summarized succinctly as

$$\Psi^\dagger \mathbf{A} \Psi = \mathbf{\Lambda}, \quad (1.84)$$

where $\mathbf{\Lambda}$ is a diagonal matrix with the n^{th} diagonal element equal to λ_n .

Spectral decomposition Equation (1.84) leads to a useful representation of the Hermitian operator \mathbf{A} . Since $\Psi^\dagger = \Psi^{-1}$, we have

$$\mathbf{A} = \Psi \mathbf{\Lambda} \Psi^\dagger. \quad (1.85)$$

This representation can also be expressed in terms of outer products [see (1.55)] as

$$\mathbf{A} = \sum_{n=1}^N \lambda_n \psi_n \psi_n^\dagger. \quad (1.86)$$

This equation, called the *spectral decomposition* of \mathbf{A} , shows that the Hermitian matrix \mathbf{A} can be expressed as a weighted sum of projection operators, with the weighting coefficients just being the eigenvalues (Lorch, 1962). Moreover, any operator that can be expressed in the form of the right-hand side of (1.86) with real λ_n is necessarily Hermitian since each individual term $\psi_n \psi_n^\dagger$ is Hermitian (see Sec. 1.3.5).

There is a similar spectral decomposition for the inverse of \mathbf{A} , if it exists:

$$\mathbf{A}^{-1} = \sum_{n=1}^N \frac{1}{\lambda_n} \psi_n \psi_n^\dagger. \quad (1.87)$$

The validity of this representation can be demonstrated by forming the product $\mathbf{A}^{-1}\mathbf{A}$ or $\mathbf{A}\mathbf{A}^{-1}$ using the right-hand sides of (1.86) and (1.87), yielding

$$\mathbf{A}^{-1}\mathbf{A} = \mathbf{A}\mathbf{A}^{-1} = \sum_{n=1}^N \sum_{m=1}^N \frac{\lambda_n}{\lambda_m} \psi_n \psi_n^\dagger \psi_m \psi_m^\dagger = \sum_{n=1}^N \psi_n \psi_n^\dagger = \mathbf{I}, \quad (1.88)$$

where we have used the representation of the unit operator \mathbf{I} from (1.62) and the orthonormality of the eigenvectors, expressed in the present notation as

$$\psi_n^\dagger \psi_m = \delta_{mn}. \quad (1.89)$$

Other Hermitian operators Though derived for a Hermitian operator in \mathbb{E}^N , the results given above apply, with some modification, to any Hermitian operator \mathcal{A} . If the operator is compact, it has a discrete spectrum, and (1.86) applies with the simple modification of setting N to ∞ . In that case Ψ and $\mathbf{\Lambda}$ are infinite square matrices.

Even if \mathcal{A} is a noncompact integral operator, a representation analogous to (1.86) can be obtained. Let $a(x, x')$ be the kernel of \mathcal{A} and assume that the eigenfunctions form a complete continuous basis. The counterpart of (1.86) is

$$a(x, x') = \int_{-\infty}^{\infty} d\nu \lambda_\nu \psi_\nu(x) \psi_\nu^*(x'). \quad (1.90)$$

To demonstrate that this representation is correct, note that it yields

$$[\mathcal{A}\psi_\nu](x) = \int_{-\infty}^{\infty} d\nu' \int_{-\infty}^{\infty} dx' \lambda_{\nu'} \psi_{\nu'}(x) \psi_{\nu'}^*(x') \psi_\nu(x') = \lambda_\nu \psi_\nu(x), \quad (1.91)$$

where the last step follows from the continuous orthonormality [*cf.* (1.22)]. Equation (1.91) shows that representation (1.90) gives the right answer when \mathcal{A} operates on

one of its eigenfunctions. Since the eigenfunctions are assumed to be complete, any function in \mathbb{U} can be written as a (continuous) linear superposition of the eigenfunctions, and the representation is correct in general.

In the discrete case, we constructed a unitary operator by arraying the column eigenvectors side by side; we can do much the same in the continuous case as well. We simply define the operator Ψ as an integral operator mapping a function of ν to a function of x by means of the kernel $\psi_\nu(x)$, so that

$$[\Psi \mathbf{F}](x) = \int_{-\infty}^{\infty} d\nu \psi_\nu(x) F(\nu). \quad (1.92)$$

(The analogy to Fourier transformation should be apparent.) The adjoint of Ψ is given by

$$[\Psi^\dagger \mathbf{f}](\nu) = \int_{-\infty}^{\infty} dx \psi_\nu^*(x) f(x) \equiv F(\nu), \quad (1.93)$$

and it follows from the orthonormality of the $\{\psi_\nu\}$ that Ψ is unitary.

From the discussion above in the discrete case, we would expect Ψ to diagonalize \mathcal{A} in some sense. To make this statement more precise, note that $\Psi^\dagger \mathcal{A} \Psi$ is an integral operator, the kernel of which we can denote (rather clumsily) as $[\Psi^\dagger \mathcal{A} \Psi](\nu, \nu')$. From the orthonormality and completeness of the eigenfunctions, we can show that

$$[\Psi^\dagger \mathcal{A} \Psi](\nu, \nu') = \lambda_\nu \delta(\nu - \nu'). \quad (1.94)$$

By comparing (1.94) and (1.83), we see that in the continuous case the effect of the unitary transformation is again to reduce \mathcal{A} to diagonal form, which here means that the kernel is proportional to the delta function $\delta(\nu - \nu')$. One can think of a matrix with continuous indices where the matrix elements are zero if the indices are not equal and infinite if they are.

1.4.6 Simultaneous diagonalization of Hermitian matrices

Many problems in imaging involve two or more Hermitian operators. For example, the deterministic properties of an imaging system are described by the Hermitian operators $\mathcal{H}^\dagger \mathcal{H}$ and $\mathcal{H} \mathcal{H}^\dagger$ (for more on this point, see Sec. 1.5.1), and the stochastic properties are described by the covariance matrix, a Hermitian matrix to be defined in Chap. 8. In addition, various Hermitian symmetry and projection operators arise, so it is of considerable value to be able to find a representation in which two or more Hermitian operators are simultaneously diagonalized.

We address that problem in this section specifically for Hermitian matrices, but essentially the same results hold for other Hermitian operators. As we shall see, the nature of the transformation to the simultaneously diagonal representation depends critically on whether the matrices commute.

Commuting matrices A well-known theorem from quantum mechanics is that two Hermitian operators can be simultaneously diagonalized by a unitary transformation if and only if they commute. We shall now learn how to find that transformation for the special case of Hermitian matrices.

Let \mathbf{A} and \mathbf{B} be commuting Hermitian matrices. We seek a unitary matrix Ψ such that $\Psi^\dagger \mathbf{A} \Psi$ and $\Psi^\dagger \mathbf{B} \Psi$ are both diagonal. We begin with the eigenvalue

equation for \mathbf{A} :

$$\mathbf{A}\boldsymbol{\psi}_n = \lambda_{An}\boldsymbol{\psi}_n. \quad (1.95)$$

For simplicity we assume that the eigenvalues are not degenerate; for a detailed discussion of the degenerate case, see Secs. 6.7.3–6.7.6. Now apply \mathbf{B} to both sides of (1.95) and use the commutativity:

$$\mathbf{B}\mathbf{A}\boldsymbol{\psi}_n = \lambda_{An}\mathbf{B}\boldsymbol{\psi}_n = \mathbf{A}\mathbf{B}\boldsymbol{\psi}_n. \quad (1.96)$$

Thus $\mathbf{B}\boldsymbol{\psi}_n$ is also an eigenvector of \mathbf{A} with eigenvalue λ_{An} . We have assumed, however, that the eigenvalues are nondegenerate, so there cannot be two linearly independent eigenvectors with the same eigenvalue. Thus $\mathbf{B}\boldsymbol{\psi}_n$ must be just a constant times $\boldsymbol{\psi}_n$; calling that constant λ_{Bn} , we see that

$$\mathbf{B}\boldsymbol{\psi}_n = \lambda_{Bn}\boldsymbol{\psi}_n. \quad (1.97)$$

Thus \mathbf{A} and \mathbf{B} share the same eigenvectors, but not necessarily the same eigenvalues. Since any Hermitian matrix is diagonalized by the unitary matrix with its normalized eigenvectors as columns, we can write

$$\boldsymbol{\Psi}^\dagger \mathbf{A} \boldsymbol{\Psi} = \boldsymbol{\Lambda}_A, \quad \boldsymbol{\Psi}^\dagger \mathbf{B} \boldsymbol{\Psi} = \boldsymbol{\Lambda}_B, \quad (1.98)$$

where $\boldsymbol{\Lambda}_A$ and $\boldsymbol{\Lambda}_B$ are diagonal, with the former having λ_{An} as its diagonal elements and the latter having λ_{Bn} .

Prewhitening If a Hermitian matrix \mathbf{A} is positive-definite (see Secs. 1.4.4 and A.8), not only can we transform it to diagonal form, we can also transform it to the unit matrix. The tool we need for this purpose is the square-root matrix defined in Sec. A.8.3. Specifically, we need $\boldsymbol{\Lambda}_A^{\frac{1}{2}}$, defined as the diagonal matrix with $\lambda_{An}^{\frac{1}{2}}$ as the diagonal elements. Since \mathbf{A} is positive-definite, its eigenvalues are positive, and we do not have to worry about taking square roots of negative numbers. Moreover, since positive-definite matrices are nonsingular, the eigenvalues are not zero, and we can define $\boldsymbol{\Lambda}_A^{-\frac{1}{2}}$ as the diagonal matrix with $\lambda_{An}^{-\frac{1}{2}}$ as the diagonal elements.

Applying $\boldsymbol{\Lambda}_A^{-\frac{1}{2}}$ to the diagonal representation of \mathbf{A} , we obtain

$$\boldsymbol{\Lambda}_A^{-\frac{1}{2}} \boldsymbol{\Psi}^\dagger \mathbf{A} \boldsymbol{\Psi} \boldsymbol{\Lambda}_A^{-\frac{1}{2}} = \boldsymbol{\Lambda}_A^{-\frac{1}{2}} \boldsymbol{\Lambda}_A \boldsymbol{\Lambda}_A^{-\frac{1}{2}} = \mathbf{I}. \quad (1.99)$$

Because of a connection with white noise, to be clarified in Chap. 8, this transformation is known as *prewhitening*. We shall have several opportunities to apply this transformation later in the book, and immediately below we apply it to simultaneous diagonalization of noncommuting Hermitian matrices.

Noncommuting matrices Consider two Hermitian matrices \mathbf{A} and \mathbf{B} that do not necessarily commute, and assume that \mathbf{A} is positive-definite and hence nonsingular. We seek a matrix \mathbf{W} such that

$$\mathbf{W}^\dagger \mathbf{A} \mathbf{W} = \mathbf{I} \quad \text{and} \quad \mathbf{W}^\dagger \mathbf{B} \mathbf{W} = \mathbf{D}, \quad (1.100)$$

where \mathbf{D} is diagonal. We do not require that $\mathbf{W}^\dagger = \mathbf{W}^{-1}$, so (1.100) is not a similarity transformation. Many books use the term *diagonalization* only for similarity transformations, but our usage is more general.

Following Fukunaga (1990), we first diagonalize \mathbf{A} by a unitary transformation, then apply a nonunitary prewhitening transformation to convert it to the unit matrix, and finally apply another unitary transformation to diagonalize \mathbf{B} . This second unitary transformation leaves the unit matrix unchanged, so both matrices have the desired form after this sequence of three transformations.

After the first step, we have

$$\mathbf{A}' \equiv \Psi^\dagger \mathbf{A} \Psi = \Lambda_A, \quad \mathbf{B}' \equiv \Psi^\dagger \mathbf{B} \Psi, \quad (1.101)$$

where Λ_A is diagonal but \mathbf{B}' is not.

After we apply the prewhitening transform, we obtain

$$\mathbf{A}'' \equiv \Lambda_A^{-\frac{1}{2}} \mathbf{A}' \Lambda_A^{-\frac{1}{2}} = \Lambda_A^{-\frac{1}{2}} \Psi^\dagger \mathbf{A} \Psi \Lambda_A^{-\frac{1}{2}} = \mathbf{I}, \quad (1.102)$$

$$\mathbf{B}'' \equiv \Lambda_A^{-\frac{1}{2}} \mathbf{B}' \Lambda_A^{-\frac{1}{2}} = \Lambda_A^{-\frac{1}{2}} \Psi^\dagger \mathbf{B} \Psi \Lambda_A^{-\frac{1}{2}}. \quad (1.103)$$

The matrix \mathbf{B}'' is still Hermitian, so it can be diagonalized by a unitary transformation. As in Sec. 1.4.5, this transformation matrix can be found by solving an eigenvalue problem:

$$\mathbf{B}'' \Phi = \Phi \mathbf{D}, \quad (1.104)$$

where \mathbf{D} is the diagonal matrix of the eigenvalues of \mathbf{B}'' , and the eigenvectors form the columns of Φ .

Now apply the final transformation to both matrices:

$$\mathbf{A}''' \equiv \Phi^\dagger \mathbf{A}'' \Phi = \Phi^\dagger \Phi = \mathbf{I}, \quad (1.105)$$

$$\mathbf{B}''' \equiv \Phi^\dagger \mathbf{B}'' \Phi = \Phi^\dagger \Lambda_A^{-\frac{1}{2}} \Psi^\dagger \mathbf{B} \Psi \Lambda_A^{-\frac{1}{2}} \Phi = \mathbf{D}. \quad (1.106)$$

The desired overall transformation matrix \mathbf{W} is thus

$$\mathbf{W} = \Psi \Lambda_A^{-\frac{1}{2}} \Phi. \quad (1.107)$$

Because of the presence of $\Lambda_A^{-\frac{1}{2}}$, the transformation matrix \mathbf{W} cannot be unitary, even if \mathbf{A} and \mathbf{B} do commute; two commuting Hermitian matrices can be simultaneously diagonalized by a unitary matrix, but converting one of them to the unit matrix requires a nonunitary transformation (except for the trivial case $\mathbf{A} = \mathbf{I}$), and it also requires that at least one of the matrices be positive-definite.

Generalized eigenvalue problems Since \mathbf{W} as given by (1.107) satisfies (1.100), we can write

$$\mathbf{W}^\dagger \mathbf{B} \mathbf{W} = \mathbf{D} = \mathbf{I} \mathbf{D} = \mathbf{W}^\dagger \mathbf{A} \mathbf{W} \mathbf{D}. \quad (1.108)$$

Since \mathbf{W}^\dagger is nonsingular, we can multiply through by its inverse in (1.108) and obtain

$$\mathbf{B} \mathbf{W} = \mathbf{A} \mathbf{W} \mathbf{D}. \quad (1.109)$$

This is the *generalized eigenvalue equation* for \mathbf{A} and \mathbf{B} .

Since \mathbf{A} has been assumed to be nonsingular, we can apply its inverse to both sides of (1.109) and get

$$\mathbf{A}^{-1} \mathbf{B} \mathbf{W} = \mathbf{W} \mathbf{D}. \quad (1.110)$$

Thus the columns of \mathbf{W} are eigenvectors of $\mathbf{A}^{-1} \mathbf{B}$. Sometimes it will be easier to find \mathbf{W} by solving a single eigenvalue problem, (1.109) or (1.110), rather than the two separate eigenvalue problems implied by (1.101) and (1.104).

1.5 SINGULAR-VALUE DECOMPOSITION

The spectral decomposition of (1.86) is a powerful tool for working with Hermitian operators, but it is not directly applicable to other kinds of linear operators. This is a significant drawback since only rarely can imaging systems be described by Hermitian operators. Fortunately, there is a closely related decomposition, known as *singular-value decomposition* or *SVD*, that is much more widely applicable.

1.5.1 Definition and properties

Consider a general linear operator \mathcal{H} that maps a vector \mathbf{f} in the Hilbert space \mathbb{U} to a vector \mathbf{g} in the Hilbert space \mathbb{V} . From this operator we can form two new operators, $\mathcal{H}^\dagger\mathcal{H}$ and $\mathcal{H}\mathcal{H}^\dagger$. As discussed in Sec. 1.4.4, both of these operators are Hermitian and nonnegative-definite, regardless of the nature of \mathcal{H} itself. In addition, we assume that both $\mathcal{H}^\dagger\mathcal{H}$ and $\mathcal{H}\mathcal{H}^\dagger$ are compact and hence have discrete spectra. The eigenvalue equation for $\mathcal{H}^\dagger\mathcal{H}$ is then

$$\mathcal{H}^\dagger\mathcal{H}\mathbf{u}_n = \mu_n\mathbf{u}_n, \quad (1.111)$$

where we know that μ_n is nonnegative and real.

Since $\mathcal{H}^\dagger\mathcal{H}$ is Hermitian, and we assume it is compact, we know from Sec. 1.4.4 that the set $\{\mathbf{u}_n\}$ can be taken as a complete, orthonormal basis in \mathbb{U} (invoking the Gram-Schmidt procedure if needed). The orthonormality is expressed as

$$\mathbf{u}_n^\dagger\mathbf{u}_m = \delta_{nm}, \quad (1.112)$$

where, in the notation of Sec. 1.3.7, $\mathbf{u}_n^\dagger\mathbf{u}_m$ denotes the scalar or inner product of \mathbf{u}_n and \mathbf{u}_m . Completeness means that

$$\sum_{n=1}^N \mathbf{u}_n\mathbf{u}_n^\dagger = \mathcal{I}_{\mathbb{U}}, \quad (1.113)$$

where $\mathbf{u}_n\mathbf{u}_n^\dagger$ denotes an outer product (see Sec. 1.3.7) and $\mathcal{I}_{\mathbb{U}}$ denotes the identity operator in \mathbb{U} .

It is conventional to order the eigenvalues by decreasing value, so that

$$\mu_1 \geq \mu_2 \geq \dots \geq \mu_R > 0, \quad (1.114)$$

where R is the number of nonzero eigenvalues of $\mathcal{H}^\dagger\mathcal{H}$ (counting multiplicity, as discussed in Sec. 1.4.3). Equation (1.114) takes advantage of the fact that all of the eigenvalues are nonnegative, which is true for the nonnegative-definite operator $\mathcal{H}^\dagger\mathcal{H}$ but not for an arbitrary Hermitian operator.

If $\mathbb{U} = \mathbb{E}^N$, then $\mathcal{H}^\dagger\mathcal{H}$ is an $N \times N$ matrix and, as noted in Sec. 1.4.3, R is its rank, which must be less than or equal to N . Though R was defined for a general matrix as the number of linearly independent rows or columns, for a Hermitian operator it is also equal to the number of nonzero eigenvalues.

If we have solved the eigenvalue problem for $\mathcal{H}^\dagger\mathcal{H}$, we can get some solutions of the corresponding problem for $\mathcal{H}\mathcal{H}^\dagger$ for free. Operating on both sides of (1.111) with \mathcal{H} yields

$$\mathcal{H}\mathcal{H}^\dagger\mathcal{H}\mathbf{u}_n = \mu_n\mathcal{H}\mathbf{u}_n, \quad (1.115)$$

which shows that $\mathcal{H}\mathbf{u}_n$ is an eigenvector of $\mathcal{H}\mathcal{H}^\dagger$ with eigenvalue μ_n . It is straightforward to show that the vectors $\{\mathcal{H}\mathbf{u}_n\}$ are orthogonal if the $\{\mathbf{u}_n\}$ are, but it does not follow that they are correctly normalized. In fact, $\|\mathcal{H}\mathbf{u}_n\|^2 = \mu_n$ rather than unity. We can, however, multiply an eigenvector by any constant and it will remain an eigenvector with the same eigenvalue. Thus, if \mathbf{u}_n is not a null vector, we can define

$$\mathbf{v}_n = \frac{1}{\sqrt{\mu_n}} \mathcal{H}\mathbf{u}_n, \quad (\mu_n \neq 0), \quad (1.116)$$

where $\sqrt{\mu_n}$ is positive and real since μ_n is. With this definition, we have

$$\mathcal{H}\mathcal{H}^\dagger \mathbf{v}_n = \mu_n \mathbf{v}_n. \quad (1.117)$$

Thus \mathbf{v}_n is an eigenvector of $\mathcal{H}\mathcal{H}^\dagger$ with eigenvalue μ_n , so $\mathcal{H}^\dagger \mathcal{H}$ and $\mathcal{H}\mathcal{H}^\dagger$ have the same eigenvalue spectra.

The $\{\mathbf{v}_n\}$ as defined by (1.116) are an orthonormal set in \mathbb{V} , but they are not necessarily complete. If some of the $\{\mu_n\}$ are zero, the corresponding $\{\mathbf{v}_n\}$ cannot be constructed by (1.116) but must be obtained by solving (1.117) directly.

If all of the eigenvectors of $\mathcal{H}\mathcal{H}^\dagger$ have been found, including those corresponding to zero eigenvalue, they form a complete orthonormal basis in \mathbb{V} and satisfy

$$\mathbf{v}_n^\dagger \mathbf{v}_m = \delta_{nm}, \quad (1.118)$$

$$\sum_{n=1}^N \mathbf{v}_n \mathbf{v}_n^\dagger = \mathcal{I}_{\mathbb{V}}. \quad (1.119)$$

The set $\{\mathbf{u}_n, \mathbf{v}_n, \mu_n\}$ is called the *singular system* of \mathcal{H} . Knowledge of this singular system allows us to construct a representation of \mathcal{H} analogous to the spectral decomposition. We shall show that

$$\mathcal{H} = \sum_{n=1}^R \sqrt{\mu_n} \mathbf{v}_n \mathbf{u}_n^\dagger, \quad (1.120)$$

where each term $\mathbf{v}_n \mathbf{u}_n^\dagger$ is to be interpreted as an outer-product operator as discussed in Sec. 1.3.7 [*cf.* (1.54)]. The sum in this equation runs over all n for which $\mu_n \neq 0$, which means $n \leq R$ with the ordering of (1.114). We could, of course, also run the sum in (1.120) from 1 to N , but the factor $\sqrt{\mu_n}$ would set to zero all terms for $n > R$ anyway.

To prove the validity of (1.120), all we have to do is show that both sides give the same result when acting on an arbitrary vector \mathbf{f} in the domain of \mathcal{H} . Since the $\{\mathbf{u}_n\}$ form a basis in \mathbb{U} , we can write the arbitrary \mathbf{f} as

$$\mathbf{f} = \sum_{n=1}^N \alpha_n \mathbf{u}_n, \quad (1.121)$$

where the coefficient α_n is given by the scalar product,

$$\alpha_n = \mathbf{u}_n^\dagger \mathbf{f}. \quad (1.122)$$

The sum in (1.121) must include all vectors in the basis, not just ones with nonzero eigenvalue; it therefore runs up to N rather than R .

Operating on this representation of \mathbf{f} with \mathcal{H} gives

$$\mathcal{H}\mathbf{f} = \sum_{n=1}^N \alpha_n \mathcal{H}\mathbf{u}_n = \sum_{n=1}^R \alpha_n \sqrt{\mu_n} \mathbf{v}_n, \quad (1.123)$$

where we have used the linearity of \mathcal{H} and (1.116). Applying the right-hand side of (1.120) to the same representation of \mathbf{f} yields

$$\begin{aligned} \mathcal{H}\mathbf{f} &= \sum_{n=1}^R \sqrt{\mu_n} \mathbf{v}_n \mathbf{u}_n^\dagger \sum_{m=1}^N \alpha_m \mathbf{u}_m = \sum_{n=1}^R \sum_{m=1}^N \alpha_m \sqrt{\mu_n} \mathbf{v}_n \mathbf{u}_n^\dagger \mathbf{u}_m \\ &= \sum_{n=1}^R \sum_{m=1}^N \alpha_m \sqrt{\mu_n} \mathbf{v}_n \delta_{nm} = \sum_{n=1}^R \alpha_n \sqrt{\mu_n} \mathbf{v}_n, \end{aligned} \quad (1.124)$$

where we have used the orthonormality of the $\{\mathbf{u}_n\}$ to set $\mathbf{u}_n^\dagger \mathbf{u}_m = \delta_{nm}$. The agreement of the final forms of (1.123) and (1.124) establishes the validity of (1.120).

Equation (1.120) is the singular-value decomposition of \mathcal{H} . Like the spectral decomposition of a Hermitian operator, it expresses the operator as a sum of outer-product operators. This sum has R nonzero terms, where R is the rank of both $\mathcal{H}^\dagger \mathcal{H}$ and $\mathcal{H}\mathcal{H}^\dagger$. We shall refer to R as the rank of \mathcal{H} as well, where the rank of a general linear operator is the number of nonzero *singular* values. This definition is consistent with our two earlier definitions of rank: the number of linearly independent rows or columns of a general matrix or the number of nonzero eigenvalues of a Hermitian operator.

In a similar fashion, \mathcal{H}^\dagger can be represented as

$$\mathcal{H}^\dagger = \sum_{k=1}^R \sqrt{\mu_k} \mathbf{u}_k \mathbf{v}_k^\dagger. \quad (1.125)$$

Again we have a sum of R outer products. If \mathcal{H} is an $M \times N$ matrix \mathbf{H} , then \mathbf{H}^\dagger is an $N \times M$ matrix, \mathbf{u}_k is an $N \times 1$ vector, \mathbf{v}_k is an $M \times 1$ vector, and each outer product in the sum is an $N \times M$ matrix, as it must be if the sum is to represent \mathbf{H}^\dagger .

1.5.2 Subspaces

It is often true that $R < N$, where R is the rank of \mathcal{H} and N is the (possibly infinite) dimension of \mathbb{U} . Under this condition, \mathbb{U} can be divided into two orthogonal subspaces⁹ (see Fig. 1.5).

⁹Recall from Sec. 1.3.6 that two subspaces are orthogonal if all vectors in one are orthogonal to all vectors in the other.

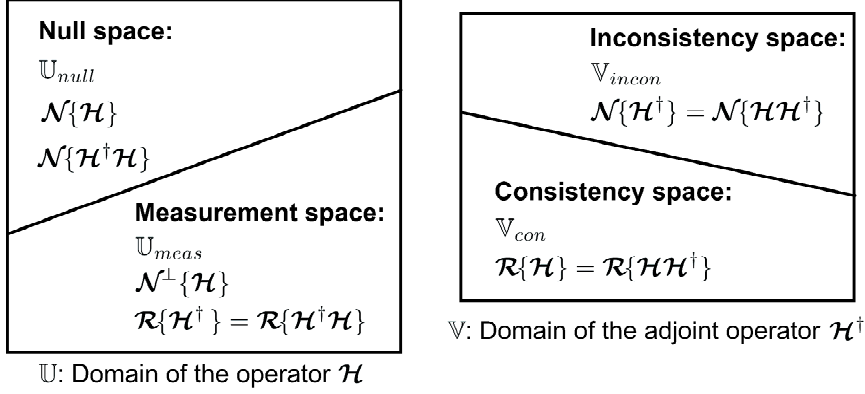

Fig. 1.5 Division of the domain of \mathcal{H} and the domain of \mathcal{H}^\dagger into orthogonal subspaces. Several alternative designations are given for each subspace.

The null space of \mathcal{H} is an $(N - R)$ -dimensional Euclidean space formally denoted $\mathcal{N}\{\mathcal{H}\}$. We shall also use the notation \mathbb{U}_{null} for $\mathcal{N}\{\mathcal{H}\}$, emphasizing that it is a subspace of \mathbb{U} . A vector \mathbf{f}_{null} in this space satisfies

$$\mathcal{H}\mathbf{f}_{null} = 0. \quad (1.126)$$

If $R = N$, $\mathcal{N}\{\mathcal{H}\}$ is trivial, in the sense that it contains only the zero vector. In that case \mathcal{H} is *one-to-one*, which means that, in the absence of noise, every \mathbf{g} is produced by exactly one \mathbf{f} .

The orthogonal complement of $\mathcal{N}\{\mathcal{H}\}$ is an R -dimensional Euclidean space formally denoted $\mathcal{N}^\perp\{\mathcal{H}\}$. We shall also refer to this subspace as *measurement space* since vectors in this space produce nonzero measurements if \mathcal{H} describes a measurement system. To emphasize this point, we denote the space by \mathbb{U}_{meas} . An arbitrary vector \mathbf{f} in \mathbb{U} can be decomposed into a sum of two orthogonal vectors, one in \mathbb{U}_{meas} and one in \mathbb{U}_{null} :

$$\mathbf{f} = \mathbf{f}_{meas} + \mathbf{f}_{null}. \quad (1.127)$$

If $R < M$, the data space \mathbb{V} can also be divided into two nontrivial orthogonal subspaces. All possible data vectors \mathbf{g} lie in \mathbb{V} , but not all vectors in \mathbb{V} can be written as $\mathcal{H}\mathbf{f}$ for some \mathbf{f} in \mathbb{U} . In other words, if $R < M$, \mathcal{H} is not *onto* and the range of \mathcal{H} is not the whole space \mathbb{V} but some subspace of it.

Though the range of \mathcal{H} is denoted formally as $\mathcal{R}\{\mathcal{H}\}$, we shall refer to it as *consistency space* and denote it \mathbb{V}_{con} . Any vector \mathbf{g} in \mathbb{V}_{con} is consistent in the sense that there is some vector \mathbf{f} in \mathbb{U} such that $\mathbf{g} = \mathcal{H}\mathbf{f}$. In an imaging context, $\mathcal{H}\mathbf{f}$ is a noise-free data vector, but a real, measured data vector, $\mathbf{g} = \mathcal{H}\mathbf{f} + \boldsymbol{\epsilon}$, contains noise which creates inconsistency in the data and requires the use of the entire space \mathbb{V} to describe an arbitrary data vector.

The orthogonal complement of \mathbb{V}_{con} will be called *inconsistency space* and denoted \mathbb{V}_{incon} . An arbitrary vector \mathbf{g} in \mathbb{V} can be decomposed into a sum of two orthogonal vectors, one in \mathbb{V}_{con} and one in \mathbb{V}_{incon} :

$$\mathbf{g} = \mathbf{g}_{con} + \mathbf{g}_{incon}. \quad (1.128)$$

If $R = M$, \mathbb{V}_{incon} is trivial and any \mathbf{g} is automatically consistent.

The division of \mathbb{U} and \mathbb{V} into orthogonal subspaces can also be viewed another way. The entire space \mathbb{V} is the domain of the adjoint operator \mathcal{H}^\dagger , but that operator can have a null space if $R < M$. The null space of \mathcal{H}^\dagger , denoted $\mathcal{N}\{\mathcal{H}^\dagger\}$, is a subspace of \mathbb{V} . Moreover, if $R < N$, the range of \mathcal{H}^\dagger is a subspace of \mathbb{U} .

It can be shown (Campbell and Meyer, 1979) that the null space of \mathcal{H}^\dagger is just \mathbb{V}_{incon} , while its orthogonal complement is \mathbb{V}_{con} . Also, the range of \mathcal{H}^\dagger is \mathbb{U}_{meas} and its orthogonal complement is \mathbb{U}_{null} . Furthermore, the range of \mathcal{H} is the same as the range of $\mathcal{H}\mathcal{H}^\dagger$ and the range of \mathcal{H}^\dagger is the same as the range of $\mathcal{H}^\dagger\mathcal{H}$. Also, the null space of \mathcal{H} is the same as the null space of $\mathcal{H}^\dagger\mathcal{H}$ and the null space of \mathcal{H}^\dagger is the same as the null space of $\mathcal{H}\mathcal{H}^\dagger$. In summary,

$$\mathcal{R}\{\mathcal{H}\} = \mathcal{R}\{\mathcal{H}\mathcal{H}^\dagger\} = \mathbb{V}_{con}; \quad (1.129a)$$

$$\mathcal{R}\{\mathcal{H}^\dagger\} = \mathcal{R}\{\mathcal{H}^\dagger\mathcal{H}\} = \mathbb{U}_{meas}; \quad (1.129b)$$

$$\mathcal{N}\{\mathcal{H}\} = \mathcal{N}\{\mathcal{H}^\dagger\mathcal{H}\} = \mathbb{U}_{null}; \quad (1.129c)$$

$$\mathcal{N}\{\mathcal{H}^\dagger\} = \mathcal{N}\{\mathcal{H}\mathcal{H}^\dagger\} = \mathbb{V}_{incon}. \quad (1.129d)$$

These various designations of spaces and subspaces are illustrated in Fig. 1.5.

1.5.3 SVD representations of vectors and operators

The great advantage of the SVD approach is that it provides a consistent set of representations for all of the vectors and operators that arise in connection with a particular linear system. We have already encountered some of these representations, and the full set is summarized in Tables 1.1 and 1.2 for reference.

Table 1.1 lists the representations of vectors in either \mathbb{U} or \mathbb{V} , including \mathbf{f} and \mathbf{g} as well as their components \mathbf{f}_{meas} , \mathbf{f}_{null} , \mathbf{g}_{con} and \mathbf{g}_{incon} . Other vectors that will be important in later discussion include the vector $\boldsymbol{\epsilon}$ in \mathbb{V} describing noise in the data and an estimated or reconstructed version of the object, denoted $\hat{\mathbf{f}}$. For completeness these representations are also given in Table 1.1.

Table 1.2 lists the singular-value decompositions for \mathcal{H} and \mathcal{H}^\dagger as well as the spectral decompositions for $\mathcal{H}^\dagger\mathcal{H}$ and $\mathcal{H}\mathcal{H}^\dagger$. This table also gives forms for $[\mathcal{H}^\dagger\mathcal{H}]^{-1}$, which exists if $R = N$, and $[\mathcal{H}\mathcal{H}^\dagger]^{-1}$, which exists if $R = M$. The correctness of these expressions can easily be verified from the orthonormality and completeness relations. Also listed in Table 1.2 are some additional operators to be discussed in Sec. 1.6.

1.6 MOORE-PENROSE PSEUDOINVERSE

A powerful tool for dealing with linear systems is the Moore-Penrose pseudoinverse, originally proposed by Moore (1920) and then apparently forgotten. Twenty years later the same concept was independently rediscovered by Sir Roger Penrose, British physicist and cosmologist and frequent collaborator of Stephen Hawking. Remarkably, Penrose published his classic paper on generalized inverses when he was in his early 20s and working toward his doctorate at Cambridge.

The literature on pseudoinverses is vast; Nashed (1976) gives a total of 1,775 references. Excellent accounts are given by Albert (1972), Ben-Israel and Greville (1974) and Campbell and Meyer (1979).

1.6.1 Penrose equations

A linear operator $\mathcal{H}^\#$ is called a *generalized inverse* or *pseudoinverse* of \mathcal{H} if it satisfies $\mathcal{H}\mathcal{H}^\#\mathcal{H} = \mathcal{H}$. This equation, which is satisfied by \mathcal{H}^{-1} if it exists, is now commonly referred to as the first *Penrose equation*. The full set of Penrose equations is:

$$\text{Penrose Eq. 1: } \mathcal{H}\mathcal{H}^\#\mathcal{H} = \mathcal{H}. \quad (1.130a)$$

$$\text{Penrose Eq. 2: } \mathcal{H}^\#\mathcal{H}\mathcal{H}^\# = \mathcal{H}^\#. \quad (1.130b)$$

$$\text{Penrose Eq. 3: } (\mathcal{H}\mathcal{H}^\#)^\dagger = \mathcal{H}\mathcal{H}^\#. \quad (1.130c)$$

$$\text{Penrose Eq. 4: } (\mathcal{H}^\#\mathcal{H})^\dagger = \mathcal{H}^\#\mathcal{H}. \quad (1.130d)$$

If \mathcal{H} has a true inverse, it satisfies all four of the Penrose equations. A matrix that satisfies Penrose Eq. 1 but not the other three is called a 1-inverse of \mathcal{H} , one that satisfies Eqs. 1 and 2 is called a (1,2)-inverse, etc. For matrices, a 1-inverse always exists and can be found by Gaussian elimination.

The Moore-Penrose pseudoinverse, denoted \mathcal{H}^+ , is the generalized inverse that satisfies all four Penrose equations. Thus the Moore-Penrose pseudoinverse is a (1,2,3,4)-inverse and is equal to the true inverse if one exists. When we use the term pseudoinverse without proper names or other qualifiers, the Moore-Penrose pseudoinverse will be understood.

It can be shown that the Moore-Penrose pseudoinverse of a matrix always exists and is always unique (Albert, 1972). If \mathcal{H} is an $M \times N$ matrix \mathbf{H} , then \mathbf{H}^+ is an $N \times M$ matrix, but the concept of pseudoinverse is not restricted to matrices. Under broad conditions, it is applicable to any bounded, linear operator \mathcal{H} mapping one separable Hilbert space to another.¹⁰

1.6.2 Pseudoinverses and SVD

We shall show that the Moore-Penrose pseudoinverse can be represented as

$$\mathcal{H}^+ = \sum_{k=1}^R \frac{1}{\sqrt{\mu_k}} \mathbf{u}_k \mathbf{v}_k^\dagger. \quad (1.131)$$

Since $\mu_k \neq 0$ if $k \leq R$, there is no worry about dividing by zero.

To show that (1.131) is a valid representation of \mathcal{H}^+ , we need to prove that the right-hand side satisfies the four Penrose equations. To prove the first one, we use (1.120) and (1.131) to write

$$\begin{aligned} \mathcal{H}\mathcal{H}^+\mathcal{H} &= \sum_{k=1}^R \sqrt{\mu_k} \mathbf{v}_k \mathbf{u}_k^\dagger \sum_{m=1}^R \frac{1}{\sqrt{\mu_m}} \mathbf{u}_m \mathbf{v}_m^\dagger \sum_{n=1}^R \sqrt{\mu_n} \mathbf{v}_n \mathbf{u}_n^\dagger \\ &= \sum_{k=1}^R \sum_{m=1}^R \sum_{n=1}^R \frac{\sqrt{\mu_k} \sqrt{\mu_n}}{\sqrt{\mu_m}} \mathbf{v}_k \mathbf{u}_k^\dagger \mathbf{u}_m \mathbf{v}_m^\dagger \mathbf{v}_n \mathbf{u}_n^\dagger. \end{aligned} \quad (1.132)$$

¹⁰Technically, the condition is that the range of the operator be closed (Ogawa, 1988). This condition is satisfied for matrices and other operators with finite-dimensional range, including especially continuous-to-discrete operators. See also Caradus (1978) and Groetsch (1977).

Note that no parentheses are needed in the last line; the following forms are all equivalent:

$$(\mathbf{v}_k \mathbf{u}_k^\dagger)(\mathbf{u}_m \mathbf{v}_m^\dagger)(\mathbf{v}_n \mathbf{u}_n^\dagger) = \mathbf{v}_k \mathbf{u}_k^\dagger \mathbf{u}_m \mathbf{v}_m^\dagger \mathbf{v}_n \mathbf{u}_n^\dagger = \mathbf{v}_k (\mathbf{u}_k^\dagger \mathbf{u}_m)(\mathbf{v}_m^\dagger \mathbf{v}_n) \mathbf{u}_n^\dagger, \quad (1.133)$$

as one can demonstrate by patiently writing out each expression in component form. The advantage of the last expression in (1.133), however, is that we can recognize the inner products $(\mathbf{u}_k^\dagger \mathbf{u}_m)$ and $(\mathbf{v}_m^\dagger \mathbf{v}_n)$, allowing us to use the orthogonality relations (1.112) and (1.118). The resulting Kronecker deltas allow us to perform two of the three sums in (1.132), and we obtain

$$\mathcal{H}\mathcal{H}^+\mathcal{H} = \sum_{k=1}^R \sum_{m=1}^R \sum_{n=1}^R \frac{\sqrt{\mu_k} \sqrt{\mu_n}}{\sqrt{\mu_m}} \delta_{km} \delta_{mn} \mathbf{v}_k \mathbf{u}_n^\dagger = \sum_{k=1}^R \sqrt{\mu_k} \mathbf{v}_k \mathbf{u}_k^\dagger, \quad (1.134)$$

which, by (1.120), is just \mathcal{H} , verifying the first Penrose equation. A similar procedure shows that the remaining Penrose equations are also valid when we represent \mathcal{H}^+ by means of (1.131).

1.6.3 Properties of the pseudoinverse

The SVD representations of Sec. 1.5.3 enable us to derive many additional properties of the Moore-Penrose pseudoinverse. We begin by deriving two additional representations for it.

Limiting representations An important limiting representation of the pseudoinverse, which will prove useful in Sec. 1.7.6, is

$$\mathcal{H}^+ = \lim_{\eta \rightarrow 0^+} [\mathcal{H}^\dagger \mathcal{H} + \eta \mathcal{I}_\mathbb{U}]^{-1} \mathcal{H}^\dagger. \quad (1.135)$$

To prove that the right-hand side of (1.135) is indeed \mathcal{H}^+ , we first represent $\mathcal{H}^\dagger \mathcal{H}$ and $\mathcal{I}_\mathbb{U}$ in terms of the SVD basis vectors (see Table 1.2) as

$$[\mathcal{H}^\dagger \mathcal{H} + \eta \mathcal{I}_\mathbb{U}] = \sum_{n=1}^R \mu_n \mathbf{u}_n \mathbf{u}_n^\dagger + \eta \sum_{n=1}^N \mathbf{u}_n \mathbf{u}_n^\dagger = \sum_{n=1}^N (\mu_n + \eta) \mathbf{u}_n \mathbf{u}_n^\dagger, \quad (1.136)$$

where the first sum could be extended to N since $\mu_n = 0$ for $n > R$. The inverse of the operator in (1.136) is given by

$$[\mathcal{H}^\dagger \mathcal{H} + \eta \mathcal{I}_\mathbb{U}]^{-1} = \sum_{n=1}^N (\mu_n + \eta)^{-1} \mathbf{u}_n \mathbf{u}_n^\dagger, \quad (1.137)$$

where $\mu_n + \eta$ cannot vanish since $\mu_n \geq 0$ and $\eta > 0$. The correctness of (1.137) can be checked by multiplying it by (1.136) and using the orthogonality relation (1.112). The result will be the SVD representation for the identity operator as given in Table 1.2.

Using (1.137), (1.125) and (1.112) again, we find

$$[\mathcal{H}^\dagger \mathcal{H} + \eta \mathcal{I}_\mathbb{U}]^{-1} \mathcal{H}^\dagger = \sum_{n=1}^N \frac{\sqrt{\mu_n}}{\mu_n + \eta} \mathbf{u}_n \mathbf{v}_n^\dagger. \quad (1.138)$$

We can pass to the limit $\eta \rightarrow 0$ by noting that

$$\lim_{\eta \rightarrow 0^+} \frac{\sqrt{\mu_n}}{\mu_n + \eta} = \begin{cases} 1/\sqrt{\mu_n} & \text{if } \mu_n \neq 0 \\ 0 & \text{if } \mu_n = 0 \end{cases} . \quad (1.139)$$

Hence,

$$\lim_{\eta \rightarrow 0^+} [\mathcal{H}^\dagger \mathcal{H} + \eta \mathbf{I}_U]^{-1} \mathcal{H}^\dagger = \sum_{n=1}^R \frac{1}{\sqrt{\mu_n}} \mathbf{u}_n \mathbf{v}_n^\dagger , \quad (1.140)$$

which, by (1.131), is just \mathcal{H}^+ .

By a similar procedure, we can also show that

$$\mathcal{H}^+ = \lim_{\eta \rightarrow 0^+} \mathcal{H}^\dagger [\mathcal{H} \mathcal{H}^\dagger + \eta \mathcal{I}_V]^{-1} . \quad (1.141)$$

Special cases If \mathbf{H} is an $N \times N$ Hermitian matrix of rank R , it can be written in terms of its spectral decomposition (see Sec. 1.4.5) as

$$\mathbf{H} = \sum_{j=1}^R \lambda_j \mathbf{u}_j \mathbf{u}_j^\dagger . \quad (1.142)$$

This expansion is a special case of SVD with $\mu_j = \lambda_j^2$ and $\mathbf{v}_j = \mathbf{u}_j$. Of course, λ_j must be real since \mathbf{H} is Hermitian. Moreover, all of the λ_j are ≥ 0 if \mathbf{H} is nonnegative-definite. In this case, the pseudoinverse of \mathbf{H} is

$$\mathbf{H}^+ = \sum_{j=1}^R \frac{1}{\lambda_j} \mathbf{u}_j \mathbf{u}_j^\dagger . \quad (1.143)$$

As a further specialization, suppose that \mathbf{H} is Hermitian and diagonal, so we can write

$$\mathbf{H} = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_N) . \quad (1.144)$$

The notation indicates that \mathbf{H} is diagonal with elements $\lambda_1, \lambda_2, \dots, \lambda_N$ along the diagonal, and we assume that all of the λ_j are real and nonnegative. In this notation, the pseudoinverse is

$$\mathbf{H}^+ = \text{diag}(\lambda_1^+, \lambda_2^+, \dots, \lambda_N^+) , \quad (1.145)$$

where

$$\lambda_j^+ = \begin{cases} 1/\lambda_j & \text{if } \lambda_j \neq 0 \\ 0 & \text{if } \lambda_j = 0 \end{cases} . \quad (1.146)$$

Other useful identities The pseudoinverse obeys the following identities (Albert, 1972):

$$[\mathcal{H}^+]^+ = \mathcal{H} ; \quad (1.147)$$

$$\mathcal{H}^+ = (\mathcal{H}^\dagger \mathcal{H})^+ \mathcal{H}^\dagger ; \quad (1.148)$$

$$\mathcal{H}^+ = \mathcal{H}^\dagger [\mathcal{H} \mathcal{H}^\dagger]^+ ; \quad (1.149)$$

$$[\mathcal{H}^\dagger]^+ = [\mathcal{H}^+]^\dagger ; \quad (1.150)$$

$$[\mathcal{H}^\dagger]^+ = [\mathcal{H} \mathcal{H}^\dagger]^+ \mathcal{H} ; \quad (1.151)$$

$$[\mathcal{H}^+\mathcal{H}]^+ = \mathcal{H}^+\mathcal{H}; \quad (1.152)$$

$$\mathcal{H}^+\mathcal{H}\mathcal{H}^\dagger = \mathcal{H}^\dagger; \quad (1.153)$$

$$\mathcal{H}^\dagger\mathcal{H}\mathcal{H}^+ = \mathcal{H}^\dagger; \quad (1.154)$$

$$\mathcal{H}^+\mathcal{H} = (\mathcal{H}^\dagger\mathcal{H})^+ (\mathcal{H}^\dagger\mathcal{H}) = (\mathcal{H}^\dagger\mathcal{H}) (\mathcal{H}^\dagger\mathcal{H})^+; \quad (1.155)$$

$$\mathcal{H}\mathcal{H}^+ = (\mathcal{H}\mathcal{H}^\dagger)^+ \mathcal{H}\mathcal{H}^\dagger = \mathcal{H}\mathcal{H}^\dagger (\mathcal{H}\mathcal{H}^\dagger)^+; \quad (1.156)$$

$$[\mathcal{H}^\dagger\mathcal{H}]^+ = \mathcal{H}^+ [\mathcal{H}^\dagger]^+; \quad (1.157)$$

$$[\mathcal{H}^\dagger\mathcal{H}]^+ = \mathcal{H}^+ [\mathcal{H}\mathcal{H}^\dagger]^+ \mathcal{H} = \mathcal{H}^\dagger [\mathcal{H}\mathcal{H}^\dagger]^+ [\mathcal{H}^\dagger]^+; \quad (1.158)$$

$$[\mathcal{H}\mathcal{H}^\dagger]^+ = [\mathcal{H}^\dagger]^+ \mathcal{H}^+. \quad (1.159)$$

All of these identities can be proved either directly from the Penrose equations or from the SVD representations of \mathcal{H} and \mathcal{H}^+ .

Pseudoinverse of a product It is not true in general that $(\mathbf{AB})^+ = \mathbf{B}^+\mathbf{A}^+$, but there is one special case in which this useful relation is valid (Harville, 1997). It holds for any $M \times N$ matrix \mathbf{A} of full column rank (*i.e.*, rank N) and any $N \times K$ matrix \mathbf{B} of full row rank (rank N again). More generally, all that can be said is that $(\mathbf{AB})^+ = (\mathbf{A}^+\mathbf{AB})^+(\mathbf{ABB}^+)^+$ (Campbell and Meyer, 1979, theorem 1.4.1).

1.6.4 Pseudoinverses and projection operators

In this section we relate the pseudoinverse to projection operators for the subspaces discussed in Sec. 1.5.2. Consider first the division of \mathbb{U} into \mathbb{U}_{meas} and \mathbb{U}_{null} . An arbitrary vector \mathbf{f} in \mathbb{U} can be expanded in terms of the basis $\{\mathbf{u}_k\}$ as

$$\mathbf{f} = \sum_{k=1}^N \alpha_k \mathbf{u}_k, \quad \alpha_k = \mathbf{u}_k^\dagger \mathbf{f}. \quad (1.160)$$

The vector $\mathcal{H}\mathbf{f}$ can be computed from (1.120) and (1.160) as follows:

$$\mathcal{H}\mathbf{f} = \sum_{k=1}^R \sqrt{\mu_k} \mathbf{v}_k \mathbf{u}_k^\dagger \sum_{n=1}^N \alpha_n \mathbf{u}_n = \sum_{k=1}^R \sum_{n=1}^N \sqrt{\mu_k} \alpha_n \mathbf{v}_k \mathbf{u}_k^\dagger \mathbf{u}_n = \sum_{n=1}^R \sqrt{\mu_n} \alpha_n \mathbf{v}_n, \quad (1.161)$$

where the last step made use of the orthogonality relation (1.112). The key point to notice here is that (in this particular basis) components f_n for which $n > R$ make no contribution to $\mathcal{H}\mathbf{f}$ since they correspond to zero singular values μ_n . Thus these components define \mathbf{f}_{null} , and we can write

$$\mathbf{f}_{null} = \sum_{n=R+1}^N \alpha_n \mathbf{u}_n. \quad (1.162)$$

The measurement component is given by

$$\mathbf{f}_{meas} = \mathbf{f} - \mathbf{f}_{null} = \sum_{m=1}^R \alpha_m \mathbf{u}_m. \quad (1.163)$$

Since \mathbf{u}_n and \mathbf{u}_m are orthogonal if $n > R$ and $m \leq R$, it follows that \mathbf{f}_{meas} and \mathbf{f}_{null} are orthogonal.

Now we bring the pseudoinverse into the discussion. Consider the operator $\mathcal{H}^+\mathcal{H}$, given from (1.120) and (1.131) as

$$\mathcal{H}^+\mathcal{H} = \sum_{k=1}^R \frac{1}{\sqrt{\mu_k}} \mathbf{u}_k \mathbf{v}_k^\dagger \sum_{m=1}^R \sqrt{\mu_m} \mathbf{v}_m \mathbf{u}_m^\dagger = \sum_{k=1}^R \mathbf{u}_k \mathbf{u}_k^\dagger. \quad (1.164)$$

The last sum is in the form of a general projection operator as in (1.60), and in fact it is just the projector onto the measurement space:

$$\mathcal{H}^+\mathcal{H}\mathbf{f} = \sum_{k=1}^R \mathbf{u}_k \mathbf{u}_k^\dagger \mathbf{f} = \sum_{k=1}^R \alpha_k \mathbf{u}_k = \mathbf{f}_{meas}, \quad (1.165)$$

where we have used (1.160) and (1.163). We can thus define a projection operator by

$$\mathcal{P}_{meas} = \mathcal{H}^+\mathcal{H}, \quad (1.166)$$

and it follows that

$$\mathbf{f}_{meas} = \mathcal{P}_{meas}\mathbf{f}. \quad (1.167)$$

The null component of \mathbf{f} is given by

$$\mathbf{f}_{null} = \mathbf{f} - \mathbf{f}_{meas} = (\mathcal{I}_\mathbb{U} - \mathcal{P}_{meas})\mathbf{f} = \mathcal{P}_{null}\mathbf{f}. \quad (1.168)$$

The projector \mathcal{P}_{null} is thus given by

$$\mathcal{P}_{null} = \mathcal{I}_\mathbb{U} - \mathcal{P}_{meas} = \mathcal{I}_\mathbb{U} - \mathcal{H}^+\mathcal{H}. \quad (1.169)$$

As a check on these formulas, note that

$$\mathcal{P}_{meas} + \mathcal{P}_{null} = \sum_{k=1}^N \mathbf{u}_k \mathbf{u}_k^\dagger = \mathcal{I}_\mathbb{U}, \quad (1.170)$$

where the sum is equal to the identity operator in \mathbb{U} by (1.113).

A similar decomposition holds for any vector \mathbf{g} in \mathbb{V} . We can write

$$\mathbf{g} = \sum_{k=1}^M \beta_k \mathbf{v}_k = \mathbf{g}_{con} + \mathbf{g}_{incon}; \quad (1.171)$$

$$\beta_k = \mathbf{v}_k^\dagger \mathbf{g}; \quad (1.172)$$

$$\mathbf{g}_{con} = \mathcal{P}_{con}\mathbf{g} = \sum_{k=1}^R \beta_k \mathbf{v}_k; \quad (1.173)$$

$$\mathbf{g}_{incon} = \mathcal{P}_{incon}\mathbf{g} = \sum_{k=R+1}^M \beta_k \mathbf{v}_k. \quad (1.174)$$

By a procedure analogous to the one used for \mathcal{P}_{meas} and \mathcal{P}_{null} , we can show that

$$\mathcal{P}_{con} = \mathcal{H}\mathcal{H}^+; \quad (1.175)$$

$$\mathcal{P}_{incon} = \mathcal{I}_V - \mathcal{H}\mathcal{H}^+. \quad (1.176)$$

Though we have derived all of these projection operators from the SVD, they also follow directly from the Penrose equations and the definitions of the subspaces. For example, to show that (1.169) is correct, we operate on $\mathcal{P}_{null}\mathbf{f}$ with \mathcal{H} , yielding

$$\mathcal{H}\mathcal{P}_{null}\mathbf{f} = [\mathcal{H} - \mathcal{H}\mathcal{H}^+\mathcal{H}]\mathbf{f}. \quad (1.177)$$

The right-hand side is identically zero, as expected, because of the first Penrose equation, (1.130a). This proves that $[\mathcal{I}_U - \mathcal{H}^+\mathcal{H}]\mathbf{f}$ is indeed a null vector of \mathcal{H} and hence that $\mathcal{I}_U - \mathcal{H}^+\mathcal{H}$ is a valid form for \mathcal{P}_{null} . We used only the first Penrose equation in this argument, but any projector must be Hermitian so the fourth equation must also be satisfied. Thus

$$\mathcal{P}_{null} = \mathcal{I}_U - \mathcal{H}^\#\mathcal{H} \quad (1.178)$$

if $\mathcal{H}^\#$ is a (1,4)-inverse.

Similar arguments can be used to derive the other three projectors from the Penrose equations. It is found that (1.166) and (1.169) hold if \mathcal{H}^+ is replaced by a (1,4)-inverse, while (1.175) and (1.176) hold if \mathcal{H}^+ is replaced by a (1,3)-inverse. Since the Moore-Penrose operator is a (1,2,3,4)-inverse, however, we are always safe in using \mathcal{H}^+ itself.

It is also possible to go in the other direction. We can *define* \mathcal{H}^+ by the projector equations (1.166) and (1.175) and use this definition to derive all four Penrose equations¹¹ and other properties of the pseudoinverse. This was the approach taken by Moore in 1935.

1.7 PSEUDOINVERSES AND LINEAR EQUATIONS

An important use of the pseudoinverse operator is to solve systems of linear equations. In imaging, such systems arise when we represent an object by a discrete vector and then try to relate the elements of this vector to a discrete image data set.

The goal of this section is to discuss two particular kinds of solutions to systems of linear equations, so-called *exact* solutions and approximate *least-squares* solutions (Lawson and Hanson, 1995), and to show how each is related to pseudoinverses. Many other kinds of solutions of linear equations will be discussed in Chap. 15, where we deal with inverse problems in general. That chapter will also discuss in detail the problems that can arise with discrete object representations, but for now we shall accept them uncritically.

1.7.1 Nature of solutions of linear equations

Noisy data So far, we have considered only ideal linear mappings from a vector \mathbf{f} to a vector \mathbf{g} . In real life, however, there is always some randomness or noise in any set of measurements, so \mathbf{g} is a random vector. There can also be systematic

¹¹It might be surprising that we can get all four equations this way, since we had to use only Eqs. 1, 3 and 4 to go from the Penrose equations to the projectors, but it can be shown that a (1,3,4)-inverse is also a 2-inverse.

errors in \mathbf{g} . To account for these errors, we must modify the basic matrix equation $\mathbf{g} = \mathbf{H}\mathbf{f}$. If we assume that \mathbf{f} is a finite vector with components $\{f_n, n = 1, \dots, N\}$, the m^{th} component of \mathbf{g} is given by

$$g_m = \sum_{n=1}^N H_{mn}f_n + \epsilon_m, \quad m = 1, \dots, M, \quad (1.179)$$

where the random numbers $\{\epsilon_m\}$ represent noise or other errors in the measurements. In matrix-vector form, we now have

$$\mathbf{g} = \mathbf{H}\mathbf{f} + \boldsymbol{\epsilon}, \quad (1.180)$$

where $\boldsymbol{\epsilon}$ is an $M \times 1$ column vector with elements $\{\epsilon_m\}$. We shall refer to $\boldsymbol{\epsilon}$ as a noise vector, though it can have both random and systematic components. The specific properties of $\boldsymbol{\epsilon}$ are not needed here but will be discussed in detail in later chapters.

Exact and approximate solutions One sense in which one might attempt to solve (1.180) would be to try to find the unknown vectors \mathbf{f} and $\boldsymbol{\epsilon}$, but there are two difficulties with this approach. One is that determination of both vectors requires solving the M equations for $M + N$ unknowns, a clear impossibility. The other difficulty is that we aren't really interested in the components of $\boldsymbol{\epsilon}$ since they are not characteristic of the object.

A more sensible approach is to attempt to find solutions to

$$\mathbf{g} = \mathbf{H}\hat{\mathbf{f}}, \quad (1.181)$$

where the caret indicates that $\hat{\mathbf{f}}$ is some approximation to \mathbf{f} . In the language of statistical decision theory, to be introduced Chap. 13, $\hat{\mathbf{f}}$ is called an *estimate* of \mathbf{f} . Since \mathbf{H} is an $M \times N$ matrix, $\hat{\mathbf{f}}$ must be an $N \times 1$ vector like \mathbf{f} itself. Thus, solution of (1.181) requires finding the N unknown values $\{\hat{f}_n\}$ from M equations (one for each component of \mathbf{g}). An exact solution of (1.181) amounts to finding a vector $\hat{\mathbf{f}}$ that would exactly reproduce \mathbf{g} if it were mapped through \mathbf{H} without noise, even though \mathbf{g} itself actually contains noise.

1.7.2 Existence and uniqueness of exact solutions

We now state several formal conditions for the existence and uniqueness of solutions of (1.181) and then discuss them from various perspectives. All of the conditions listed under each theorem below are mathematically equivalent. A good general reference to this section is Strang (1980).

Existence theorems Equation (1.181) has *at least* one exact solution for a *particular* \mathbf{g} if and only if

- (a) \mathbf{g} can be expressed as a linear combination of the columns of \mathbf{H} ;
- (b) The data are consistent;
- (c) \mathbf{g} lies in \mathbb{V}_{con} ;
- (d) $\mathbf{H}\mathbf{H}^+\mathbf{g} = \mathbf{g}$.

Equation (1.181) has *at least* one exact solution for *every* \mathbf{g} if and only if

- (a) The columns of \mathbf{H} span $\mathbb{V} = \mathbb{E}^M$;
- (b) $R = M$;
- (c) A right inverse of \mathbf{H} exists;
- (d) \mathbf{H} is *onto*;
- (e) \mathbb{V}_{incon} is trivial;
- (f) $\mathbf{H}\mathbf{H}^\dagger$ is nonsingular.

These conditions can be satisfied only if $M \leq N$.

Uniqueness theorems Equation (1.181) has *at most* one solution for every \mathbf{g} if and only if

- (a) The columns of \mathbf{H} are linearly independent;
- (b) $R = N$;
- (c) A left inverse of \mathbf{H} exists;
- (d) \mathbf{H} is *one-to-one*;
- (e) \mathbb{U}_{null} is trivial;
- (f) $\mathbf{H}^\dagger\mathbf{H}$ is nonsingular.

These conditions can be satisfied only if $M \geq N$. Putting the existence and uniqueness conditions together, we see that a unique, exact solution exists only if \mathbf{H} is square and full rank, $M = N = R$.

Discussion A system of linear equations is said to be *underdetermined* if the number of measurements is less than the number of unknowns, or $M < N$ in our notation. There are not enough measurements to determine all of the unknown values f_n in this case. Conversely, the system is said to be *overdetermined* if $M > N$. The implication of the word overdetermined is that the data are inconsistent so that no exact solution exists.

In fact, it is possible to have an exact solution to (1.181) even if $M > N$. All that is required is that the particular \mathbf{g} lie entirely in \mathbb{V}_{con} as expressed by the first set of existence conditions above. Suppose, for example, that we somehow generate noise-free measurements (as in computer simulations). Then the data vector is given precisely by $\mathbf{g} = \mathbf{H}\mathbf{f}$, so (1.181) has an exact solution, namely $\hat{\mathbf{f}} = \mathbf{f}$. Thus the first set of existence conditions can be satisfied if there is no noise in the data.

Of course, the assumption of noise-free measurements is highly artificial. Real, noisy measurements are unlikely to be confined to any subspace of \mathbb{V} . If there is a nontrivial inconsistency space, chances are that noisy data will have a component in it. Thus the only practical way to avoid inconsistent data is to have no inconsistency space, which is a paraphrase of the second set of existence conditions above. There is no inconsistency space if $R = M$. Since $R \leq \min(M, N)$, the condition $M > N$ implies $M > R$. An overdetermined system of equations thus necessarily

has an inconsistency space. Barring noise-free data or other bizarre circumstances, there will be no exact solution to (1.181) in that case.

Next we discuss the uniqueness theorems. If a solution to (1.181) exists but \mathbf{H} has a null space, as it will if $R < N$, the solution is not unique. All we have to do to construct another solution is to add any null vector to the original solution. If $\hat{\mathbf{f}}$ satisfies (1.181), then so does $\hat{\mathbf{f}} + \mathbf{f}_{null}$, where \mathbf{f}_{null} is any vector such that $\mathbf{H}\mathbf{f}_{null} = \mathbf{0}$. All of the uniqueness conditions listed above thus amount to saying that there is no nontrivial null space.

1.7.3 Explicit solutions for consistent data

Right inverse If $R = M$, at least one exact solution to (1.181) exists, which is the same thing as saying that the right inverse of \mathbf{H} exists. In the present problem, the right inverse \mathbf{H}_R^{-1} is an $N \times M$ matrix that satisfies (1.38), or

$$\mathbf{H}\mathbf{H}_R^{-1} = \mathbf{I}_M, \quad (1.182)$$

where \mathbf{I}_M is the $M \times M$ unit matrix. In terms of \mathbf{H}_R^{-1} , an exact solution to (1.181) is given by

$$\hat{\mathbf{f}} = \mathbf{H}_R^{-1}\mathbf{g}. \quad (1.183)$$

With (1.182), it is easy to see that this $\hat{\mathbf{f}}$ satisfies (1.181).

To construct the right inverse explicitly, we note that the rank of the $M \times M$ matrix $\mathbf{H}\mathbf{H}^\dagger$ is also R , a point which follows from (1.129d). Thus, if $R = M$, $\mathbf{H}\mathbf{H}^\dagger$ is invertible, and the right inverse of \mathbf{H} is given by

$$\mathbf{H}_R^{-1} = \mathbf{H}^\dagger (\mathbf{H}\mathbf{H}^\dagger)^{-1}, \quad (R = M). \quad (1.184)$$

Direct substitution shows that (1.184) satisfies (1.182).

Consistency and pseudoinverses An exact solution to (1.181) exists if the data are consistent, or \mathbf{g} lies entirely in \mathbb{V}_{con} . That will be the case either if we have somehow generated noise-free data or if there is no nontrivial inconsistency space. A mathematical statement that covers both contingencies is that \mathbf{g} is consistent if

$$\mathbf{H}\mathbf{H}^+\mathbf{g} = \mathbf{g}, \quad (1.185)$$

where we recall from (1.175) that $\mathbf{H}\mathbf{H}^+ = \mathbf{P}_{con}$ (and we use \mathbf{P} instead of \mathcal{P} since we are dealing explicitly with matrices).

If the data are consistent, one solution to (1.181) is

$$\hat{\mathbf{f}} = \mathbf{H}^+\mathbf{g}. \quad (1.186)$$

To show that this is a solution, operate on it with \mathbf{H} . The result is

$$\mathbf{H}\hat{\mathbf{f}} = \mathbf{H}\mathbf{H}^+\mathbf{g} = \mathbf{g}, \quad (1.187)$$

where the last step follows from the consistency condition (1.185).

If the data are consistent because there is no nontrivial inconsistency space, then $R = M$ and the right inverse exists. In this case, right inverse and Moore-Penrose pseudoinverse are identical, but (1.186) is more general than (1.183). The pseudoinverse provides a solution to (1.181) even when there *is* an inconsistency space but the particular \mathbf{g} happens to have no inconsistent component.

General exact solution While (1.187) provides a solution to (1.181), it is not the most general solution if \mathbf{H} has a nontrivial null space. The general solution to (1.181) is

$$\hat{\mathbf{f}} = \mathbf{H}^+ \mathbf{g} + [\mathbf{I}_N - \mathbf{H}^+ \mathbf{H}] \mathbf{y}, \quad (1.188)$$

where \mathbf{y} is an arbitrary vector in \mathbb{U} . Since $\mathbf{I}_N - \mathbf{H}^+ \mathbf{H}$ is just \mathbf{P}_{null} , the second term in (1.188) is a null vector of \mathbf{H} . Thus the solution to (1.181) is unique if and only if $\mathbf{P}_{null} = \mathbf{0}$ or $\mathbf{H}^+ \mathbf{H} = \mathbf{I}_N$.

To demonstrate that (1.188) is a solution to (1.181) for consistent data, we again operate on it with \mathbf{H} , yielding

$$\mathbf{H} \hat{\mathbf{f}} = \mathbf{H} \mathbf{H}^+ \mathbf{g} + [\mathbf{H} - \mathbf{H} \mathbf{H}^+ \mathbf{H}] \mathbf{y}. \quad (1.189)$$

The first term is \mathbf{g} by the consistency condition (1.185), while the second term is zero by the first Penrose equation, so (1.188) is indeed a solution to (1.181) if the data are consistent. Furthermore, (1.188) must be the most general solution to (1.181); we cannot add any vector in \mathbb{U}_{meas} to this $\hat{\mathbf{f}}$ and still have it satisfy (1.181), and $[\mathbf{I}_N - \mathbf{H}^+ \mathbf{H}] \mathbf{y}$ is the general form for a vector in \mathbb{U}_{null} .

A way of selecting among the various solutions specified by (1.188) will be given in Sec. 1.7.5.

Unique, exact solutions Since \mathbf{H} has a null space unless $R = N$, and we have already said that we must have $R = M$ for *any* solution to exist in general, a unique, exact solution to (1.181) exists for all \mathbf{g} only if $R = M = N$. In this case \mathbf{H} is a square, nonsingular matrix, and the unique solution is given by

$$\hat{\mathbf{f}} = \mathbf{H}^{-1} \mathbf{g}, \quad (R = M = N). \quad (1.190)$$

Only rarely will the conditions necessary for the applicability of (1.190) be satisfied in real imaging problems.

1.7.4 Least-squares solutions

The method of least squares is a powerful and widely applicable method for drawing inferences from incomplete or noisy data (Lawson and Hanson, 1995). As with so much of the mathematics in this book, this method originated with Gauss. In 1801 an astronomer named G. Piazzi briefly observed and then lost the asteroid we now know as Ceres. Thinking it was a new planet, Piazzi and other astronomers tried in vain to locate this elusive heavenly body. Gauss assumed that it travelled in an elliptical orbit, and he found the parameters of the ellipse by least-squares fitting to Piazzi's data. He astounded the astronomy community, not only by telling them where to find the asteroid, but also by predicting its future path. He then waited another eight years before he revealed how he had done it (Campbell and Meyer, 1979).

In this section we discuss least-squares solutions to (1.181) for the case $R < M$ where no exact solution exists. We shall refer to the difference $\mathbf{g} - \mathbf{H} \hat{\mathbf{f}}$ as the *residual vector* or simply the residual.¹² It represents the amount by which a

¹²Do not confuse the residual with the measurement error ϵ . The latter is the difference between the data \mathbf{g} and the image of the unknown vector \mathbf{f} while the former is the difference between the data and the image of the estimate.

particular estimate $\hat{\mathbf{f}}$ fails to reproduce the data when imaged through \mathbf{H} . A least-squares solution to (1.181) is one for which the \mathbb{L}_2 norm of the residual vector is the smallest. Formally, we write

$$\hat{\mathbf{f}}_{LS} = \underset{\hat{\mathbf{f}}}{\operatorname{argmin}} \|\mathbf{g} - \mathbf{H}\hat{\mathbf{f}}\|^2. \quad (1.191)$$

This notation means that $\hat{\mathbf{f}}_{LS}$ (where LS denotes least-squares) is the $\hat{\mathbf{f}}$ argument for which the norm is minimum. Since we are using the \mathbb{L}_2 norm, this means that the sum of the squares of the components of the residual is minimum. A statistical justification for the least-squares solution will be given in Chap. 13, but for now we merely investigate its mathematical properties.

Normal equation To find an explicit equation for $\hat{\mathbf{f}}_{LS}$, we write the squared norm in (1.191) as the scalar product of the residual with itself. Various equivalent forms are:

$$\begin{aligned} \|\mathbf{g} - \mathbf{H}\hat{\mathbf{f}}\|^2 &= (\mathbf{g} - \mathbf{H}\hat{\mathbf{f}}, \mathbf{g} - \mathbf{H}\hat{\mathbf{f}}) \\ &= (\mathbf{g}, \mathbf{g}) - (\mathbf{H}\hat{\mathbf{f}}, \mathbf{g}) - (\mathbf{g}, \mathbf{H}\hat{\mathbf{f}}) + (\mathbf{H}\hat{\mathbf{f}}, \mathbf{H}\hat{\mathbf{f}}) \\ &= \|\mathbf{g}\|^2 - 2\operatorname{Re}(\mathbf{g}, \mathbf{H}\hat{\mathbf{f}}) + \|\mathbf{H}\hat{\mathbf{f}}\|^2 \\ &= \|\mathbf{g}\|^2 - 2\operatorname{Re}(\mathbf{H}^\dagger \mathbf{g}, \hat{\mathbf{f}}) + (\mathbf{H}^\dagger \mathbf{H}\hat{\mathbf{f}}, \hat{\mathbf{f}}), \end{aligned} \quad (1.192)$$

where we have made use of several properties of scalar products and adjoints (see Secs. 1.1.4 and 1.3.5), and Re denotes real part. If \mathbf{H} and $\hat{\mathbf{f}}$ are real, the Re is irrelevant.

In some problems there may be constraints on the possible values of \hat{f}_n ; for example, the values may have to be nonnegative if \mathbf{f} represents an irradiance or other intrinsically nonnegative quantity. Such constraints are discussed in detail in Chap. 15, but for now we assume that each \hat{f}_n can take on any value in $(-\infty, \infty)$.

With that assumption, the least-squares solution must occur at a point in \mathbb{U} where all derivatives of the residual norm vanish. If a component \hat{f}_n can be complex, the residual norm is a function of $2N$ variables (the real and imaginary parts of \hat{f}_n for $n = 1, \dots, N$), so $2N$ derivatives must vanish. It is convenient, however, to take \hat{f}_n and its complex conjugate \hat{f}_n^* as the independent variables instead of the real and imaginary parts. These quantities can be regarded as components of two *independent* vectors $\hat{\mathbf{f}}$ and $\hat{\mathbf{f}}^\dagger$. Rules for differentiating with respect to these vectors are discussed in App. A, Sec. A.9.5. Applying these rules to (1.192), we find¹³

$$\frac{\partial}{\partial \hat{\mathbf{f}}^\dagger} \|\mathbf{g} - \mathbf{H}\hat{\mathbf{f}}\|^2 = \left[-\mathbf{H}^\dagger \mathbf{g} + \mathbf{H}^\dagger \mathbf{H}\hat{\mathbf{f}} \right]^\dagger. \quad (1.193)$$

For a least-squares solution, this vector derivative must vanish, which requires that

$$\mathbf{H}^\dagger \mathbf{H}\hat{\mathbf{f}} = \mathbf{H}^\dagger \mathbf{g}. \quad (1.194)$$

¹³If all quantities are real, we can forgo the subtleties of differentiating with respect to a complex vector and use the conventions of Sec. A.9.2 rather than those of Sec. A.9.5. The result is that adjoint is replaced by transpose and an additional factor of 2 appears in (1.193). The factor of 2 can be cancelled in (1.194) when the derivative is set to zero.

This important result is called the *normal equation*. Solving the normal equation is equivalent to finding a least-squares solution to the original equation, (1.181). A least-squares solution to (1.181) must satisfy (1.194). The same conclusion is reached by differentiating (1.192) with respect to $\hat{\mathbf{f}}$ rather than $\hat{\mathbf{f}}^\dagger$.

Existence and uniqueness We can now pose two important questions: Does a least-squares solution to (1.181) exist, and is it unique?

The answer to the first question is straightforward. If no $\hat{\mathbf{f}}$ drives the norm of the residual to zero, then that norm must have some minimum value, and an estimate $\hat{\mathbf{f}}$ for which it attains the minimum value is a least-squares solution. In other words, there is *always* at least one exact solution to (1.194). One way to think about this result is that the modified data $\mathbf{H}^\dagger \mathbf{g}$ are always consistent. The operator \mathbf{H}^\dagger wipes out the inconsistent part of \mathbf{g} since the inconsistency space is precisely the null space of \mathbf{H}^\dagger .

Next consider the second question. The least-squares solution is certainly not unique if \mathbf{H} has a null space ($R < N$). If it does, we can generate an infinite set of least-squares solutions simply by adding arbitrary null vectors \mathbf{f}_{null} . Since $\mathbf{H}\mathbf{f}_{null} = \mathbf{0}$, the norm of the residual in (1.191) is unaffected by the null vectors. If the residual achieves its minimum norm for some $\hat{\mathbf{f}}$, it must have exactly the same norm for $\hat{\mathbf{f}} + \mathbf{f}_{null}$.

Another way to make the same point is to note that $\mathbf{H}^\dagger \mathbf{H}$ is singular if $R < N$. The null space of $\mathbf{H}^\dagger \mathbf{H}$ is the same as the null space of \mathbf{H} , so if (1.194) holds for some $\hat{\mathbf{f}}$, it holds also for $\hat{\mathbf{f}} + \mathbf{f}_{null}$. Thus the least-squares solution is unique if and only if $\mathbf{H}^\dagger \mathbf{H}$ is nonsingular or $R = N$, in which case the solution is given by

$$\hat{\mathbf{f}}_{LS} = (\mathbf{H}^\dagger \mathbf{H})^{-1} \mathbf{H}^\dagger \mathbf{g}, \quad (R = N). \quad (1.195)$$

General least-squares solutions We have seen that any $\hat{\mathbf{f}}$ that minimizes $\|\mathbf{g} - \mathbf{H}\hat{\mathbf{f}}\|$ also satisfies the normal equation (1.194). As we shall now show, the general solution to (1.194) has exactly the same form as (1.188):

$$\hat{\mathbf{f}}_{LS} = \mathbf{H}^+ \mathbf{g} + [\mathbf{I}_N - \mathbf{H}^+ \mathbf{H}] \mathbf{y}, \quad (1.196)$$

where again \mathbf{y} is an arbitrary vector in \mathbb{U} . Operating on $\hat{\mathbf{f}}_{LS}$ with $\mathbf{H}^\dagger \mathbf{H}$ yields

$$\mathbf{H}^\dagger \mathbf{H} \hat{\mathbf{f}}_{LS} = \mathbf{H}^\dagger \mathbf{H} \mathbf{H}^+ \mathbf{g} + [\mathbf{H}^\dagger \mathbf{H} - \mathbf{H}^\dagger \mathbf{H} \mathbf{H}^+ \mathbf{H}] \mathbf{y}. \quad (1.197)$$

From (1.154), $\mathbf{H}^\dagger \mathbf{H} \mathbf{H}^+ = \mathbf{H}^\dagger$, and from the first Penrose equation $\mathbf{H}^\dagger \mathbf{H} \mathbf{H}^+ \mathbf{H} = \mathbf{H}^\dagger \mathbf{H}$, so the right-hand side of (1.197) reduces to $\mathbf{H}^\dagger \mathbf{g}$, proving that (1.196) indeed satisfies (1.194). Moreover, it must be the most general solution. We cannot add any vector in \mathbb{U}_{meas} and still have (1.194) satisfied, and we have already added the most general vector in \mathbb{U}_{null} .

1.7.5 Minimum-norm solutions

There is an interesting analogy between (1.188) or (1.196) and the general solution to an inhomogeneous differential equation. The first term, $\mathbf{H}^+ \mathbf{g}$, is a particular solution to (1.181) or (1.194), while the second term is the general solution to the appropriate homogeneous equation, $\mathbf{H}\hat{\mathbf{f}} = \mathbf{0}$ or $\mathbf{H}^\dagger \mathbf{H}\hat{\mathbf{f}} = \mathbf{0}$. What we are here calling

a null vector would be called a solution to the homogeneous equation in the theory of differential equations. That solution would usually be adjusted to satisfy boundary conditions, and we must look for an analogous subsidiary condition in our problem.

Since the various solutions in (1.188) or (1.196) differ by null vectors of $\mathbf{H}^\dagger \mathbf{H}$, one approach is to choose the solution that contains no such null vector, *i.e.*, one that lies entirely in measurement space. Since the measurement and null spaces are orthogonal, the norm of the solution is given by

$$\|\hat{\mathbf{f}}\|^2 = \|\hat{\mathbf{f}}_{meas}\|^2 + \|\hat{\mathbf{f}}_{null}\|^2. \quad (1.198)$$

The first term on the right has the same value for all solutions. Since the second term is nonnegative, $\|\hat{\mathbf{f}}\|$ is a minimum if $\|\hat{\mathbf{f}}_{null}\| = 0$. An exact solution with no null component is called a *minimum-norm exact* solution and denoted $\hat{\mathbf{f}}_{MN}$. Similarly, a least-squares solution with no null component is called a *minimum-norm least-squares* (MNLS) solution and denoted $\hat{\mathbf{f}}_{MNLS}$. The norm referred to here should not be confused with the one given in (1.191), where a least-squares solution is defined as the one with minimum norm of the residual. The norm implied in the designation *MN* is the norm of $\hat{\mathbf{f}}$ itself, not the norm of $\mathbf{g} - \mathbf{H}\hat{\mathbf{f}}$.

To apply the minimum-norm condition to (1.181), we note that $\mathbf{H}^+ \mathbf{g}$ lies in \mathcal{U}_{meas} and $[\mathbf{I}_N - \mathbf{H}^+ \mathbf{H}]\mathbf{y}$ lies in \mathcal{U}_{null} . The choice of \mathbf{y} that minimizes the norm of $\hat{\mathbf{f}}$ is the one that makes the null component vanish, namely, $\mathbf{y} = \mathbf{0}$. Thus the minimum-norm solution to (1.181) for consistent data is

$$\hat{\mathbf{f}}_{MN} = \mathbf{H}^+ \mathbf{g}. \quad (1.199)$$

Since the general least-squares solution has the same structure as the general exact solution, the MNLS solution is also the pseudoinverse solution:

$$\hat{\mathbf{f}}_{MNLS} = \mathbf{H}^+ \mathbf{g}. \quad (1.200)$$

Since (1.199) and (1.200) have the same form, we can simply forget about the distinction between consistent and inconsistent data. In either case we can seek the unique, minimum-norm solution $\mathbf{H}^+ \mathbf{g}$.

Explicit solutions in the SVD domain Since the eigenvectors of $\mathbf{H}\mathbf{H}^\dagger$ form a basis in \mathbb{V} , we can represent an arbitrary data vector \mathbf{g} as (see Table 1.1)

$$\mathbf{g} = \sum_{k=1}^M \beta_k \mathbf{v}_k, \quad (1.201)$$

where

$$\beta_k = \mathbf{v}_k^\dagger \mathbf{g}. \quad (1.202)$$

Similarly, an arbitrary estimate of the object can be represented as

$$\hat{\mathbf{f}} = \sum_{k=1}^N \hat{\alpha}_k \mathbf{u}_k, \quad (1.203)$$

where

$$\hat{\alpha}_k = \mathbf{u}_k^\dagger \hat{\mathbf{f}}. \quad (1.204)$$

With the SVD representation for \mathbf{H}^+ and the orthonormality relations, the expansion coefficients for $\hat{\mathbf{f}}_{MN}$ or $\hat{\mathbf{f}}_{MNLS}$ are given by

$$\hat{\alpha}_k = \begin{cases} \beta_k/\sqrt{\mu_k} & \text{if } \mu_k \neq 0 \\ 0 & \text{if } \mu_k = 0 \end{cases}. \quad (1.205)$$

The coefficients in the estimate are thus obtained by an operation called *inverse filtering*, where each β_k is divided by $\sqrt{\mu_k}$, no matter how small μ_k is. The process is truncated at $k = R$, so we never divide by zero, but we can divide by a very small number in some cases.

With these coefficients, the explicit form of the minimum-norm estimates is

$$\hat{\mathbf{f}}_{MN} = \hat{\mathbf{f}}_{MNLS} = \sum_{k=1}^R \frac{\beta_k}{\sqrt{\mu_k}} \mathbf{u}_k. \quad (1.206)$$

An algorithm to obtain these estimates is:

- (a) Perform an SVD on \mathbf{H} , obtaining $\{\mathbf{u}_k, \mathbf{v}_k, \mu_k\}$;
- (b) Use the vectors $\{\mathbf{v}_k\}$ to compute $\{\beta_k\}$;
- (c) Compute $\{\hat{\alpha}_k, k = 1, \dots, R\}$ via (1.205);
- (d) Form the weighted sum in (1.203) to compute $\hat{\mathbf{f}}$.

Unfortunately this algorithm is not practical for large matrices. If there are more than a few thousand elements (pixels, say) in the vectors \mathbf{f} and \mathbf{g} , the SVD cannot be performed on current computers. In such cases we can use iterative algorithms, to be introduced in Sec. 1.7.6.

Noise amplification Another serious problem with the SVD algorithm is that (1.205) requires dividing by all nonzero singular values, no matter how small they may be. This step has the effect of amplifying the errors in data coefficients β_k for which μ_k is small. A full treatment of this problem must wait until we have established statistical models for the noise, but a simple analysis will illustrate the problem.

If we represent the actual vector \mathbf{f} (not its estimate) by

$$\mathbf{f} = \sum_{k=1}^N \alpha_k \mathbf{u}_k, \quad \alpha_k = \mathbf{u}_k^\dagger \mathbf{f}, \quad (1.207)$$

and the noise by

$$\boldsymbol{\epsilon} = \sum_{k=1}^M \gamma_k \mathbf{v}_k, \quad \gamma_k = \mathbf{v}_k^\dagger \boldsymbol{\epsilon}, \quad (1.208)$$

then the expansion coefficients for \mathbf{g} are given by [cf. (1.161)]

$$\beta_k = \sqrt{\mu_k} \alpha_k + \gamma_k. \quad (1.209)$$

Substituting (1.209) into (1.206), we find

$$\hat{\mathbf{f}}_{MN} = \hat{\mathbf{f}}_{MNLS} = \sum_{k=1}^R \left[\alpha_k + \frac{\gamma_k}{\sqrt{\mu_k}} \right] \mathbf{u}_k = \mathbf{f}_{meas} + \sum_{k=1}^R \frac{\gamma_k}{\sqrt{\mu_k}} \mathbf{u}_k, \quad (1.210)$$

where we have used (1.165) in the last step.

Were it not for the noise, the pseudoinverse solution would thus exactly reproduce \mathbf{f}_{meas} . Noise in the data causes error, of course, and (1.210) shows that the error can become very large if μ_k is near zero. This large noise amplification for small singular values is the major drawback to pseudoinverse solutions. Methods of dealing with this problem will be discussed in Chap. 15.

1.7.6 Iterative calculation of pseudoinverse solutions

In this section we discuss an important iterative technique for finding the pseudoinverse solution of a system of linear equations. This method will work when the matrix is too large for direct SVD computation, but it does not actually yield the pseudoinverse matrix; instead, for any given \mathbf{g} , it computes $\mathbf{H}^+\mathbf{g}$ iteratively. If we actually knew \mathbf{H}^+ , computation of $\mathbf{H}^+\mathbf{g}$ would be just a matrix-vector multiply, but the iterative methods have to be run anew for each \mathbf{g} .

The starting point for developing an iterative algorithm is the limiting representation (1.135). If \mathcal{H} is the $M \times N$ matrix \mathbf{H} , that representation can be rewritten as

$$\mathbf{H}^+ = \lim_{\eta \rightarrow 0^+} [\mathbf{H}^\dagger \mathbf{H} + \eta \mathbf{I}]^{-1} \mathbf{H}^\dagger = \lim_{\eta \rightarrow 0^+} [\mathbf{I} - \mathbf{\Omega}]^{-1} \mathbf{H}^\dagger, \quad (1.211)$$

where \mathbf{I} is the $N \times N$ identity matrix and $\mathbf{\Omega}$ is an $N \times N$ Hermitian matrix given by

$$\mathbf{\Omega} = (1 - \eta)\mathbf{I} - \mathbf{H}^\dagger \mathbf{H}. \quad (1.212)$$

From App. A, we know that we can express $[\mathbf{I} - \mathbf{\Omega}]^{-1}$ by a *Neumann series*. Provided the series converges uniformly, we can write [see (A.59)]

$$[\mathbf{I} - \mathbf{\Omega}]^{-1} = \sum_{j=0}^{\infty} \mathbf{\Omega}^j. \quad (1.213)$$

Convergence To determine the conditions under which the Neumann series converges, we use the representations for \mathbf{I} and $\mathbf{H}^\dagger \mathbf{H}$ from Table 1.2 and write $\mathbf{\Omega}$ in SVD form as

$$\mathbf{\Omega} = (1 - \eta)\mathbf{I} - \mathbf{H}^\dagger \mathbf{H} = \sum_{n=1}^N (1 - \eta - \mu_n) \mathbf{u}_n \mathbf{u}_n^\dagger. \quad (1.214)$$

The SVD representation for the j^{th} power of a matrix is obtained simply by raising each coefficient to the j^{th} power:

$$\mathbf{\Omega}^j = \sum_{n=1}^N (1 - \eta - \mu_n)^j \mathbf{u}_n \mathbf{u}_n^\dagger. \quad (1.215)$$

The proof that (1.215) is correct makes use of the orthonormality of the $\{\mathbf{u}_n\}$ j times.

Now consider the effect of this matrix operating on an arbitrary vector \mathbf{f} in \mathbb{U} .

The squared norm of $\mathbf{\Omega}^j \mathbf{f}$ is

$$\begin{aligned} \|\mathbf{\Omega}^j \mathbf{f}\|^2 &= \left\| \sum_{n=1}^N (1 - \eta - \mu_n)^j \mathbf{u}_n \mathbf{u}_n^\dagger \sum_{m=1}^N \alpha_m \mathbf{u}_m \right\|^2 \\ &= \left\| \sum_{n=1}^N (1 - \eta - \mu_n)^j \alpha_n \mathbf{u}_n \right\|^2 = \sum_{n=1}^N |1 - \eta - \mu_n|^{2j} |\alpha_n|^2. \end{aligned} \quad (1.216)$$

By the triangle inequality (see Sec. 1.1.2),

$$\left\| \sum_{j=0}^J \mathbf{\Omega}^j \mathbf{f} \right\| \leq \sum_{j=0}^J \|\mathbf{\Omega}^j \mathbf{f}\| = \sum_{j=0}^J \left[\sum_{n=1}^N |1 - \eta - \mu_n|^{2j} |\alpha_n|^2 \right]^{\frac{1}{2}}. \quad (1.217)$$

But

$$|1 - \eta - \mu_n|^{2j} \leq \max_n |1 - \eta - \mu_n|^{2j}, \quad (1.218)$$

so

$$\begin{aligned} \left\| \sum_{j=0}^J \mathbf{\Omega}^j \mathbf{f} \right\| &\leq \sum_{j=0}^J \max_n |1 - \eta - \mu_n|^j \left[\sum_{n=1}^N |\alpha_n|^2 \right]^{\frac{1}{2}} \\ &= \|\mathbf{f}\| \max_n \sum_{j=0}^J |1 - \eta - \mu_n|^j. \end{aligned} \quad (1.219)$$

The remaining sum over j , an ordinary geometric series, converges absolutely if

$$|1 - \eta - \mu_n| < 1. \quad (1.220)$$

Small singular values cause no problem since $\mu_n \geq 0$ and $\eta > 0$. The geometric series converges for all n if the *maximum* singular value satisfies

$$\mu_{max} < 2 - \eta. \quad (1.221)$$

If (1.221) is satisfied, we can pass to the limit $J \rightarrow \infty$, and (1.219) becomes

$$\left\| \sum_{j=0}^{\infty} \mathbf{\Omega}^j \mathbf{f} \right\| \leq \|\mathbf{f}\| \max_n \sum_{j=0}^{\infty} |1 - \eta - \mu_n|^j = \max_n \frac{\|\mathbf{f}\|}{1 - |1 - \eta - \mu_n|}. \quad (1.222)$$

In the limit $\eta \rightarrow 0$, the right-hand side is finite provided $\mu_{max} < 2$. Thus, under this condition, the pseudoinverse can be represented as

$$\mathbf{H}^+ = \lim_{\eta \rightarrow 0^+} \sum_{j=0}^{\infty} \mathbf{\Omega}^j \mathbf{H}^\dagger, \quad (1.223)$$

where $\mathbf{\Omega}$ is given by (1.212). This form for \mathbf{H}^+ will be manipulated into an iterative algorithm below.

A trick Suppose, however, that the condition (1.221) is not satisfied. With a simple trick, we can still use the Neumann series. Define a new matrix \mathbf{H}' by

$$\mathbf{H}' = C\mathbf{H}, \quad (1.224)$$

where C is a real constant. All of the eigenvalues μ_n are scaled by $|C|^2$, so if C is chosen such that $|C|^2\mu_{max} < 2$, the Neumann series for \mathbf{H}' converges, and (1.223) becomes

$$[\mathbf{H}']^+ = \lim_{\eta \rightarrow 0^+} \sum_{j=0}^{\infty} [\mathbf{\Omega}']^j [\mathbf{H}']^\dagger, \quad (1.225)$$

where $\mathbf{\Omega}'$ is defined like $\mathbf{\Omega}$ but with \mathbf{H}' in place of \mathbf{H} . The pseudoinverse of the original \mathbf{H} is then found from

$$[\mathbf{H}']^+ = \frac{1}{C} \mathbf{H}^+. \quad (1.226)$$

This trick can be used even if μ_{max} is not known. If the series diverges, simply pick a $C < 1$, scale the matrix by (1.224), and try again. If it still diverges, use a smaller C . When it converges, $|C|^2\mu_{max}$ will be less than 2.

Landweber algorithm In order to convert the Neumann series into an iterative algorithm, we define partial sums of the series as

$$\hat{\mathbf{f}}^{(k)} = \lim_{\eta \rightarrow 0^+} \sum_{j=0}^k \mathbf{\Omega}^j \mathbf{H}^\dagger \mathbf{g}. \quad (1.227)$$

If the series converges, then

$$\hat{\mathbf{f}}^{(\infty)} = \mathbf{H}^+ \mathbf{g} = \hat{\mathbf{f}}_{MNLS}. \quad (1.228)$$

Now consider $\hat{\mathbf{f}}^{(k+1)}$, given by

$$\hat{\mathbf{f}}^{(k+1)} = \lim_{\eta \rightarrow 0} \sum_{j=0}^{k+1} \mathbf{\Omega}^j \mathbf{H}^\dagger \mathbf{g} = \lim_{\eta \rightarrow 0} \left\{ \mathbf{H}^\dagger \mathbf{g} + \sum_{j=1}^{k+1} \mathbf{\Omega}^j \mathbf{H}^\dagger \mathbf{g} \right\}. \quad (1.229)$$

If we let $m = j - 1$, this equation becomes

$$\hat{\mathbf{f}}^{(k+1)} = \lim_{\eta \rightarrow 0} \left\{ \mathbf{H}^\dagger \mathbf{g} + \sum_{m=0}^k \mathbf{\Omega}^{m+1} \mathbf{H}^\dagger \mathbf{g} \right\} = \lim_{\eta \rightarrow 0} \left\{ \mathbf{H}^\dagger \mathbf{g} + \mathbf{\Omega} \hat{\mathbf{f}}^{(k)} \right\}. \quad (1.230)$$

We can now insert the definition of $\mathbf{\Omega}$ from (1.212) and pass to the limit $\eta \rightarrow 0$; the result is

$$\hat{\mathbf{f}}^{(k+1)} = \hat{\mathbf{f}}^{(k)} + \mathbf{H}^\dagger \left[\mathbf{g} - \mathbf{H} \hat{\mathbf{f}}^{(k)} \right]. \quad (1.231)$$

Thus the $(k+1)^{th}$ partial sum (or estimate of \mathbf{f}) can be calculated from the k^{th} by adding a correction term $\mathbf{H}^\dagger [\mathbf{g} - \mathbf{H} \hat{\mathbf{f}}^{(k)}]$. The algorithm converges under the same conditions as required for the convergence of the Neumann series.

Moreover, if the algorithm converges at all, it converges to $\hat{\mathbf{f}}_{MNLS}$, provided the initial estimate contains no null functions. One way to see this is to note that the correction term is zero if $\hat{\mathbf{f}}^{(k)}$ satisfies the normal equation, (1.194), so the convergent estimate is at least an *LS* solution. The *MN* part comes about since each correction step makes use of \mathbf{H}^\dagger , an operator that erases null functions. If the

initial estimate is chosen by (1.227) with $k = 0$, it is given by $\hat{\mathbf{f}}^{(0)} = \mathbf{H}^\dagger \mathbf{g}$; since this vector contains no null functions, neither will any subsequent estimates, and the convergence point will be $\hat{\mathbf{f}}_{MMLS}$.

The algorithm described by (1.231) has been frequently rediscovered in various communities. In image processing it is known as the van Cittert or Landweber algorithm (Landweber, 1951), and in tomography it is called SIRT (simultaneous iterative reconstruction technique). As we shall see below, it is also closely related to the Jacobi method from numerical analysis.

Other iterative methods One approach (Golub and van Loan, 1989) to devising a whole family of iterative pseudoinversion algorithms is to define a *splitting* of the matrix $\mathbf{H}^\dagger \mathbf{H}$ by

$$\mathbf{H}^\dagger \mathbf{H} = \mathbf{A} - \mathbf{B}, \quad (1.232)$$

where \mathbf{A} can be any $N \times N$ matrix so long as \mathbf{A}^{-1} exists. Some simple matrix algebra is then used to rewrite the normal equation (1.194):

$$(\mathbf{A} - \mathbf{B})\hat{\mathbf{f}} = \mathbf{H}^\dagger \mathbf{g}; \quad (1.233)$$

$$\mathbf{A}\hat{\mathbf{f}} = \mathbf{H}^\dagger \mathbf{g} + \mathbf{B}\hat{\mathbf{f}} = \mathbf{H}^\dagger \mathbf{g} + \mathbf{A}\hat{\mathbf{f}} - \mathbf{H}^\dagger \mathbf{H}\hat{\mathbf{f}}; \quad (1.234)$$

$$\hat{\mathbf{f}} = \hat{\mathbf{f}} + \mathbf{A}^{-1} [\mathbf{H}^\dagger \mathbf{g} - \mathbf{H}^\dagger \mathbf{H}\hat{\mathbf{f}}]. \quad (1.235)$$

So far, this equation is algebraically equivalent to (1.194); to convert it into an iterative algorithm, we assume that $\hat{\mathbf{f}}$ on the right-hand side refers to the current estimate $\hat{\mathbf{f}}^{(k)}$, and that the entire right-hand side is then the rule for forming the next estimate $\hat{\mathbf{f}}^{(k+1)}$. This procedure, known as a *fixed-point iteration*, is discussed in more detail in Sec. 15.4. Here it yields

$$\hat{\mathbf{f}}^{(k+1)} = \hat{\mathbf{f}}^{(k)} + \mathbf{A}^{-1} [\mathbf{H}^\dagger \mathbf{g} - \mathbf{H}^\dagger \mathbf{H}\hat{\mathbf{f}}^{(k)}]. \quad (1.236)$$

If the algorithm converges, then $[\mathbf{H}^\dagger \mathbf{g} - \mathbf{H}^\dagger \mathbf{H}\hat{\mathbf{f}}^{(k)}]$ is zero and (1.194) is satisfied. We can thus write

$$\hat{\mathbf{f}}^{(\infty)} = \hat{\mathbf{f}}_{LS}, \quad (1.237)$$

regardless of the choice of \mathbf{A} , so long as the algorithm converges. It does not follow, however, that $\hat{\mathbf{f}}^{(\infty)} = \hat{\mathbf{f}}_{MMLS} = \mathbf{H}^\dagger \mathbf{g}$ since the matrix \mathbf{A}^{-1} can introduce null functions. It can be shown that (1.231) does indeed converge so long as the maximum eigenvalue of $\mathbf{A}^{-1}\mathbf{B}$ is less than 1 (Golub and van Loan, 1989, p. 508).

Different iterative algorithms are generated by different choices of \mathbf{A} . If $\mathbf{A} = \mathbf{I}$ and $\mathbf{B} = \mathbf{I} - \mathbf{H}^\dagger \mathbf{H}$, then (1.236) reverts to the Landweber algorithm. A classical method called the *Jacobi iteration* is obtained by letting \mathbf{A} be a diagonal matrix with the same diagonal elements as $\mathbf{H}^\dagger \mathbf{H}$, or

$$A_{mn} = [\mathbf{H}^\dagger \mathbf{H}]_{mn} \delta_{mn}. \quad (1.238)$$

The resulting iteration rule, in component form, is

$$\begin{aligned} \hat{f}_n^{(k+1)} &= \hat{f}_n^{(k)} + \frac{1}{A_{nn}} [\mathbf{H}^\dagger \mathbf{g} - \mathbf{H}^\dagger \mathbf{H}\hat{\mathbf{f}}^{(k)}]_n \\ &= \frac{1}{A_{nn}} \left[(\mathbf{H}^\dagger \mathbf{g})_n - \sum_{m=1}^{n-1} (\mathbf{H}^\dagger \mathbf{H})_{nm} \hat{f}_m^{(k)} - \sum_{m=n+1}^N (\mathbf{H}^\dagger \mathbf{H})_{nm} \hat{f}_m^{(k)} \right]. \end{aligned} \quad (1.239)$$

It is only the normalizing factor $1/A_{nn}$ that distinguishes the Jacobi and Landweber algorithms.

Another classical method, the *Gauss-Seidel iteration*, corresponds to taking \mathbf{A} as the lower-triangular part of $\mathbf{H}^\dagger \mathbf{H}$, *i.e.*,

$$A_{mn} = \begin{cases} [\mathbf{H}^\dagger \mathbf{H}]_{mn} & \text{if } n \leq m \\ 0 & \text{if } n > m \end{cases} . \quad (1.240)$$

The Gauss-Seidel iteration rule is

$$\hat{f}_n^{(k+1)} = \frac{1}{A_{nn}} \left[(\mathbf{H}^\dagger \mathbf{g})_n - \sum_{m=1}^{n-1} (\mathbf{H}^\dagger \mathbf{H})_{nm} \hat{f}_m^{(k+1)} - \sum_{m=n+1}^N (\mathbf{H}^\dagger \mathbf{H})_{nm} \hat{f}_m^{(k)} \right] . \quad (1.241)$$

The only difference between Jacobi and Gauss-Seidel is that the latter makes use of an updated component $\hat{f}_m^{(k+1)}$ as soon as it is available, while the former waits until all components have been computed and then updates the entire vector $\hat{\mathbf{f}}^{(k)}$ to $\hat{\mathbf{f}}^{(k+1)}$ simultaneously [compare the first sums in (1.241) and (1.239)].

Like the Landweber algorithm, Gauss-Seidel has been frequently rediscovered. It was proposed by Kaczmarz (1937), who proved its convergence for nonsingular matrices. It was rediscovered in a tomography context by Gordon *et al.* (1970), who gave it the name ART (algebraic reconstruction technique), and it has been widely used in that field (and widely called by that name) ever since.

There are many other iterative algorithms for solving (1.181) or (1.194). For very large and sparse matrices, an important class of algorithms (of which ART is an example) is called *row-action methods*. The distinguishing features of these methods are that they do not make any modifications to the original matrix (unlike Gaussian elimination, for example), that they require access to only a single row of the matrix at a time, and that, when a new iterate $\hat{\mathbf{f}}^{(k+1)}$ is computed, only the immediately preceding iterate $\hat{\mathbf{f}}^{(k)}$ is required. For a comprehensive survey of row-action algorithms, see Censor (1981).

1.8 REPRODUCING-KERNEL HILBERT SPACE

We close this chapter with a discussion of a kind of vector space called a *reproducing-kernel Hilbert space*, which is particularly useful for representing functions that are smooth in some sense. Since smooth functions are very important in imaging applications, reproducing-kernel Hilbert spaces will arise in many different contexts in this book.

A formal definition of a reproducing-kernel Hilbert space is that it is a function space in which each function can be evaluated at a point by use of a bounded linear functional (Weinert, 1983; Wahba, 1990; Daubechies, 1992; Zayed, 1993). Our most familiar function space, $\mathbb{L}_2(\mathbf{R})$, does not have this property since it contains discontinuous or even mildly singular functions. In fact, functions in $\mathbb{L}_2(\mathbf{R})$ are not necessarily even defined pointwise. There are, however, many ways to select a subspace of $\mathbb{L}_2(\mathbf{R})$ that is a reproducing-kernel Hilbert space.

By the Riesz representation theorem (1.24), a bounded linear functional can be written as a scalar product. Thus, in a reproducing-kernel Hilbert space there exists a vector $\mathbf{h}(x')$ such that, for all \mathbf{f} in the space,

$$(\mathbf{h}(x'), \mathbf{f})_{rk} = f(x') , \quad (1.242)$$

where $(\cdot, \cdot)_{rk}$ denotes a scalar product in the space. Here $\mathbf{h}(x')$ and \mathbf{f} are both vectors in the space, though $\mathbf{h}(x')$ is characterized by the scalar parameter x' . Any vector in a function space can be identified with a function; in (1.242), \mathbf{f} is identified with $f(x)$ and $\mathbf{h}(x')$ is identified with the function of x denoted $h(x, x')$, with x' regarded as a fixed parameter. To fully specify the reproducing-kernel Hilbert space, we must define the scalar product and find the kernel $h(x, x')$ such that (1.242) is satisfied.

1.8.1 Positive-definite Hermitian operators

We can start with a compact, positive-definite Hermitian operator \mathcal{A} on $\mathbb{L}_2(\mathbf{R})$ and use it to identify the subspace of $\mathbb{L}_2(\mathbf{R})$ that constitutes a reproducing-kernel Hilbert space related to the operator. Since \mathcal{A} is compact, it satisfies an eigenvalue equation like (1.67) with a discrete spectrum $\{\lambda_n, n = 1, \dots, \infty\}$, and the eigenvectors $\{\psi_n\}$ form an orthonormal basis in $\mathbb{L}_2(\mathbf{R})$. Thus any vector \mathbf{f} in $\mathbb{L}_2(\mathbf{R})$ can be expressed as [cf. (1.63)]

$$\mathbf{f} = \sum_{n=1}^{\infty} \alpha_n \psi_n, \quad \alpha_n = \psi_n^\dagger \mathbf{f}. \quad (1.243)$$

An equivalent representation of \mathbf{f} as a function rather than as an abstract vector is

$$f(x) = \sum_{n=1}^{\infty} \alpha_n \psi_n(x), \quad \alpha_n = \int_{-\infty}^{\infty} dx \psi_n^*(x) f(x). \quad (1.244)$$

The \mathbb{L}_2 norm of \mathbf{f} is

$$\|\mathbf{f}\|_2 = \left[\sum_{n=1}^{\infty} |\alpha_n|^2 \right]^{\frac{1}{2}} = \left[\sum_{n=1}^{\infty} \left| \int_{-\infty}^{\infty} dx \psi_n^*(x) f(x) \right|^2 \right]^{\frac{1}{2}} = \left[\int_{-\infty}^{\infty} dx |f(x)|^2 \right]^{\frac{1}{2}}, \quad (1.245)$$

where the last step follows from (1.62) with the recognition that the unit operator in \mathbb{L}_2 has the kernel $\delta(x - x')$.

To construct a reproducing-kernel Hilbert space associated with \mathcal{A} , we define the norm in the space as

$$\|\mathbf{f}\|_{rk}^2 = \sum_{n=1}^{\infty} \frac{1}{\lambda_n} |\alpha_n|^2. \quad (1.246)$$

Since we have assumed that \mathcal{A} is positive-definite, none of the eigenvalues is zero for finite n , but they may approach zero rapidly as $n \rightarrow \infty$. It is possible for the sum in (1.246) to diverge if $|\alpha_n|^2$ falls off more slowly with increasing n than λ_n does. A vector \mathbf{f} (or equivalently, a function $f(x)$) is said to be in this reproducing-kernel Hilbert space if $\|\mathbf{f}\|_{rk}$ is finite.

For a normed space to be a Hilbert space, the norm must be derivable from a scalar product. A suitable definition of scalar product is

$$(\mathbf{f}_1, \mathbf{f}_2)_{rk} = (\mathbf{f}_1, \mathcal{A}^{-1} \mathbf{f}_2)_2 = (\mathcal{A}^{-1} \mathbf{f}_1, \mathbf{f}_2)_2, \quad (1.247)$$

where $(\cdot, \cdot)_2$ denotes the \mathbb{L}_2 scalar product. The equality of the two \mathbb{L}_2 scalar products in (1.247) holds because \mathcal{A}^{-1} is a Hermitian operator in \mathbb{L}_2 .

With (1.87), it is straightforward to show that the norm (1.246) is compatible with the scalar product (1.247) in the sense that

$$\|\mathbf{f}\|_{rk}^2 = (\mathbf{f}, \mathbf{f})_{rk}. \quad (1.248)$$

The kernel for this reproducing-kernel Hilbert space is simply the kernel of \mathcal{A} when it is expressed as an integral operator. Combining (1.25) and (1.86), we find

$$\begin{aligned} [\mathcal{A}\mathbf{f}](x) &= \int_{-\infty}^{\infty} dx' h(x, x') f(x') = \sum_{n=1}^{\infty} \lambda_n (\boldsymbol{\psi}_n, \mathbf{f}) \boldsymbol{\psi}_n(x) \\ &= \int_{-\infty}^{\infty} dx' \left[\sum_{n=1}^{\infty} \lambda_n \boldsymbol{\psi}_n(x) \boldsymbol{\psi}_n^*(x') \right] f(x'). \end{aligned} \quad (1.249)$$

Hence,

$$h(x, x') = \sum_{n=1}^{\infty} \lambda_n \boldsymbol{\psi}_n(x) \boldsymbol{\psi}_n^*(x'), \quad (1.250)$$

which is the functional counterpart of the spectral decomposition (1.86). The corresponding vector in the reproducing-kernel Hilbert space is given by

$$\mathbf{h}(x') = \sum_{n=1}^{\infty} [\lambda_n \boldsymbol{\psi}_n^*(x')] \boldsymbol{\psi}_n, \quad (1.251)$$

where the quantity in square brackets is the expansion coefficient.

Next consider the scalar product, defined as in (1.247), between $\mathbf{h}(x')$ and an arbitrary \mathbf{f} in the reproducing-kernel space. We have

$$(\mathbf{h}(x'), \mathbf{f})_{rk} = (\mathcal{A}^{-1} \mathbf{h}(x'), \mathbf{f})_2. \quad (1.252)$$

But, from (1.87), (1.89) and (1.251), we find

$$\mathcal{A}^{-1} \mathbf{h}(x') = \sum_{n=1}^{\infty} \boldsymbol{\psi}_n^*(x') \boldsymbol{\psi}_n. \quad (1.253)$$

After some algebra of the sort that by now should be standard, we find

$$(\mathbf{h}(x'), \mathbf{f})_{rk} = f(x'), \quad (1.254)$$

so (1.242) is satisfied.

1.8.2 Nonnegative-definite Hermitian operators

So far, we have considered reproducing-kernel Hilbert spaces based on positive-definite operators, but (1.250) and (1.251) suggest a more general approach. Consider an operator \mathcal{B} defined by

$$\mathcal{B} = \sum_{n=1}^N \mu_n \mathbf{u}_n \mathbf{u}_n^\dagger, \quad (1.255)$$

where $\{\mathbf{u}_n, n = 1, \dots, N\}$ is any orthonormal set in $\mathbb{L}_2(\mathbb{R})$ and $\{\mu_n\}$ is any set of positive real numbers. The operator \mathbf{B} constructed in this way is nonnegative-definite and Hermitian. Since N is not infinite, however, \mathbf{B} is singular in $\mathbb{L}_2(\mathbb{R})$. For the same reason, $\{\mathbf{u}_n\}$ is not a basis in $\mathbb{L}_2(\mathbb{R})$.

The reproducing-kernel Hilbert space associated with this operator is the ND subspace of $\mathbb{L}_2(\mathbb{R})$ spanned by $\{\mathbf{u}_n, n = 1, \dots, N\}$. Any vector in this space can be represented as

$$\mathbf{f} = \sum_{n=1}^N \beta_n \mathbf{u}_n, \quad \beta_n = \mathbf{u}_n^\dagger \mathbf{f}. \quad (1.256)$$

The norm is now defined by

$$\|\mathbf{f}\|_{rk}^2 = \sum_{n=1}^N \frac{1}{\mu_n} |\beta_n|^2. \quad (1.257)$$

None of the factors $|\beta_n|^2$ can be infinite since \mathbf{f} is also in $\mathbb{L}_2(\mathbb{R})$, none of the μ_n is zero by definition, and there is a finite number of terms, so the norm in (1.257) is finite for any \mathbf{f} in the space.

The corresponding scalar product is given by

$$(\mathbf{f}_1, \mathbf{f}_2)_{rk} = \sum_{n=1}^N \frac{1}{\mu_n} \beta_{1n}^* \beta_{2n}, \quad (1.258)$$

where β_{1n} and β_{2n} are expansion coefficients for \mathbf{f}_1 and \mathbf{f}_2 , respectively. The rk scalar product can be related to an \mathbb{L}_2 scalar product by (Helstrom, 1995)

$$(\mathbf{f}_1, \mathbf{f}_2)_{rk} = (\mathbf{f}_1, \tilde{\mathbf{f}}_2)_2, \quad (1.259)$$

where $\tilde{\mathbf{f}}_2$ is any vector in $\mathbb{L}_2(\mathbb{R})$ related to \mathbf{f}_2 by

$$\mathbf{f}_2 = \mathbf{B} \tilde{\mathbf{f}}_2. \quad (1.260)$$

Since \mathbf{B} is singular in $\mathbb{L}_2(\mathbb{R})$, there will be an infinity of vectors in that space that can serve as $\tilde{\mathbf{f}}_2$; it does not matter which we choose since the scalar product of $\mathbf{B} \tilde{\mathbf{f}}_2$ with an \mathbf{f}_1 in the span of $\{\mathbf{u}_n\}$ will not be affected by null vectors of \mathbf{B} in $\tilde{\mathbf{f}}_2$.

The reproducing kernel of the space associated with \mathbf{B} is given by

$$h(x, x') = \sum_{n=1}^N \mu_n u_n(x) u_n^*(x'). \quad (1.261)$$

The relations in (1.258)–(1.261) agree with those given earlier if $N \rightarrow \infty$ and \mathbf{B} is nonsingular.

An important special case of (1.258)–(1.261) is where N is finite and all $\mu_n = 1$. In this case, \mathbf{B} is the projector on the ND subspace spanned by $\{\mathbf{u}_n, n = 1, \dots, N\}$ and the reproducing kernel is the kernel of the projection operator.

Table 1.1 SVD Representations of Vectors

$$\mathbf{f} = \sum_{n=1}^N \alpha_n \mathbf{u}_n, \quad \alpha_n = \mathbf{u}_n^\dagger \mathbf{f}$$

$$\hat{\mathbf{f}} = \sum_{n=1}^N \hat{\alpha}_n \mathbf{u}_n, \quad \hat{\alpha}_n = \mathbf{u}_n^\dagger \hat{\mathbf{f}}$$

$$\mathbf{g} = \sum_{k=1}^M \beta_k \mathbf{v}_k, \quad \beta_k = \mathbf{v}_k^\dagger \mathbf{g}$$

$$\boldsymbol{\epsilon} = \sum_{k=1}^M \gamma_k \mathbf{v}_k, \quad \gamma_k = \mathbf{v}_k^\dagger \boldsymbol{\epsilon}$$

$$\mathbf{v}_n = \frac{1}{\sqrt{\mu_n}} \mathcal{H} \mathbf{u}_n, \quad (\mu_n \neq 0)$$

$$\mathbf{f}_{meas} = \sum_{n=1}^R \alpha_n \mathbf{u}_n, \quad \mathbf{f}_{null} = \sum_{n=R+1}^N \alpha_n \mathbf{u}_n$$

(where $\mathbf{f} \equiv \mathbf{f}_{meas} + \mathbf{f}_{null}$ and $\mathcal{H} \mathbf{f}_{null} \equiv \mathbf{0}$)

$$\mathbf{g}_{con} = \sum_{k=1}^R \beta_k \mathbf{v}_k, \quad \mathbf{g}_{incon} = \sum_{k=R+1}^M \beta_k \mathbf{v}_k$$

(where $\mathbf{g} \equiv \mathbf{g}_{con} + \mathbf{g}_{incon}$ and $\mathcal{H}^\dagger \mathbf{g}_{incon} \equiv \mathbf{0}$)

Table 1.2 SVD Representations of Operators

$\mathcal{H}^\dagger \mathcal{H} = \sum_{k=1}^R \mu_k \mathbf{u}_k \mathbf{u}_k^\dagger$	$\mathcal{H} \mathcal{H}^\dagger = \sum_{k=1}^R \mu_k \mathbf{v}_k \mathbf{v}_k^\dagger$
$\mathcal{H} = \sum_{k=1}^R \sqrt{\mu_k} \mathbf{v}_k \mathbf{u}_k^\dagger$	$\mathcal{H}^\dagger = \sum_{k=1}^R \sqrt{\mu_k} \mathbf{u}_k \mathbf{v}_k^\dagger$
$[\mathcal{H}^\dagger \mathcal{H}]^{-1} = \sum_{k=1}^N \frac{1}{\mu_k} \mathbf{u}_k \mathbf{u}_k^\dagger$	(provided $N = R$)
$[\mathcal{H} \mathcal{H}^\dagger]^{-1} = \sum_{k=1}^M \frac{1}{\mu_k} \mathbf{v}_k \mathbf{v}_k^\dagger$	(provided $M = R$)

$\mathcal{I}_U = \sum_{k=1}^N \mathbf{u}_k \mathbf{u}_k^\dagger$	(Identity operator in \mathbb{U})
$\mathcal{P}_{null} = \mathcal{I}_U - \mathcal{H}^+ \mathcal{H} = \sum_{k=R+1}^N \mathbf{u}_k \mathbf{u}_k^\dagger$	(Projector of \mathbf{f} onto null space)
$\mathcal{P}_{con} = \mathcal{H} \mathcal{H}^+ = \sum_{k=1}^R \mathbf{v}_k \mathbf{v}_k^\dagger$	(Projector of \mathbf{g} onto consistency space)
$\mathcal{I}_V = \sum_{k=1}^M \mathbf{v}_k \mathbf{v}_k^\dagger$	(Identity operator in \mathbb{V})
$\mathcal{P}_{incon} = \mathcal{I}_V - \mathcal{H} \mathcal{H}^+ = \sum_{k=R+1}^M \mathbf{v}_k \mathbf{v}_k^\dagger$	(Projector of \mathbf{g} onto inconsistency space)

2

Dirac Delta and Other Generalized Functions

Optical imaging systems are often experimentally characterized by imaging a small, bright light source. If the dimensions of this source are much smaller than the spatial resolution capability of the imaging system, the object is essentially a mathematical point. Such an object is called a *point source*, and its image is the *point spread function* or PSF of the system. A more general source can be decomposed into a collection of points; if the system is linear, the response to the general object is obtained by adding up the responses to the individual points.

The mathematical construct that corresponds to a physical point source is the *delta function*, introduced by P. A. M. Dirac in quantum mechanics. There are three basic ways of defining a delta function. The first is an intuitive approach, where we simply postulate a function that is zero except at a single point, but infinite at that point in such a way that the integral of the function is constrained to be unity. A second, somewhat better approach is to consider a sequence of well-behaved functions, all of which integrate to unity. The width of these functions tends to zero and the amplitude tends to infinity in order to hold the integral constant. The delta function is defined as the limit of this sequence.

Both of these approaches leave many mathematical questions unanswered. They do not make it clear just when the definition is valid or how the delta function can legitimately be manipulated in practice. The third approach, which puts the delta function on a firmer mathematical footing, requires the *theory of distributions*, originally developed by Laurent Schwartz (1950). We give a brief summary of this theory in the next section, but then make use of all three approaches to delta functions in what follows. The hope is that this strategy will allow delta functions to be understood at several different levels of rigor. The reader who is content with a less rigorous development can jump to Sec. 2.2 without loss of continuity.

2.1 THEORY OF DISTRIBUTIONS

2.1.1 Basic concepts

In brief, a distribution is a linear, continuous functional that maps a function $t(x)$ to a real or complex number. For simplicity, we assume initially that $t(x)$ is a real, scalar-valued function of a single real variable x . We have seen in Chap. 1 that the general form of a bounded, continuous, linear functional on a Hilbert space is given by the Riesz representation theorem, (1.24), as

$$\Phi\{t(x)\} = \int_{-\infty}^{\infty} dx g(x)t(x), \quad (2.1)$$

where $g(x)$, known as the kernel of the functional, must lie in the Hilbert space (Gohberg and Goldberg, 1981, p. 61). If the Hilbert space is \mathbb{L}_2 , $g(x)$ must be square-integrable.

If we give up on the requirement that the kernel lie in a Hilbert space, we can define a wider class of functionals known as distributions. When we do so, we shall always write the distribution in the Riesz form, like (2.1), but then $g(x)$ need not be a square-integrable function or even a function at all in the conventional sense. All we have to do is specify the mapping rule of the functional, and that, in turn, will give meaning to the kernel function, which we then term a *generalized function*.

As a simple example, consider the function $g(x) = 1/x$. We might be tempted to define a functional using this kernel as

$$\Phi_{1/x}\{t(x)\} = \int_{-\infty}^{\infty} dx \frac{t(x)}{x}, \quad (2.2)$$

but this integral is not well defined (unless $t(0) = 0$) because of the singularity at $x = 0$. Converting the integral to a contour integral in the complex plane, we have three options in dealing with this pole. We can indent the contour above the pole, indent it below the pole, or take the Cauchy principal value (see App. B) at the singularity. Since these three options can lead to three different numerical values for the integral, we must make an arbitrary choice. In some practical applications, the physics of the situation dictates the use of the Cauchy principal value, and in that case it is useful to define a functional by

$$\Phi_{1/x}\{t(x)\} = \lim_{\epsilon \rightarrow 0} \left\{ \int_{-\infty}^{-\epsilon} dx \frac{t(x)}{x} + \int_{\epsilon}^{\infty} dx \frac{t(x)}{x} \right\}. \quad (2.3)$$

Now we have a clearly specified functional, provided that $t(x)$ is sufficiently well behaved that the limit exists. This functional gives meaning to the generalized function $\mathcal{P}\{1/x\}$, where \mathcal{P} denotes the Cauchy principal value, and we can write

$$\Phi_{1/x}\{t(x)\} \equiv \int_{-\infty}^{\infty} dx t(x) \mathcal{P} \left\{ \frac{1}{x} \right\}, \quad (2.4)$$

where the right-hand side must be interpreted according to (2.3). We have thus succeeded in defining a distribution and, simultaneously, a generalized function. It is important to note, however, that the generalized function is defined only by its

action within an integral, and then only when certain restrictions are replaced on the function $t(x)$ that appears in the integrand.

One caution regarding terminology: The distinction between a distribution (a functional) and its kernel (a generalized function) is often blurred. For example, it is often said that a delta function is a distribution. What this means is that the delta function is a generalized function that can be used as the kernel in a functional.

2.1.2 Well-behaved functions

As the example above shows, definition of a distribution as a functional places some restrictions on the functions in the domain of the functional. For the distribution associated with $\mathcal{P}\{1/x\}$, the requirement on $t(x)$ is that the limit in (2.3) exist.

Different kinds of distribution require different properties for the functions $t(x)$. The strongest requirements are that the nonzero values of $t(x)$ be confined to a finite interval $a < x < b$ and that the function and all of its derivatives be bounded and continuous within this region. If these conditions are satisfied, we say that $t(x)$ is infinitely differentiable and has compact support. Such functions are called *test functions*. The space of all test functions with support (a, b) will be denoted by $\mathbb{T}(a, b)$. Because $t(x)$ is bounded and has compact support, it necessarily lies in $\mathbb{L}_2(a, b)$, but not all functions in $\mathbb{L}_2(a, b)$ are test functions, so $\mathbb{T}(a, b)$ is a subspace of $\mathbb{L}_2(a, b)$.

It is actually fairly difficult to construct test functions since infinitely differentiable functions such as polynomials or Gaussians tend not to have compact support. One way to form test functions meeting the necessary conditions is to use as a building block the function $h(x)$ defined by (Richards and Youn, 1990)

$$h(x) = \begin{cases} \exp(-1/x) & \text{if } x > 0 \\ 0 & \text{if } x \leq 0 \end{cases}, \quad (2.5)$$

which is plotted in Fig. 2.1a. It is not difficult to show that all derivatives of this function exist everywhere, even at the transition point $x = 0$.

Amusingly, in the theory of functions of a complex variable, $\exp(-1/z)$ is the archetype of a function that has an essential singularity (see App. B). Within an arbitrarily small radius of the origin in the complex plane, $\exp(-1/z)$ takes on all finite values an infinite number of times. The complex function $\exp(-1/z)$ is as ill-behaved as a function can be, while the real function $\exp(-1/x)$ is the paragon of good behavior.

By use of $h(x)$ we can construct a test function on (a, b) as

$$t(x) = h\left(\frac{x-a}{b-a}\right) h\left(\frac{b-x}{b-a}\right). \quad (2.6)$$

As required, this function vanishes unless x is in the interval (a, b) , and it is infinitely differentiable within this interval (see Fig. 2.1b). More general test functions can be constructed by superimposing shifted and scaled versions of the function defined by (2.5) (see Richards and Youn, 1990, Chap. 1).

Fig. 2.1 (a) Plot of the building-block function $h(x)$ from (2.5); (b) plot of the test function $t(x)$ from (2.6), with $(a, b) = (-4, 4)$.

The requirement of compact support is often onerous, and it is useful to define distributions based on infinitely differentiable functions without compact support. Following Lighthill (1958), we define a *good function* as one that is everywhere differentiable any number of times and such that it and all of its derivatives vanish faster than $|x|^{-N}$ for all N as $x \rightarrow \pm\infty$. In other words, $t(x)$ is a good function if all derivatives exist and

$$\lim_{x \rightarrow \pm\infty} \{|x|^N t(x)\} = 0 \quad \text{for all } N. \quad (2.7)$$

An example of a good function is the Gaussian $\exp(-\pi x^2)$. Good functions are also called *open-support test functions* (Richards and Youn, 1990) or Schwartz functions (Strichartz, 1994). The space of all good functions is often called *Schwartz space*.

A *fairly good function* (Lighthill, 1958) is infinitely differentiable but may be unbounded as $x \rightarrow \pm\infty$. The requirement is that it must not blow up faster than some power of x . Specifically, $t(x)$ is a fairly good function if

$$\lim_{x \rightarrow \pm\infty} \{|x|^{-N} t(x)\} = 0 \quad \text{for some } N. \quad (2.8)$$

Any polynomial is a fairly good function, since it is infinitely differentiable and (2.8) is satisfied for N greater than the degree of the polynomial, but $\exp(x)$ is not a fairly good function. Fairly good functions are also called *test functions of slow growth*.

2.1.3 Approximation of other functions

Many functions of practical interest do not fit into any of the categories of well-behaved functions defined above. In optics, for example, the transmission of light through a rectangular slit is described by the *rect function*, defined by

$$\text{rect}\left(\frac{x}{L}\right) \equiv \begin{cases} 1 & \text{if } |x| < L/2 \\ 0 & \text{if } |x| > L/2 \end{cases}. \quad (2.9)$$

This function has compact support but is not continuous at $x = \pm L/2$, so it is not a test function. As another example, the *Heaviside unit step function*, defined by

$$\text{step}(x) \equiv \begin{cases} 1 & \text{if } x > 0 \\ 0 & \text{if } x < 0 \end{cases}, \quad (2.10)$$

satisfies (2.8) but is not differentiable at $x = 0$, so it is not a fairly good function.

Nevertheless, these and other functions of practical importance can be approximated arbitrarily closely by test functions or good functions, depending on their behavior at infinity, so the restrictions of differentiability are not so demanding as might appear (Zemanian, 1965, p. 3, 1987).

To illustrate this point, we note that the building-block function $h(kx)$ is a fairly good function for all k . (In fact, it is the best of the fairly good functions since it remains bounded at infinity.) In terms of this function,

$$\text{step}(x) = \lim_{k \rightarrow \infty} h(kx), \quad (2.11)$$

as illustrated in Fig. 2.2. The limit implies uniform convergence, which means that the maximum value of the difference between $h(kx)$ and $\text{step}(x)$ tends to zero:

$$\lim_{k \rightarrow \infty} \max_x |\text{step}(x) - h(kx)| = 0 \quad \text{for all } x, \quad (2.12)$$

except possibly at the isolated point $x = 0$, where the step function has been deliberately left undefined. The technical term is that it *converges uniformly almost everywhere*. The proof of this result is elementary, but see Sec. 2.3.2 for some cautions about using it.

Fig. 2.2 Plot of the limiting representation of a step function from (2.11); The four curves are for $k = 0, 3, 10$ and 30 .

A test function approximating $\text{rect}(x/L)$ can also be obtained from $h(x)$:

$$\text{rect}\left(\frac{x}{L}\right) = \lim_{k \rightarrow \infty} h\left[k\left(x - \frac{L}{2}\right)\right] h\left[-k\left(x + \frac{L}{2}\right)\right]. \quad (2.13)$$

This function vanishes identically unless $-L/2 < x < L/2$, and it is infinitely differentiable inside that interval, so it qualifies as a test function. Again, the representation converges uniformly to $\text{rect}(x/L)$ except at the isolated points $x = \pm L/2$.

A general procedure for approximating integrable functions by good functions will be given in Sec. 2.2.5.

2.1.4 Formal definition of distributions

In order to define distributions, we must first define the notion of convergence of test functions, which is stronger than the uniform convergence used above. Our development follows Richards and Youn (1990).

A sequence of test functions $\{t_n(x)\}$ is said to converge to a specific test function $t(x)$ as $n \rightarrow \infty$ if:

- (a) The functions $t(x)$ and all of the $t_n(x)$ have a common region of support (a, b) ;
- (b) For each k , the sequence of k^{th} derivatives $\{t_n^{(k)}(x)\}$ converges to $t^{(k)}(x)$.

A distribution Φ is defined as a linear, continuous mapping from the space \mathbb{T} of test functions to the real or complex numbers. Linearity and continuity are defined in Sec. 1.3.2 of Chap. 1; their interpretation in the present notation is:

- (a) (Linearity) $\Phi\{\alpha s(x) + \beta t(x)\} = \alpha\Phi\{s(x)\} + \beta\Phi\{t(x)\}$ for all test functions $s(x)$ and $t(x)$ and all constants α and β ;
- (b) (Continuity) If $t_n(x) \rightarrow t(x)$ in the sense defined above, then $\Phi\{t_n(x)\} \rightarrow \Phi\{t(x)\}$.

The continuity condition will allow us to interchange distribution operations and limits at will; the interchange is valid *by definition*.

A specific, if not very interesting, distribution is the one defined by an ordinary function. If $f(x)$ is a piecewise-continuous function on the real line, it defines a distribution Φ_f given by

$$\Phi_f\{t(x)\} = \int_{-\infty}^{\infty} dx f(x) t(x). \quad (2.14)$$

It is easy to demonstrate that this distribution satisfies the requirements of linearity and continuity.

2.1.5 Properties of distributions

In this section we give several important properties of distributions. The proofs can be found in Messiah (1961) or Richards and Youn (1990).

The linear combination of two distributions is a distribution. If Φ_1 and Φ_2 are distributions, $\Phi = \alpha\Phi_1 + \beta\Phi_2$ is a distribution defined such that

$$\Phi\{t(x)\} = \alpha\Phi_1\{t(x)\} + \beta\Phi_2\{t(x)\}. \quad (2.15)$$

It follows from this definition that the product of a generalized function and a constant behaves just as one would expect from (2.1). When the product is used in an integral, we can simply take the constant out of the integral.

As an extension of (2.15), if the infinite series $\sum_i \Phi_i\{t(x)\}$ is summable, its sum defines a distribution.

Integrals of distributions can also be defined. If Φ_λ is a distribution that depends on a parameter λ that can vary continuously in some domain Λ , and if the integral

$$I\{t(x)\} = \int_{\Lambda} \Phi_\lambda\{t(x)\} d\lambda \quad (2.16)$$

converges for all test functions $t(x)$, then it defines a distribution (Messiah, 1961) I given by

$$I = \int_{\Lambda} \Phi_\lambda d\lambda. \quad (2.17)$$

Derivatives of distributions (or, more correctly, derivative distributions) can be defined by analogy with the familiar operation of integration by parts. If Φ_g is a distribution corresponding to the kernel $g(x)$, which may be an ordinary function or a generalized one, then a distribution $\Phi_{g'}$, where prime denotes derivative, can be defined by

$$\Phi_{g'}\{t(x)\} \equiv -\Phi_g\left\{\frac{dt(x)}{dx}\right\} = -\int_{-\infty}^{\infty} dx g(x) \frac{dt(x)}{dx} = \int_{-\infty}^{\infty} dx g'(x) t(x). \quad (2.18)$$

If $g(x)$ is an ordinary differentiable function, then (2.18) is simply a statement of integration by parts. If $g(x)$ is a generalized function, the last form in this equation can be regarded as a definition of the new generalized function $g'(x)$. It is straightforward to verify that the definition in (2.18) satisfies the requirements of linearity and continuity, so we have indeed defined a legitimate distribution.

Next we inquire about the product of two generalized functions. Suppose the kernel $g(x) = f(x)h(x)$, where $f(x)$ or $h(x)$ or both may be generalized functions. The distribution Φ_g corresponding to $g(x)$ does not necessarily exist, and there are only a few conditions where we can be sure that it does (Messiah, 1961). If $f(x)$ has derivatives of all orders, then Φ_g exists for all $h(x)$. This statement can easily be proven by noting that $f(x)t(x)$ is a test function in that case. Another case where the product distribution is guaranteed to exist is when both $f(x)$ and $h(x)$ are square-integrable functions, since in that case the product kernel is also square-integrable and the Riesz representation theorem applies. With these exceptions, however, we cannot be sure that products of generalized functions (or, loosely, products of distributions) make any sense. For example, we shall see that the square of a delta function is not defined.

2.1.6 Tempered distributions

Tempered distributions are defined exactly as other distributions except that the conditions on the test functions are relaxed. In particular, we require infinite differentiability but not compact support. Thus *tempered distributions are continuous, linear functionals acting on good functions* as defined above. Moreover, it will be useful to allow the number returned by the functional to be complex, so a tempered distribution is a mapping from the space of good functions to \mathbb{C}^1 .

Tempered distributions are a subset of all distributions. Since a tempered distribution is well defined for differentiable functions of open support, it is also well defined for test functions with compact support. Thus a tempered distribution

is a distribution, but not all distributions are tempered distributions. All of the distributions discussed in this chapter are, however, tempered distributions.

The main motivation for introducing tempered distributions is in connection with Fourier theory, as explored further in the next chapter. A wide variety of other distributions, based on other kinds of test functions, can also be defined (Zemanian, 1965, 1987), but we shall not need them.

2.2 ONE-DIMENSIONAL DELTA FUNCTION

2.2.1 Intuitive definition and elementary properties

As noted in the introduction, the simplest — and least rigorous — approach to defining the delta function is simply to require it to vanish everywhere except at a single point, say $x = x_0$:

$$\delta(x - x_0) = 0 \quad \text{if } x \neq x_0. \quad (2.19)$$

If this function were to be finite at $x = x_0$, its integral would vanish, no matter how the integral was defined. Thus, for $\delta(x - x_0)$ to have nontrivial properties, it must be infinite at x_0 , or at least in an infinitesimal neighborhood around x_0 . We require that this infinity be such that the integral of the function is unity, *i.e.*,

$$\int_{-\infty}^{\infty} dx \delta(x - x_0) = 1. \quad (2.20)$$

Because of (2.19), we also have

$$\int_{x_0 - \epsilon}^{x_0 + \epsilon} dx \delta(x - x_0) = 1, \quad (2.21)$$

where ϵ is any finite positive number.

A number of elementary properties follow from these equations (Gaskill, 1978; Barrett and Swindell, 1981, 1996). The most important is the so-called *sifting property* which arises when the delta function $\delta(x - x_0)$ is multiplied by another function $f(x)$ in the integrand of an integral. Since the delta function is zero for $x \neq x_0$, the behavior of $f(x)$ for $x \neq x_0$ is irrelevant. We can thus write

$$\int_{-\infty}^{\infty} dx f(x) \delta(x - x_0) = \int_{x_0 - \epsilon}^{x_0 + \epsilon} dx f(x) \delta(x - x_0), \quad (2.22)$$

where ϵ is arbitrarily small. Then, if $f(x)$ is continuous at x_0 , it does not vary over the range of integration in the limit as ϵ approaches zero, and we can replace it by $f(x_0)$, obtaining

$$\begin{aligned} \int_{-\infty}^{\infty} dx f(x) \delta(x - x_0) &= \lim_{\epsilon \rightarrow 0} \int_{x_0 - \epsilon}^{x_0 + \epsilon} dx f(x) \delta(x - x_0) \\ &= f(x_0) \lim_{\epsilon \rightarrow 0} \int_{x_0 - \epsilon}^{x_0 + \epsilon} dx \delta(x - x_0) = f(x_0). \end{aligned} \quad (2.23)$$

This result is called the *sifting property* because integration of $f(x) \delta(x - x_0)$ sifts out the value of $f(x)$ at $x = x_0$. A more general statement of the property is that

$$\int_a^b dx f(x) \delta(x - x_0) = \begin{cases} f(x_0) & \text{if } a < x_0 < b \\ 0 & \text{if } x_0 < a \text{ or } x_0 > b \end{cases}. \quad (2.24)$$

Another way to state the same property is to write

$$f(x) \delta(x - x_0) = f(x_0) \delta(x - x_0), \quad (2.25)$$

which is true in the sense that both sides of the equation yield the same result when integrated over an arbitrary interval (a, b) . A special case of (2.25) is

$$x \delta(x) = 0. \quad (2.26)$$

Additional properties may be derived by simple changes of variable in (2.24). Letting $x' = -x$ and setting x_0 to zero shows that

$$\delta(x) = \delta(-x). \quad (2.27)$$

Thus the delta function is an inherently even function. Similarly, the transformation $x' = ax$, where a is a real constant, leads to

$$\delta(ax - x_0) = |a|^{-1} \delta(x - x_0/a) \quad (2.28)$$

and the special case

$$\delta(ax) = |a|^{-1} \delta(x). \quad (2.29)$$

In these equations, the absolute value arises since the direction of integration is reversed if a is negative.

Now suppose the argument of a delta function is itself a function, as in $\delta[g(x)]$. This delta function is zero except where its argument vanishes. Suppose that

$$g(x) = 0 \text{ at } x = x_n, \quad n = 1, \dots, N. \quad (2.30)$$

Then $\delta[g(x)] = 0$ unless $x = x_n$ and we can write

$$\int_{-\infty}^{\infty} dx f(x) \delta[g(x)] = \sum_{n=1}^N \int_{x_n-\epsilon}^{x_n+\epsilon} dx f(x) \delta[g(x)]. \quad (2.31)$$

If $g(x)$ is differentiable at the points x_n , we can expand it in a Taylor series about that point. By definition, $g(x_n) = 0$, and we shall assume that the first derivative $g'(x_n) \neq 0$. Since ϵ is arbitrarily small, all higher terms in the Taylor series can be neglected without approximation. We thus have

$$\begin{aligned} \int_{-\infty}^{\infty} dx f(x) \delta[g(x)] &= \sum_{n=1}^N \int_{x_n-\epsilon}^{x_n+\epsilon} dx f(x) \delta[g'(x_n)(x - x_n)] \\ &= \sum_{n=1}^N \frac{1}{|g'(x_n)|} \int_{x_n-\epsilon}^{x_n+\epsilon} dx f(x) \delta(x - x_n) = \sum_{n=1}^N \frac{f(x_n)}{|g'(x_n)|}, \end{aligned} \quad (2.32)$$

where we have used (2.29), recognizing that $g'(x_n)$ is a constant. This result can be summarized succinctly as

$$\delta[g(x)] = \sum_{n=1}^N \frac{\delta(x - x_n)}{|g'(x_n)|}. \quad (2.33)$$

Again, the sense of this equation, as with all equations involving delta functions, is that it is true when both sides are multiplied by a suitable function and integrated over some interval.

2.2.2 Limiting representations

The delta function can be put on a somewhat more rigorous footing if it is defined as the limit of an ordinary function. We define a *Dirac sequence*¹ as a set of functions $\psi_k(x)$ with the following properties:

- (a) $\psi_k(x) \geq 0$ for all k ;
- (b) $\psi_k(x) = \psi_k(-x)$ for all k ;
- (c) $\int_{-\infty}^{\infty} dx \psi_k(x) = 1$ for all k ;
- (d) The width of $\psi_k(x)$ decreases uniformly with increasing k .

This set of requirements follows Lang (1993, pp. 227–228), except that he does not include property (b), so his results are more general. Other authors omit property (a), and we shall also relax it eventually.

The width in property (d) is defined in terms of the integral of ψ_k over a finite interval. By property (c), if the function is integrated over $(-\infty, \infty)$, the result is unity. If it is integrated over an interval $(-\beta, \beta)$, where $0 < \beta < \infty$, the result is $1 - \epsilon$, where $0 \leq \epsilon \leq 1$. The value ϵ is the fraction of the integral contributed by the part of ψ_k that lies outside $(-\beta, \beta)$, and 2β is the width of ψ_k at level ϵ as defined by

$$\int_{-\beta}^{\beta} dx \psi_k(x) = 1 - \epsilon. \quad (2.34)$$

The width 2β can obviously depend on both ϵ and the index k . The formal definition of width in property (d) is basically that, whatever ϵ is chosen as a reference, the resulting width 2β decreases as the index k is increased.

The key result from formal analysis that we need is that the Dirac sequence can be used to approximate a bounded, continuous function $f(x)$ arbitrarily closely. That is,

$$\lim_{k \rightarrow \infty} \int_{-\infty}^{\infty} dx f(x) \psi_k(x - x_0) = f(x_0), \quad (2.35)$$

where the limit is to be understood in the sense of uniform convergence² (Lang, 1993, p. 228). The particular form of integral in (2.35) is called a *convolution*, and we say that $f(x)$ is *convolved with* $\psi_k(x)$ in this integral. Equation (2.35) says that this convolution converges to $f(x_0)$ as $k \rightarrow \infty$ provided $\psi_k(x)$ satisfies the conditions for a Dirac sequence.

Another way to write the result of (2.35) is

$$\delta(x - x_0) = \lim_{k \rightarrow \infty} \psi_k(x - x_0), \quad (2.36)$$

by which we mean that use of the right-hand side will reproduce the sifting property, (2.24), for all $f(x)$ that are bounded and continuous at $x = x_0$.

¹The term *Dirac family* is also used, especially when k is not restricted to be an integer, but we shall not make this distinction.

²Actually the function $f(x)$ need not be continuous everywhere for (2.35) to hold. It is sufficient if it is measurable and continuous in the neighborhood of x_0 . Specifically, if $f(x)$ is in $L_p(\mathbb{R}^1)$, with $1 \leq p < \infty$, and is continuous over some range $x_0 - \epsilon < x < x_0 + \epsilon$, then the integral in (2.35) converges in the L_p sense to $f(x_0)$ (Lang, 1993, pp. 234–235).

There are many possible choices for the functions $\{\psi_k(x)\}$, and each choice yields a different limiting representation for the delta function. One choice is a sequence of Gaussians, $\psi_k(x) = k \exp(-\pi k^2 x^2)$, so that

$$\delta(x) = \lim_{k \rightarrow \infty} k \exp(-\pi k^2 x^2) = \lim_{\epsilon \rightarrow 0^+} \frac{1}{\epsilon} \exp[-\pi(x/\epsilon)^2], \quad (2.37)$$

where $\epsilon = 1/k$ [not to be confused with the ϵ in (2.34)]. This particular Dirac sequence is illustrated in Fig. 2.3.

Other choices for the $\{\psi_k\}$ yield

$$\delta(x) = \lim_{\epsilon \rightarrow 0^+} \frac{1}{\epsilon} \operatorname{rect}\left(\frac{x}{\epsilon}\right), \quad (2.38)$$

$$\delta(x) = \lim_{\epsilon \rightarrow 0^+} \frac{\epsilon/\pi}{x^2 + \epsilon^2}, \quad (2.39)$$

$$\delta(x) = \lim_{\epsilon \rightarrow 0^+} \frac{1}{2\epsilon} \exp\left(-\frac{|x|}{\epsilon}\right), \quad (2.40)$$

$$\delta(x) = \lim_{\epsilon \rightarrow 0^+} \frac{1}{2\epsilon} \operatorname{sech}^2\left(\frac{|x|}{\epsilon}\right). \quad (2.41)$$

With all of these forms, it is straightforward to show that $\delta(x) = 0$ if $x \neq 0$ and that

$$\int_{-\infty}^{\infty} dx \delta(x) = 1, \quad (2.42)$$

as required. Furthermore, for all of these examples, $\psi_k(0)$ tends to infinity, though limiting representations of the delta function can be constructed for which this is not the case (see, for example, Kanwal, 1983, pp. 10–12).

Fig. 2.3 Plot of the limiting representation of a delta function as a sequence of Gaussians from (2.37). The three curves shown are for $k = 0.5, 1.0$ and 2.0 .

A somewhat more subtle representation, which will turn out to be very useful, is based on the sinc function, defined as

$$\operatorname{sinc}(u) \equiv \frac{\sin(\pi u)}{\pi u}, \quad (2.43)$$

and plotted in Fig. 2.4. The sinc function is frequently referred to as the *Dirichlet kernel*, after the Prussian mathematician Peter Gustave Lejeune Dirichlet (1805–1859), disciple of Gauss and mentor of Riemann (Bell, 1937).

Fig. 2.4 Plot of the sinc function defined in (2.43).

We could consider a sequence of functions $\psi_k(x) = k \operatorname{sinc}(kx)$, but since the sinc function can go negative, this choice for ψ_k does not define a Dirac sequence. Nevertheless, $\psi_k(0) \rightarrow \infty$ as $k \rightarrow \infty$ and the integral of $\psi_k(x)$ over $(-\infty, \infty)$ is unity for all k , leading us to expect that the limit behaves as a delta function and that it is possible to write

$$\delta(x) = \lim_{k \rightarrow \infty} k \operatorname{sinc}(kx) = \lim_{k \rightarrow \infty} \frac{\sin(\pi kx)}{\pi x}. \quad (2.44)$$

This statement is true, in the sense that the right-hand side yields the sifting property, (2.24), if suitable restrictions are placed on the function $f(x)$ that appears in that equation. For example, it is sufficient to require that $f(x)$ be differentiable, with $f'(x)$ bounded and continuous, and $f(\pm\infty) = 0$ (Stakgold, 1967, p. 27; Kanwal, 1983, pp. 6–7). Moreover, it works for all functions in the space $\mathbb{L}_p(-\infty, \infty)$, with $1 < p < \infty$, provided the limit is interpreted as limit in the mean (see Champeney, 1987, p. 35, and Sec. 3.2.2 in Chap. 3 of this book).

Another useful way to write (2.44) is to recognize that the sinc function is the integral of an exponential, so that we also have

$$\delta(x) = \lim_{k \rightarrow \infty} \int_{-k/2}^{k/2} d\nu \exp(2\pi i \nu x). \quad (2.45)$$

We shall often write this equation in the simplified form,

$$\delta(x) = \int_{-\infty}^{\infty} d\nu \exp(2\pi i \nu x), \quad (2.46)$$

where the infinite integral is to be understood in the sense of the limit in (2.45).

A useful form akin to (2.44) is the *comb function*, defined by

$$\operatorname{comb}(x) = \lim_{N \rightarrow \infty} \frac{\sin(\pi Nx)}{\sin(\pi x)}, \quad (2.47)$$

where N is an integer that tends to ∞ . The reason for the name of this function can be discerned from Fig. 2.5. For finite N , the function has sharp peaks like teeth on a comb for all integer values of x ; as N tends to infinity, the heights of the peaks tend to infinity while the widths tend to zero. That these peaks tend to delta functions can be seen by examining the one at $x = 0$. For a small neighborhood of $x = 0$, the denominator of (2.47) is approximately πx , which is also the denominator in (2.44). Thus, for $|x| < 1/2$, $\text{comb}(x)$ is indistinguishable from $\delta(x)$. Furthermore, for integer N , $\sin(\pi Nx)/\sin(\pi x)$ is periodic with period 1, so there must be other delta peaks at all integer values of x . We can therefore write

$$\text{comb}(x) = \sum_{n=-\infty}^{\infty} \delta(x - n). \quad (2.48)$$

Another way to express the comb function is to recognize that $\sin(\pi Nx)/\sin(\pi x)$ is the sum of a geometric series:

$$\sum_{n=-M}^M \exp(2\pi inx) = \frac{\sin(\pi Nx)}{\sin(\pi x)}, \quad (2.49)$$

where $N = 2M + 1$. Thus we can write

$$\text{comb}(x) = \sum_{n=-\infty}^{\infty} \exp(2\pi inx). \quad (2.50)$$

The difference between $\text{comb}(x)$ from (2.50) and $\delta(x)$ from (2.46) is only in the appearance of the sum rather than the integral; the replacement of integral by sum results in an infinite comb of delta functions.

With any of the limiting forms discussed in this section, the various properties listed in Sec. 2.2.1 can be derived by ordinary rules for manipulating integrals.

Fig. 2.5 Plot of a representation of the comb function from (2.49).

2.2.3 Distributional approach

In Sec. 2.2.1 we simply postulated, in a very nonrigorous way, the existence of a function that vanished except for a single point and became infinite at that point in such a way as to maintain an integral equal to one. The limiting representations of Sec. 2.2.2 remove some, but not all, of the mathematical uncertainties associated

with this definition. One question left unanswered is when it is valid to interchange the order of an integral and a limit; the limit of an integral is not necessarily the integral of the limit. Also, we have not clearly specified the conditions that have to be placed on $f(x)$ in order for our expressions to be valid.

These uncertainties are removed by using the theory of distributions to define a delta function. In this view, $\delta(x)$ is a generalized function associated with the distribution Φ_δ in such a way that

$$\Phi_\delta\{t(x)\} = \int_{-\infty}^{\infty} dx \delta(x) t(x) \equiv t(0), \quad (2.51)$$

where $t(x)$ is a test function. The same equation can be used to define a tempered distribution if $t(x)$ is a good function as defined in Sec. 2.1.2.

To get a more general sifting property analogous to (2.24), we simply define another distribution, rather clumsily designated as $\Phi_{\delta_{x_0}}$, specified by

$$\Phi_{\delta_{x_0}}\{t(x)\} = \int_{-\infty}^{\infty} dx \delta(x - x_0) t(x) \equiv t(x_0). \quad (2.52)$$

There can be no question of the validity of this equation since it is just a definition, not something derived from (2.51). We define the result of the distribution to be $t(x_0)$, and the integral expression involving $\delta(x - x_0)$ is just a convenient mnemonic for this definition.

We can proceed in this way, avoiding all questions of validity by just defining whatever distributions we need. We do not do so willy-nilly, however, but try to choose definitions consistent with ordinary functionals in the Riesz form, (2.1). Moreover, the resulting distribution must satisfy the requirements of linearity and continuity discussed in Sec. 2.1.4. We illustrate this approach in the next section where we define the derivative of a delta function.

2.2.4 Derivatives of delta functions

If $\delta(x)$ is defined by the limit of a Dirac sequence as in (2.36) and the functions $\psi_k(x)$ are all differentiable, it is natural to define the derivative of a delta function as

$$\delta'(x - x_0) = \lim_{k \rightarrow \infty} \psi'_k(x - x_0), \quad (2.53)$$

where the prime denotes derivative. With this definition and the assumption that $f(x)$ is differentiable, we have

$$\begin{aligned} \int_{-\infty}^{\infty} dx f(x) \delta'(x - x_0) &= \lim_{k \rightarrow \infty} \int_{-\infty}^{\infty} dx f(x) \psi'_k(x - x_0) \\ &= - \lim_{k \rightarrow \infty} \int_{-\infty}^{\infty} dx f'(x) \psi_k(x - x_0) = - \int_{-\infty}^{\infty} dx f'(x) \delta(x - x_0) = -f'(x_0), \end{aligned} \quad (2.54)$$

where we have performed an integration by parts and made use of the fact that all of the ψ_k vanish at infinity.

Repetition of this procedure and consideration of finite limits of integration lead to the conclusion that

$$\int_a^b dx f(x) \delta^{(n)}(x - x_0) = \begin{cases} (-1)^n f^{(n)}(x_0) & \text{if } a < x_0 < b \\ 0 & \text{if } x_0 < a \text{ or } x_0 > b \end{cases}, \quad (2.55)$$

where $f^{(n)}(x)$ is the n^{th} derivative of $f(x)$.

The development of (2.54) and (2.55) raises a number of mathematical questions about differentiability, support and the validity of interchanging limits and integrals. All of these problems are avoided by use of distributions. In Sec. 2.1.5, we discussed derivatives of distributions, and it is easy to apply this idea here. By analogy to (2.18), we define a distribution

$$\Phi_{\delta'}\{t(x)\} = \int_{-\infty}^{\infty} dx \delta'(x) t(x) \equiv -\Phi_{\delta}\{t'(x)\} = -t'(0), \quad (2.56)$$

where the generalized function $\delta'(x)$ is defined by this equation. Similarly, higher derivatives of the delta function are associated with other new distributions, and we have in general

$$\int_{-\infty}^{\infty} dx t(x) \delta^{(n)}(x - x_0) = (-1)^n t^{(n)}(x_0), \quad (2.57)$$

where we have abandoned the Φ notation since it was getting impossibly clumsy.

From either the Dirac-sequence approach or the distributional one, the following operational properties of derivatives of the delta function can be derived:

$$\delta^{(n)}(x - x_0) = 0 \quad \text{if } x \neq x_0, \quad (2.58)$$

$$\int_{-\infty}^{\infty} dx \delta^{(n)}(x - x_0) = 0 \quad \text{if } n > 0, \quad (2.59)$$

$$\delta^{(n)}(x) = (-1)^n \delta^{(n)}(-x), \quad (2.60)$$

$$x \delta'(x) = -\delta(x). \quad (2.61)$$

All of these equations are true in the sense that, when multiplied by a test function and integrated, both sides yield the same result.

2.2.5 A synthesis

As we have seen, the distributional approach to delta functions avoids many mathematical difficulties, basically by defining them away. Anytime we need a previously undefined result, such as the derivative of a delta function, we simply define a new distribution. The rigor of equations such as (2.56) and (2.57) is beyond reproach since they are merely definitions; virtually any definition of distribution is allowed, so long as it satisfies the basic requirements of continuity and linearity. The price we have paid is that the definitions are restricted to test functions (or at least good functions), and we might want to use the results more widely. From the viewpoint of Dirac sequences, on the other hand, (2.56) and (2.57) can be derived directly since there is no difficulty in differentiating a delta function so long as the $\{\psi_k\}$ are themselves differentiable. The difficulty in that case is that it is not always clear what restrictions have to be placed on the function $f(x)$ that appears along with the generalized function $g(x)$ in an integral of the form $\int f(x) g(x) dx$.

To illustrate this dichotomy, consider an integral where the function $f(x)$ is bounded but discontinuous at $x = x_0$. Then, from the Dirac-sequence view, there is no problem in showing that

$$\int_{-\infty}^{\infty} dx f(x) \delta(x - x_0) = \frac{1}{2} \lim_{x \rightarrow x_0^+} f(x) + \frac{1}{2} \lim_{x \rightarrow x_0^-} f(x) = \frac{1}{2}[f(x_0^+) + f(x_0^-)]. \quad (2.62)$$

This very useful result would be meaningless in a strict distributional treatment since the distribution is defined only with respect to continuous test functions. What we need is an approach that will allow more flexibility in the choice of $f(x)$ yet retain the rigor and clarity of distributions.

The way to achieve this synthesis is to use test functions to approximate more general functions. We have seen two examples of how this can be done in Sec. 2.1.2, but we shall now make use of properties of Dirac sequences to develop a general procedure.

The functions $\psi_k(x)$ used in a Dirac sequence need not be test functions, but they can be. A Dirac sequence of test functions can be constructed from our building-block function, $h(x)$, as defined in (2.5). The functions

$$s_k(x) \equiv kh(kx + \frac{1}{2})h(-kx + \frac{1}{2}) \quad (2.63)$$

are test functions with support $(-\epsilon, \epsilon)$, where $\epsilon = 1/2k$, and with a proper normalizing constant to satisfy condition (c) of Sec. 2.2.2, they also satisfy all of the requirements for a Dirac sequence. Using these functions or any similar test functions that qualify as a Dirac sequence, we define the k^{th} approximant of a function $f(x)$ as

$$\hat{f}_k(x) \equiv \int_{-\infty}^{\infty} dx' f(x') s_k(x - x'). \quad (2.64)$$

If $f(x)$ has support $(-a, a)$, then $\hat{f}_k(x)$ has support $(-a - \epsilon, a + \epsilon)$, which approaches $(-a, a)$ as $k \rightarrow \infty$.

To complete the demonstration that $\hat{f}_k(x)$ is a test function, we need to show that all of its derivatives exist. For this purpose, we must assume that it is legitimate to differentiate under the integral sign, which it is if the resulting integral exists (perhaps in the Lebesgue sense³). For example, it is legitimate if $f(x)$ has a finite number of finite discontinuities. Under these conditions, we have

$$\frac{d^n \hat{f}_k(x)}{dx^n} = \int_{-\infty}^{\infty} dx' f(x') \frac{d^n s_k(x - x')}{dx^n}. \quad (2.65)$$

Since s_k is a test function for all k , all of its derivatives are guaranteed to exist everywhere. Thus $\hat{f}_k(x)$ is a test function of support $(-a - \epsilon, a + \epsilon)$ for all k and, since $\epsilon = 1/k$, $\hat{f}_\infty(x)$ is a test function of support $(-a, a)$. Moreover, we know from the discussion in Sec. 2.2.2 that $\hat{f}_k(x)$ converges uniformly to $f(x)$ at every point where $f(x)$ is continuous. If $f(x)$ is bounded but discontinuous at $x = x_0$, then $\hat{f}_k(x_0)$ can be shown to converge to the average as in (2.62) since $s_k(x) = s_k(-x)$.

Thus integrable functions of compact support can be uniformly approximated by test functions $\hat{f}_k(x)$. If $f(x)$ does not have compact support, but interchange of differentiation and integration is still legitimate, $\hat{f}_k(x)$ is a good function instead of a test function.

To summarize, all of the functionals considered here can be written in the form $\int f(x)g(x)dx$. In the distributional approach, $g(x)$ is a generalized function and $f(x)$ is restricted to be a test function (or a good function for a tempered distribution). The generalized function itself has no restrictions at all placed on it

³For a concise introduction to Lebesgue integration, see Champeney (1987) or Friedman (1991).

since it is defined by the functional. In the Dirac-sequence approach, $g(x)$ is the limit of a sequence of functions obeying conditions (a)–(d) of Sec. 2.2.2, while $f(x)$ can be any function for which the product $f(x)g(x)$ is integrable. The synthesis suggested in this section combines these two approaches by allowing $g(x)$ to be a generalized function, defined by its distribution, but representing $f(x)$ as the limit of a Dirac sequence of test functions. Since a wide variety of functions can be so represented, the distributional results derived for test functions can be more widely applied. The reader is cautioned, however, not to use limiting representations for both $f(x)$ and $g(x)$; see Sec. 2.3.2 for an example where the order of the limits cannot be interchanged.

2.2.6 Delta functions as basis vectors

The sifting property of delta functions has a useful interpretation in terms of vector spaces. If $f(x)$ is a square-integrable function and hence a vector in $\mathbb{L}_2(-\infty, \infty)$ (see Chap. 1), then it can be expanded in terms of various sets of basis vectors for that space. As discussed in Sec. 1.1.6, the basis vectors need not lie in the space for which they form the basis. The example given in that section was the Fourier basis, in which the basis vectors are the set $\{\exp(2\pi i\nu x)\}$, indexed by the continuous variable ν . The delta functions $\{\delta(x - a)\}$ can also be considered as a continuous basis, this time indexed by the continuous variable a . Since the delta functions are not square-integrable, they are not in $\mathbb{L}_2(-\infty, \infty)$, but they can be used to expand a continuous function in that space. The required expansion is just the sifting property,

$$f(x) = \int_{-\infty}^{\infty} da f(a) \delta(x - a), \quad (2.66)$$

from which we see that the expansion coefficients are just the values of the function.

This viewpoint runs into some difficulties when $f(x)$ is not continuous since then $f(a)$ is not uniquely defined. We can avoid these difficulties by confining $f(x)$ to the space of test functions, or we can appeal to the argument of the last section that certain discontinuous functions can be approximated arbitrarily closely by test functions.

2.3 OTHER GENERALIZED FUNCTIONS IN 1D

2.3.1 Generalized functions as limits

As we have seen, the generalized function $\delta(x)$ can be defined in two mathematically defensible ways: either in terms of a distribution or as the limit of an ordinary function. Either of these approaches can be extended to define a wide variety of other generalized functions. The distributional approach merely defines whatever generalized functions we need; suitable definitions will be given in the sections that follow. The limiting-sequence approach, however, requires that we be able to place suitable restrictions on the functions in the sequence. We have done this in Sec. 2.2.2 for the delta function, but we now need to examine how to extend the method to other generalized functions.

The key mathematical result justifying the limiting-sequence approach is that any generalized function $g(x)$, no matter how wild, can be written as the limit of a

sequence of good functions (Lighthill, 1958; Richards and Youn, 1990):

$$g(x) = \lim_{k \rightarrow \infty} w_k(x), \quad (2.67)$$

where $w_k(x)$ is a good function for all k . The distribution associated with $g(x)$ is, of course,

$$\Phi_g\{t(x)\} = \int_{-\infty}^{\infty} dx g(x) t(x) = \lim_{k \rightarrow \infty} \int_{-\infty}^{\infty} dx w_k(x) t(x), \quad (2.68)$$

where $t(x)$ is a test function.

In the sections below, we shall show how to define new generalized functions distributionally and to devise suitable limiting representations of them.

2.3.2 Generalized functions related to the delta function

Step function Consider the function $\text{step}(x)$, which we defined as an ordinary discontinuous function in (2.10). A distributional definition of the step function is

$$\Phi_{\text{step}}\{t(x)\} \equiv \int_0^{\infty} dx t(x) = \int_{-\infty}^{\infty} dx t(x) \text{step}(x), \quad (2.69)$$

where the first integral defines the functional and the second defines the generalized function $\text{step}(x)$. We have already seen in (2.11) one way in which this generalized function can be written as the limit of a sequence of fairly good functions. Other representations can be derived from any of the Dirac sequences used to define $\delta(x)$. If we have a Dirac sequence of functions $\{\psi_k(x)\}$ that converges to $\delta(x)$, we can define $\text{step}(x)$ as

$$\text{step}(x) = \lim_{k \rightarrow \infty} \int_{-\infty}^x dx' \psi_k(x'). \quad (2.70)$$

Each integral in this limit is a fairly good function if $\psi_k(x)$ is a test function.⁴

The shifted step function $\text{step}(x - x_0)$ is defined distributionally (without the cumbersome Φ notation) as

$$\int_{-\infty}^{\infty} dx t(x) \text{step}(x - x_0) = \int_{x_0}^{\infty} dx t(x). \quad (2.71)$$

It is easy to modify the limiting representation of $\text{step}(x)$ into one for $\text{step}(x - x_0)$.

Derivative of a step function We can define a derivative of $\text{step}(x)$, even though it is not differentiable in the conventional sense. From the discussion in Sec. 2.1.5, and especially (2.18), we have

$$\int_{-\infty}^{\infty} dx t(x) \frac{d}{dx} \text{step}(x) = - \int_{-\infty}^{\infty} dx t'(x) \text{step}(x) = - \int_0^{\infty} dx t'(x) = t(0), \quad (2.72)$$

⁴The result in (2.70) is a bit weaker than the theorem of (2.67), which says that any generalized function can be expressed as the limit of a sequence of good functions. The integrals in (2.70) are not good functions since they do not approach zero as $x \rightarrow \infty$, but they are better than most fairly good functions since they do not grow at infinity either. If we wanted to write $\text{step}(x)$ as the limit of a sequence of good functions, we could do so by multiplying (2.70) by a factor such as $\exp(-x^2/k^2)$. This factor becomes unity for all finite x in the limit as $k \rightarrow \infty$, but meets the requirements for a good function at all k .

since $t(\infty) = 0$ for any test function $t(x)$. Comparison of the first and last forms of (2.72) shows that

$$\frac{d}{dx} \text{step}(x) = \delta(x), \quad (2.73)$$

since both sides of this equation yield the same result when multiplied by a test function and integrated.

We can get the same result from a limiting sequence. If $\text{step}(x)$ is represented by (2.70), its derivative is

$$\frac{d}{dx} \text{step}(x) = \lim_{k \rightarrow \infty} \frac{d}{dx} \int_{-\infty}^x dx' \psi_k(x') = \lim_{k \rightarrow \infty} \psi_k(x) = \delta(x). \quad (2.74)$$

Thus we see from this viewpoint also that the derivative of a step function is the delta function.

This is a good point at which to illustrate a potential pitfall when manipulating generalized functions. Since we have two different limiting representations for $\text{step}(x)$, (2.11) and (2.70), it might be expected that the derivative of either one could be used to represent $\delta(x)$ in an integral of the form $\int \delta(x) f(x) dx$. That expectation is correct if $f(x)$ is continuous at $x = 0$, as it must be if it is a test function, but the two representations give different results if $f(x)$ has a discontinuity at $x = 0$. Use of the derivative of (2.70) to represent $\delta(x)$ yields $[f(0^+) + f(0^-)]/2$ as in (2.62), but use of the derivative of $h(kx)$ to represent $\delta(x)$, as in (2.11), can give only $f(0^+)$ since $h(kx)$ and all of its derivatives are zero for $x \leq 0$.

The reason for the discrepancy between these two results is that *both* $f(x)$ and $g(x)$ are being represented as limits in $\int f(x) g(x) dx$, and it matters in which order the limits are taken. No problem would arise if either $f(x)$ or $g(x)$ were continuous. The limiting representations are useful, but two of them should not be used in the same integral.

Signum function Closely related to $\text{step}(x)$ is the function $\text{sgn}(x)$, pronounced signum of x . Treated as a conventional (though discontinuous) function, $\text{sgn}(x)$ is defined as

$$\text{sgn}(x) \equiv \begin{cases} 1 & \text{if } x > 0 \\ -1 & \text{if } x < 0 \end{cases}. \quad (2.75)$$

Distributionally, it is defined by

$$\Phi_{\text{sgn}}\{t(x)\} = \int_{-\infty}^{\infty} t(x) \text{sgn}(x) dx \equiv \int_0^{\infty} t(x) dx - \int_{-\infty}^0 t(x) dx. \quad (2.76)$$

Thus

$$\text{sgn}(x) = 2 \text{step}(x) - 1, \quad (2.77)$$

which, when combined with the distributional definition of $\text{step}(x)$ and the rules for manipulating distributions given in Sec. 2.1.5, will reproduce (2.76). Any valid limiting representation for the step function gives one for the signum function via (2.77). Similarly, we can show either distributionally or by a limiting representation that

$$\frac{d}{dx} \text{sgn}(x) = 2 \delta(x). \quad (2.78)$$

Products of delta functions Consider an integral of the form

$$I(x_0, x_1) = \int_{-\infty}^{\infty} dx t(x) \delta(x - x_0) \delta(x - x_1), \quad (2.79)$$

where $t(x)$ is a test function. As noted above, we can represent $\delta(x - x_0)$ as the limit of a Dirac sequence of test functions, and the product of two test functions is a test function. Thus there is no problem in passing to the limit of the sequence and writing

$$I(x_0, x_1) = t(x_1) \delta(x_1 - x_0), \quad (2.80)$$

which is identically zero if $x_0 \neq x_1$. If $x_0 = x_1$, $I(x_0, x_1)$ is infinite, so the square of a delta function is not defined directly, but $I(x_0, x_1)$ itself may be treated as a generalized function. It is easy to establish that it corresponds to the functional

$$\Phi_I\{s(x_0)\} = \int_{-\infty}^{\infty} dx_0 I(x_0, x_1) s(x_0) = s(x_1) t(x_1), \quad (2.81)$$

where $s(x)$ is a test function. In other words, the product of two delta functions, $\delta(x - x_0) \delta(x - x_1)$, behaves as a double generalized function; it has to be integrated twice before arriving at a simple number. In the example above, the two integrals were over x and x_0 , but in fact any two of the three variables can be chosen. The following operational rule holds:

$$t(x) \delta(x - x_0) \delta(x - x_1) = t(x_0) \delta(x - x_0) \delta(x - x_1) = t(x_1) \delta(x - x_0) \delta(x - x_1). \quad (2.82)$$

Although this rule does not work if $x_0 = x_1$, there is one way we can define something akin to the square of a delta function. The integral in (2.45) is a useful limiting form for the delta function that often arises in spectral analysis. If we denote this integral by $d_k(x)$, its square can be written as

$$[d_k(x)]^2 = \int_{-k/2}^{k/2} d\nu \int_{-k/2}^{k/2} d\nu' \exp[2\pi i(\nu - \nu')x]. \quad (2.83)$$

For k large, $[d_k(x)]^2$ is sharply peaked like a delta representation; its width varies as $1/k$, but its peak amplitude grows as k^2 , so it does not integrate to unity as desired in a Dirac sequence. If integrated against a slowly varying function $f(x)$, a useful approximation might be

$$\int_{-\infty}^{\infty} dx [d_k(x)]^2 f(x) \simeq k f(0), \quad (2.84)$$

provided $f(x) \simeq f(0)$ for $|x| < 1/k$. Since $d_k(x) \rightarrow \delta(x)$ as $k \rightarrow \infty$, we can express this result loosely as (Bjorken and Drell, 1964, p. 101)

$$[\delta(x)]^2 \simeq k \delta(x), \quad k \rightarrow \infty. \quad (2.85)$$

A better way to express the same mathematics, however, is

$$\lim_{k \rightarrow \infty} \frac{1}{k} [d_k(x)]^2 = \lim_{k \rightarrow \infty} \frac{1}{k} \int_{-k/2}^{k/2} d\nu \int_{-k/2}^{k/2} d\nu' \exp[2\pi i(\nu - \nu')x] = \delta(x). \quad (2.86)$$

This equation can also be written as

$$\lim_{k \rightarrow \infty} k \operatorname{sinc}^2(kx) = \delta(x), \quad (2.87)$$

providing yet another useful limiting representation for the delta function.

2.3.3 Other point singularities

$1/x$ As an illustration of the concept of distributions, we introduced the generalized function $\mathcal{P}\{1/x\}$ in (2.4). The use of this function in complex integrals was also discussed in App. B. Henceforth, we drop the designation \mathcal{P} and write $1/x$, with the understanding that the function is defined by a principal-value integral.

An alternative definition of $1/x$ (Lighthill, 1958) is that it is the odd generalized function $g(x)$ that satisfies $xg(x) = 1$. By this definition, $g(x)$ coincides with the ordinary function $1/x$ for $x \neq 0$, while the requirement that $g(x)$ be odd guarantees that the value at $x = 0$ is zero.

As with any other generalized function, $1/x$ can be represented as the limit of good or fairly good functions. One such representation can be derived by using (2.39) to represent a delta function and convolving that representation with $1/x$:

$$\frac{1}{x} = \lim_{\epsilon \rightarrow 0^+} \frac{\epsilon}{\pi} \int_{-\infty}^{\infty} dx' \left(\frac{1}{x-x'} \right) \left(\frac{1}{x'^2 + \epsilon^2} \right) = \lim_{\epsilon \rightarrow 0} \frac{x}{x^2 + \epsilon^2}, \quad (2.88)$$

where the integral has been performed by contour methods, taking advantage of the distributional definition of $1/x$, (2.4), for guidance in handling the pole on the contour. The representation of (2.88) is illustrated in Fig. 2.6a.

Fig. 2.6 (a) Plot of a representation of the generalized function $1/x$ from (2.88); (b) plot of a similar representation of the generalized function $1/x^2$ from (2.91).

The final form of (2.88) shows again that the generalized function $1/x$ agrees exactly with the ordinary function $1/x$ except at $x = 0$, where the ordinary function is not defined. The limit of the ordinary function $1/x$ as $x \rightarrow 0$ is $\pm\infty$, depending on the direction of approach. The generalized $1/x$, on the other hand, is zero at $x = 0$, corresponding to the deletion of the neighborhood of $x = 0$ from any integral in which it appears [cf. (2.3)].

$1/x^m$ From the generalized function $1/x$, we can use the rule for forming derivatives of generalized functions, (2.18), to define new generalized functions $1/x^m$ by (Lighthill, 1958)

$$\frac{1}{x^m} \equiv \frac{(-1)^{m-1}}{(m-1)!} \frac{d^{m-1}}{dx^{m-1}} \frac{1}{x}, \quad (2.89)$$

where m is an integer greater than one. Limiting representations can be obtained by differentiating (2.88) the appropriate number of times.

The generalized function $1/x^2$ will prove to be important in analysis of tomographic imaging systems. By (2.89) it should be interpreted as

$$\int_{-\infty}^{\infty} dx \frac{t(x)}{x^2} = -\mathcal{P} \int_{-\infty}^{\infty} dx \frac{t'(x)}{x}. \quad (2.90)$$

Again, the generalized function $1/x^2$ coincides with the ordinary function if $x \neq 0$, but, unlike $1/x$, it is not correct to say that the generalized $1/x^2$ is zero at $x = 0$. To see what does happen at the origin, we take the first derivative of (2.88), obtaining

$$\frac{1}{x^2} = \lim_{\epsilon \rightarrow 0} \left[\frac{2x^2}{(x^2 + \epsilon^2)^2} - \frac{1}{x^2 + \epsilon^2} \right], \quad (2.91)$$

which is depicted in Fig. 2.6b. For $x \neq 0$, the first term limits to $2/x^2$ and the second to $-1/x^2$, so the sum has the proper behavior. For $x \equiv 0$, however, the first term is zero and the second term limits to $-\infty$. Moreover, this singularity has an infinite integral over any vanishingly small region, *i. e.*,

$$\lim_{b \rightarrow 0} \int_{-b}^b \frac{dx}{x^2} = -\infty. \quad (2.92)$$

We can say, very loosely, that $1/x^2$ behaves like a delta function of *weight negative infinity* at the origin (Richards and Youn, 1990, pp. 76–77). One way to understand this wild singularity is to say that it arises from differentiating across the infinite discontinuity of $1/x$ at $x = 0$ [*cf.* (2.79)]. Nevertheless, when integrated from $-\infty$ to ∞ , the infinities from the two terms in (2.91) cancel, giving

$$\int_{-\infty}^{\infty} \frac{dx}{x^2} = 0. \quad (2.93)$$

This result could be anticipated from (2.90) by letting $t(x) \rightarrow 1$ (or $t'(x) \rightarrow 0$), but it is definitely not what one would expect by taking the integrand at face value. A function denoted $1/x^2$ might be expected to be positive everywhere (which, in fact, is true except for the isolated point $x = 0$), so a zero integral is a surprise.

These subtleties illustrate some of the potential difficulties in interpreting generalized functions and the need for anchoring the theory in clear definitions. In the present example, the basic definition from which all interpretations must be derived is (2.90).

Noninteger powers Noninteger powers of x present some new subtleties. In what follows, we shall consider functions of the form $|x|^\alpha$ to avoid complications with noninteger powers of negative numbers. As the notation implies, $|x|^\alpha$ is an even generalized function. For $\alpha > 0$, $|x|^\alpha$ is a continuous function, bounded for all finite x , so there is no difficulty in interpreting integrals of the form $\int |x|^\alpha t(x) dx$, where $t(x)$ is a test function. For $-1 < \alpha < 0$, there is also no problem since $|x|^\alpha$ is singular but integrable at $x = 0$. To extend the definition of $|x|^\alpha$ to noninteger $\alpha < -1$, we make use of the derivatives of $|x|^\alpha$. In particular, if $x \neq 0$,

$$\frac{d}{dx} |x|^\alpha = \alpha |x|^{\alpha-1} \operatorname{sgn}(x), \quad (2.94)$$

suggesting that we define the generalized function $|x|^{\alpha-1}$ by

$$|x|^{\alpha-1} = \frac{1}{\alpha} \frac{d}{dx} \{|x|^\alpha \operatorname{sgn}(x)\}, \quad -1 < \alpha < 0. \quad (2.95)$$

The distribution corresponding to $|x|^{\alpha-1}$ is, by (2.18),

$$\int_{-\infty}^{\infty} dx t(x) |x|^{\alpha-1} = -\frac{1}{\alpha} \int_{-\infty}^{\infty} dx \frac{dt(x)}{dx} |x|^\alpha \operatorname{sgn}(x) \quad \text{for } \alpha > -1. \quad (2.96)$$

Since $t(x)$ need only be a good function, and not strictly a test function, for this integral to converge, (2.96) defines a tempered distribution.

This process can be extended to include all noninteger negative α by defining (Lighthill, 1958)

$$|x|^\alpha = \frac{1}{(\alpha+1)(\alpha+2)\cdots(\alpha+n)} \frac{d^n}{dx^n} \{|x|^{\alpha+n} \operatorname{sgn}(x)\}, \quad (2.97)$$

where n is an integer such that $\alpha+n > -1$.

To illustrate this result, consider the generalized function $|x|^{-3/2}$, defined according to (2.97) by

$$|x|^{-3/2} = -2 \frac{d}{dx} \left\{ \frac{\operatorname{sgn}(x)}{\sqrt{|x|}} \right\}. \quad (2.98)$$

Distributionally, this equation means

$$\int_{-\infty}^{\infty} dx t(x) |x|^{-3/2} = 2 \int_{-\infty}^{\infty} dx \frac{t'(x) \operatorname{sgn}(x)}{\sqrt{|x|}}. \quad (2.99)$$

There is no problem with this definition at $x=0$ since $t'(x)$ is necessarily finite and continuous there and $1/\sqrt{x}$ is an integrable singularity.

Though (2.98) and (2.99) are the formal definition of $|x|^{-3/2}$, further insight can be obtained by use of limiting representations. We choose

$$\frac{1}{\sqrt{|x|}} = \lim_{\epsilon \rightarrow 0} \frac{1}{(x^2 + \epsilon^2)^{1/4}} \quad (2.100)$$

and

$$\operatorname{sgn}(x) = \lim_{\epsilon \rightarrow 0} \frac{x}{(x^2 + \epsilon^2)^{1/2}}, \quad (2.101)$$

from which we find

$$\frac{1}{|x|^{3/2}} = -2 \lim_{\epsilon \rightarrow 0} \frac{d}{dx} \frac{x}{(x^2 + \epsilon^2)^{3/4}} = \lim_{\epsilon \rightarrow 0} \left\{ \frac{3x^2}{(x^2 + \epsilon^2)^{7/4}} - \frac{2}{(x^2 + \epsilon^2)^{3/4}} \right\}. \quad (2.102)$$

As with the function $1/x^2$, this form shows a strong negative singularity at the origin [*cf.* (2.91)].

$x^{-m} \operatorname{sgn}(x)$ and $\ln|x|$ Though singular at the origin, $\ln|x|$ is an ordinary, integrable function, and functionals of the form $\int t(x) \ln|x| dx$ are easily evaluated. Away from the origin, the following derivative relations hold:

$$\frac{d}{dx} \ln|x| = \frac{1}{x}, \quad (x \neq 0), \quad (2.103)$$

and

$$\frac{d}{dx}\{(\ln|x|)\operatorname{sgn}(x)\} = \frac{1}{|x|} = \frac{\operatorname{sgn}(x)}{x}, \quad (x \neq 0). \quad (2.104)$$

The first of these equations is valid without the exclusion of the origin if $1/x$ is understood as the generalized function (Richards and Youn, 1990, p. 72), but the second is more problematical. The generalized functions $x^{-1}\operatorname{sgn}(x)$ and $x^{-m}\operatorname{sgn}(x)$ turn out not to be uniquely definable.

We could simply define a generalized function $g(x)$ by $d\{(\ln|x|)\operatorname{sgn}(x)\}/dx$ and call it $1/|x|$, but it would obey some very strange manipulation rules (Lighthill, 1958, p. 38). For example, we would hope that $g(ax)$ would equal $g(x)/|a|$, but instead we find

$$\begin{aligned} g(ax) &= \frac{d\{(\ln|x| + \ln|a|)\operatorname{sgn}(a)\operatorname{sgn}(x)\}}{a\,dx} = \frac{1}{|a|} \frac{d}{dx}\{(\ln|x|)\operatorname{sgn}(x) + (\ln|a|)\operatorname{sgn}(x)\} \\ &= \frac{1}{|a|}\{g(x) + 2(\ln|a|)\delta(x)\}. \end{aligned} \quad (2.105)$$

Since a is arbitrary, we must conclude that $1/|x|$ is not uniquely defined. The best we can say is that it is *any* generalized function that satisfies

$$\frac{1}{|x|} = \frac{d}{dx}\{(\ln|x|)\operatorname{sgn}(x)\} + 2C\delta(x) = \frac{d}{dx}\{(\ln|x| + C)\operatorname{sgn}(x)\}, \quad (2.106)$$

where C is an arbitrary constant (Lighthill, 1958; Champeney, 1987). Similarly,

$$\begin{aligned} x^{-m}\operatorname{sgn}(x) &= \frac{(-1)^{m-1}}{(m-1)!} \frac{d^m}{dx^m}\{(\ln|x| + C)\operatorname{sgn}(x)\} \\ &= \frac{(-1)^{m-1}}{(m-1)!} \frac{d^m}{dx^m}\{(\ln|x|)\operatorname{sgn}(x)\} + C'\delta^{m-1}(x), \end{aligned} \quad (2.107)$$

where m is a positive integer and C and C' are arbitrary.

2.4 MULTIDIMENSIONAL DELTA FUNCTIONS

2.4.1 Multidimensional distributions

The theory of distributions is easily extended to functions of two or more variables. We shall refer to a scalar-valued function of n scalar variables as an n -dimensional (or n D) function for short.

A function $t(x, y)$ is a 2D test function if all partial derivatives exist and it has compact support in the x - y plane. For example, a suitable support region would be the square of side $2L$ centered on the origin, in which case $t(x, y) = 0$ unless $-L < x < L$ and $-L < y < L$. More generally, we denote the support region by \mathbf{S} and say that $t(x, y) = 0$ unless (x, y) lies in \mathbf{S} . The test functions themselves lie in a subset of $\mathbb{L}_2(\mathbb{R}^2)$ denoted $\mathbb{T}(\mathbf{S})$ for test functions of support \mathbf{S} .

Good functions and fairly good functions in 2D are defined by analogy with (2.7) and (2.8), respectively. A good function in 2D is one for which all partial derivatives exist and

$$\lim_{x \rightarrow \pm\infty} \{|x|^N t(x, y)\} = 0 \quad \text{for all } N \text{ and all } y;$$

$$\lim_{y \rightarrow \pm\infty} \{|y|^N t(x, y)\} = 0 \quad \text{for all } N \text{ and all } x. \quad (2.108)$$

A fairly good function in 2D is one for which all partial derivatives exist and

$$\begin{aligned} \lim_{x \rightarrow \pm\infty} \{|x|^{-N} t(x, y)\} &= 0 \quad \text{for some } N \text{ and all } y; \\ \lim_{y \rightarrow \pm\infty} \{|y|^{-N} t(x, y)\} &= 0 \quad \text{for some } N \text{ and all } x. \end{aligned} \quad (2.109)$$

Similar definitions apply in three or more dimensions.

A 2D distribution is a linear, continuous functional that maps a test function $t(x, y)$ to a real or complex number. A 2D tempered distribution is defined the same way except that $t(x, y)$ need only be a good function. In both cases, the functional can be written in terms of a generalized function $g(x, y)$ as

$$\Phi_g\{t(x, y)\} = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy t(x, y) g(x, y). \quad (2.110)$$

Again, the extension to higher dimensions is obvious.

Vector notation In 2D problems we can define a vector \mathbf{r} with Cartesian components (x, y) , so that (2.110) can be written more compactly as

$$\Phi_g\{t(\mathbf{r})\} = \int_{\infty} d^2r t(\mathbf{r}) g(\mathbf{r}), \quad (2.111)$$

where $d^2r = dx dy$ and the subscript ∞ on the integral sign denotes an integral over the infinite x - y plane.

To extend this notation to n -dimensional (n D) functionals, all we have to do is to replace d^2r by $d^n r$ in (2.111). For example, in 3D, \mathbf{r} is a vector with Cartesian components (x, y, z) , $d^3r = dx dy dz$ and the integral runs over the infinite 3D volume. No notational distinction will be made between 2D and 3D vectors unless both appear in the same problem; \mathbf{r} will denote the general position vector in any number of dimensions, and the dimensionality will usually be clear by context (*e.g.*, from $d^n r$).

We also adopt the convention that r , without the boldface type, is the magnitude of the vector \mathbf{r} in any number of dimensions. Thus, $r = \sqrt{x^2 + y^2}$ in 2D or $\sqrt{x^2 + y^2 + z^2}$ in 3D.

2.4.2 Multidimensional delta functions

The 2D delta function $\delta(\mathbf{r})$ is the generalized function associated with the distribution Φ_δ , defined by

$$\Phi_\delta\{t(\mathbf{r})\} = \int_{\infty} d^2r t(\mathbf{r}) \delta(\mathbf{r}) \equiv t(\mathbf{0}), \quad (2.112)$$

where $t(\mathbf{0})$ is $t(\mathbf{r})$ evaluated at $\mathbf{r} = \mathbf{0}$, (*i.e.*, $x = 0, y = 0$). It follows from this definition that

$$\delta(\mathbf{r}) = \delta(x) \delta(y), \quad (\mathbf{r} \text{ a 2D vector}), \quad (2.113)$$

since

$$\int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy t(x, y) \delta(x) \delta(y) = \int_{-\infty}^{\infty} dy t(0, y) \delta(y) = t(0, 0). \quad (2.114)$$

In performing these integrals, we have used the fact that $t(x, y)$ for fixed y is a test function of x , and vice versa.

The extension to n D is straightforward, and the following properties of n D delta functions are easily established:

$$\delta(\mathbf{r} - \mathbf{r}_0) = 0 \quad \text{if } \mathbf{r} \neq \mathbf{r}_0; \quad (2.115)$$

$$\int_{\infty} d^n r \delta(\mathbf{r} - \mathbf{r}_0) = 1; \quad (2.116)$$

$$\delta(\mathbf{r}) = \delta(-\mathbf{r}); \quad (2.117)$$

$$\int_{\infty} d^n r t(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}_0) = t(\mathbf{r}_0); \quad (2.118)$$

$$\int_S d^n r t(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}_0) = t(\mathbf{r}_0) \quad \text{if } \mathbf{r}_0 \text{ is in region } \mathbf{S}; \quad (2.119)$$

$$t(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}_0) = t(\mathbf{r}_0) \delta(\mathbf{r} - \mathbf{r}_0); \quad (2.120)$$

$$\delta(a\mathbf{r} - \mathbf{r}_0) = |a|^{-n} \delta(\mathbf{r} - \mathbf{r}_0/a). \quad (2.121)$$

Multidimensional limiting representations Any of the Dirac sequences introduced in Sec. 2.2.2 can be used to construct a limiting representation for a multidimensional delta function in Cartesian coordinates. In 2D, we have

$$\delta(\mathbf{r}) = \delta(x) \delta(y) = \lim_{k \rightarrow \infty} \psi_k(x) \psi_k(y). \quad (2.122)$$

For example, the 2D generalization of (2.40) is

$$\begin{aligned} \delta(\mathbf{r}) &= \lim_{k \rightarrow \infty} k^2 \exp[-\pi k^2(x^2 + y^2)] = \lim_{\epsilon \rightarrow 0} \frac{1}{\epsilon^2} \exp[-\pi(x^2 + y^2)/\epsilon^2] \\ &= \lim_{\epsilon \rightarrow 0} \frac{1}{\epsilon^2} \exp\left[-\frac{\pi r^2}{\epsilon^2}\right], \end{aligned} \quad (2.123)$$

where $\epsilon = 1/k$. The last form follows since $x^2 + y^2 = r^2$ in 2D.

The extension of (2.122) to n D is

$$\delta(\mathbf{r}) = \lim_{k \rightarrow \infty} \prod_{j=1}^n \psi_k(x_j), \quad (2.124)$$

where x_j , $j = 1, \dots, n$, are the Cartesian components of \mathbf{r} . In particular, (2.123) generalizes to

$$\delta(\mathbf{r}) = \lim_{\epsilon \rightarrow 0^+} \frac{1}{\epsilon^n} \exp\left[-\frac{\pi r^2}{\epsilon^2}\right]. \quad (2.125)$$

2.4.3 Delta functions in polar coordinates

The reader is cautioned that the product form of (2.124) is valid in Cartesian coordinates only. In 2D polar coordinates (r, θ) , the following is true:

$$\delta(\mathbf{r}) = \frac{\delta(r)}{\pi r}, \quad (2.126)$$

where $r = |\mathbf{r}| = \sqrt{x^2 + y^2}$. As with all equations involving delta functions, (2.126) must hold if both sides are multiplied by a test function and integrated. We convert the test function $t(x, y)$ to polar coordinates by defining $t_p(r, \theta) = t(x, y)$ and using the usual transformation formulas from (x, y) to (r, θ) . We have two options for computing the integral in question. One is to write

$$\int_{\infty}^{\infty} d^2r t(\mathbf{r}) \delta(\mathbf{r}) = \int_0^{2\pi} d\theta \int_0^{\infty} r dr t_p(r, \theta) \frac{\delta(r)}{\pi r} = \frac{1}{\pi} \int_0^{2\pi} d\theta \int_0^{\infty} dr t_p(r, \theta) \delta(r). \quad (2.127)$$

At this point we can treat r as a dummy 1D variable of integration and use (2.62) to obtain

$$\int_0^{\infty} dr t_p(r, \theta) \delta(r) = \int_{-\infty}^{\infty} dr t_p(r, \theta) \text{step}(r) \delta(r) = \frac{1}{2} t_p(0, \theta). \quad (2.128)$$

Since $t_p(r, \theta)$ is a test function, it must be independent of θ at $r = 0$, so we have

$$\int_{\infty}^{\infty} d^2r t(\mathbf{r}) \delta(\mathbf{r}) = \frac{t_p(0, 0)}{2\pi} \int_0^{2\pi} d\theta = t(\mathbf{0}), \quad (2.129)$$

as required.

The other option for performing this integral without appealing to (2.62) is to allow r to assume negative values, which we do by redefining r as $|\mathbf{r}|$ if \mathbf{r} is in quadrants 1 or 2 and $-|\mathbf{r}|$ if it is in quadrants 3 or 4. Then $d^2r = |r| dr d\theta$, and the infinite plane is traversed by letting θ run from 0 to π while r runs from $-\infty$ to ∞ . This yields

$$\int_{\infty}^{\infty} d^2r t(\mathbf{r}) \delta(\mathbf{r}) = \int_0^{\pi} d\theta \int_{-\infty}^{\infty} |r| dr t_p(r, \theta) \frac{\delta(r)}{\pi} |r| = \frac{t_p(0, 0)}{\pi} \int_0^{\pi} d\theta = t(\mathbf{0}). \quad (2.130)$$

Both of these approaches establish the validity of (2.126) in 2D. The 3D counterpart is

$$\delta(\mathbf{r}) = \frac{\delta(r)}{2\pi r^2}, \quad (2.131)$$

where now $r = |\mathbf{r}| = \sqrt{x^2 + y^2 + z^2}$.

Dimensions and dimensions Equations (2.126) and (2.131) afford an opportunity to comment on some semantic and notational points. In the former equation, \mathbf{r} is a 2D vector while r , its magnitude, is a scalar. We refer to $\delta(\mathbf{r})$ as a 2D delta function, meaning that it can be used to perform a 2D integral. The right-hand side of the equation involves $\delta(r)$, a delta function with a scalar argument, which we refer to as a 1D delta function since it can be used to perform only a single integral, namely the one over the scalar r (or $|\mathbf{r}|$). That disparity in dimensions caused no problem

in the calculation above since the integral over θ was trivial once the one over r was performed.

We adopt the terminology that an n D delta function is one that can be used to perform n integrals. Some authors use a notation such as $\delta_n(\mathbf{r})$ to state explicitly the dimensionality of the delta function, but we shall not do so. Instead, we use the convention that the dimensionality of the delta function is the same as the dimensionality of the vector (or scalar) in its argument. By this rule, $\delta(\mathbf{r})$ is an n D delta function if \mathbf{r} is an n D vector, but $\delta(r)$ is always a 1D delta function.

Having said this, we now introduce a completely different usage of the word dimension. In physical problems, *dimensional analysis* is a very useful tool for ensuring that equations are consistent and independent of the particular system of units chosen. One way to perform a dimensional analysis is to note that all physical quantities can be expressed in terms of mass (M), length (L), time (T) and charge (Q). Different *units* can be used, but the *dimensions* of a physical quantity are always the same. Speed, for example, can be measured in cm/sec or furlongs/fortnight, but it always has dimensions of L/T . An equation like $v = dx/dt$ (where $v =$ speed, $x =$ position and $t =$ time) is dimensionally consistent since dx has dimensions of length and dt dimensions of time, so speed has dimensions of L/T as required. We shall often use square brackets to denote dimension. Here $[dx] = L$, $[dt] = T$ and $[v] = L/T$. Note that the fact that dx and dt are infinitesimal is of no import for purposes of dimensional analysis. Neither is the distinction between a vector and a scalar; speed and velocity have the same dimensions.

These same concepts can be applied to equations involving delta functions. The equation $\int dx t(x) \delta(x) = t(0)$ must be dimensionally consistent, in the sense of dimensional analysis. To be concrete, assume that x is a spatial position and hence has dimensions of length. The test function $t(x)$ can represent any physical quantity, so we denote its (unknown) dimensions as $[t(x)]$. The dimensions of the right-hand side of the equation, namely, $[t(x)]$, must match those of the left-hand side. On the left, however, dimensional analysis yields $[dx][\delta(x)][t(x)]$, so consistency demands that

$$[\delta(x)] = \frac{1}{[dx]} = \frac{1}{[x]}, \quad (2.132)$$

or $1/L$ if x is a length. In (confusing) words, the one-dimensional delta function has dimensions equal to the reciprocal of the dimensions of its argument.

If delta functions have dimensions, their limiting representation must as well. To apply dimensional analysis to (2.40), for example, we must first determine the dimensions of ϵ . Recall that an exponential can be expressed as a power series, and one cannot add quantities with different dimensions. Thus each term in the power series must be dimensionless, requiring that ϵ have the same dimensions as r , say L . The exponential function itself, being a sum of powers of the exponent, is also dimensionless, and the delta function represented by (2.40) has dimensions of $1/[\epsilon]$ or $1/L$ as required.

Similarly, an n D delta function has dimensions of

$$[\delta(\mathbf{r})] = \frac{1}{[d^n r]} = \frac{1}{[\mathbf{r}]^n}. \quad (2.133)$$

Thus, if \mathbf{r} is a 3D position vector, then $\delta(\mathbf{r})$ must be assigned the dimensions of $1/L^3$ for purposes of dimensional analysis. The 1D delta function $\delta(r)$, on the other hand, has dimensions of just $1/L$. Equations (2.126) and (2.131) are dimensionally

consistent since the denominators serve to balance the dimensions of the two sides. (Note that an angle, being the ratio of an arc length to a radius, is dimensionless.)

To add further to the confusion, we remind the reader that yet another usage of dimension was introduced in the last chapter. The test functions $t(\mathbf{r})$, which map from \mathbb{R}^n to $\mathbb{T}(\mathbf{S})$, are themselves vectors in a Hilbert space of infinite dimensionality. Here are all three usages in a single sentence: An n -dimensional delta function, which has dimensions $1/L^n$, is a basis vector for an infinite-dimensional space. Caveat lector.

2.4.4 Line masses and plane masses

The 1D delta function $\delta(r)$, where r is the magnitude of an n D vector, is defined for all points in an n D space; it just happens that it is nonzero only at a single point in that space, namely the origin. One can devise other 1D delta functions that are also defined at all points in an n D space but are nonzero over lines or planes. Consider, for example, a delta function of the form $\delta(\mathbf{r} \cdot \hat{\mathbf{n}})$ where \mathbf{r} is a 2D vector, $\hat{\mathbf{n}}$ is a 2D unit vector and the dot indicates the usual 2D scalar product. This delta function is nonzero everywhere that its argument vanishes, or for the set of points \mathbf{r} such that $\mathbf{r} \cdot \hat{\mathbf{n}} = 0$. Since this equation requires that \mathbf{r} be perpendicular to $\hat{\mathbf{n}}$, the delta function is nonzero along a line through the origin and normal to $\hat{\mathbf{n}}$. Similarly, the delta function $\delta(\mathbf{r} \cdot \hat{\mathbf{n}} - p)$ is nonzero along a line normal to $\hat{\mathbf{n}}$ and a distance p from the origin as shown in Fig. 2.7. To use either of these delta functions in an integral, it is convenient to use a rotated coordinate system where \mathbf{r} has Cartesian coordinates (x', y') , with the x' -axis parallel to $\hat{\mathbf{n}}$. In this system, a test function $t(\mathbf{r})$ is given by $t_{rot}(x', y')$ and $\mathbf{r} \cdot \hat{\mathbf{n}} = x'$. We therefore have

$$\int_{\infty}^{\infty} d^2r t(\mathbf{r}) \delta(\mathbf{r} \cdot \hat{\mathbf{n}} - p) = \int_{-\infty}^{\infty} dx' \int_{-\infty}^{\infty} dy' t_{rot}(x', y') \delta(x' - p) = \int_{-\infty}^{\infty} dy' t_{rot}(p, y'). \quad (2.134)$$

Since $\delta(\mathbf{r} \cdot \hat{\mathbf{n}} - p)$ is 1D, we can go no further. The result of using this 1D delta function in a 2D integral is a specific number, namely the line integral of the test function along the line $\mathbf{r} \cdot \hat{\mathbf{n}} = p$. Thus $\delta(\mathbf{r} \cdot \hat{\mathbf{n}} - p)$ qualifies as a generalized function

Fig. 2.7 Illustration of the line $\mathbf{r} \cdot \hat{\mathbf{n}} = p$ in 2D.

and defines the functional specified in (2.134). Unlike the delta function $\delta(\mathbf{r} - \mathbf{r}_0)$, however, it does not sift out a single point from the test function.

In 3D, the delta function $\delta(\mathbf{r} \cdot \hat{\mathbf{n}} - p)$ has a different interpretation. Again it is nonzero for those points \mathbf{r} for which the argument vanishes, or $\mathbf{r} \cdot \hat{\mathbf{n}} = p$. In 3D, however, this equation specifies a plane, so the result of using the generalized function $\delta(\mathbf{r} \cdot \hat{\mathbf{n}} - p)$ in a 3D integral is the integral of the test function over the plane normal to $\hat{\mathbf{n}}$ and a distance p from the origin. We refer to $\delta(\mathbf{r} \cdot \hat{\mathbf{n}} - p)$ as a line mass or line delta function in 2D and as a plane mass or plane delta function in 3D. Both of these constructs will prove to be very important when we discuss tomography in Chap. 16.

If we wish to construct a line mass in 3D, one way to do so is to define a generalized function $g_{\hat{\mathbf{n}}}(\mathbf{r})$ by

$$g_{\hat{\mathbf{n}}}(\mathbf{r}) = \int_{-\infty}^{\infty} dl \delta(\mathbf{r} - \hat{\mathbf{n}}l). \quad (2.135)$$

Since the integrand is a 3D delta function and a single integral is performed, $g_{\hat{\mathbf{n}}}(\mathbf{r})$ is a 2D delta function or, equivalently, a line delta function in 3D. It is nonzero for all points along a line through the origin and parallel to $\hat{\mathbf{n}}$.

The line delta functions discussed above are all nonzero along *straight* lines. An example of a line delta function in 2D where the line is not straight is the ring delta function,

$$\delta(r - R) = \delta(|\mathbf{r}| - R), \quad \mathbf{r} \text{ a 2D vector.} \quad (2.136)$$

Not to be confused with $\delta(\mathbf{r} - \mathbf{R})$, the ring delta function is nonzero along a circle of radius R centered on the origin in the 2D plane. The same expression $\delta(\mathbf{r} - \mathbf{R})$ but with \mathbf{r} a 3D vector would be nonzero along a shell of radius R and infinitesimal thickness in the 3D space.

2.4.5 Multidimensional derivatives of delta functions

Various partial derivatives of multidimensional delta function can be defined by analogy to the 1D derivatives discussed in Sec. 2.2.4. If \mathbf{r} is an n D vector with Cartesian coordinates $\{x_j : j = 1, \dots, N\}$, then the first partial derivatives of $\delta(\mathbf{r} - \mathbf{r}_0)$ are defined by

$$\int_{\infty} d^n r t(\mathbf{r}) \frac{\partial}{\partial x_j} \delta(\mathbf{r} - \mathbf{r}_0) = - \left. \frac{\partial t(\mathbf{r})}{\partial x_j} \right|_{\mathbf{r}=\mathbf{r}_0}. \quad (2.137)$$

Higher partial derivatives are defined similarly. For example, gradients and Laplacians of a delta function are defined by

$$\int_{\infty} d^n r t(\mathbf{r}) \nabla \delta(\mathbf{r} - \mathbf{r}_0) = -\nabla t(\mathbf{r}_0); \quad (2.137)$$

$$\int_{\infty} d^n r t(\mathbf{r}) \nabla^2 \delta(\mathbf{r} - \mathbf{r}_0) = \nabla^2 t(\mathbf{r}_0). \quad (2.138)$$

A general differential operator acting on a delta function is defined in terms of its adjoint acting on the test function (see Sec. 1.3.5). The adjoint of ∇ is $-\nabla$ (which is a statement of integration by parts), while ∇^2 is self-adjoint or Hermitian.

2.4.6 Other point singularities

In discussing various imaging applications in later chapters, we shall encounter some multidimensional point singularities similar to the 1D ones defined in Sec. 2.3.3. A

very common one will be the function $1/|\mathbf{r} - \mathbf{r}_0|$, where \mathbf{r} and \mathbf{r}_0 are vectors in 2D or 3D. Unlike the 1D function $1/|x - x_0|$, $1/|\mathbf{r} - \mathbf{r}_0|$ is an integrable singularity, and no special definition of a generalized function is needed. To prove this contention in 2D, we make the change of variables, $\mathbf{r}' = \mathbf{r} - \mathbf{r}_0$, and write

$$\begin{aligned} \int_{-\infty}^{\infty} d^2r \frac{t(\mathbf{r})}{|\mathbf{r} - \mathbf{r}_0|} &= \int_{-\infty}^{\infty} d^2r' \frac{t(\mathbf{r}' + \mathbf{r}_0)}{|\mathbf{r}'|} = \int_0^{2\pi} d\theta' \int_0^{\infty} r' dr' \frac{t(\mathbf{r}' + \mathbf{r}_0)}{r'} \\ &= \int_0^{2\pi} d\theta' \int_0^{\infty} dr' t(\mathbf{r}' + \mathbf{r}_0), \end{aligned} \quad (2.139)$$

which must converge if $t(\mathbf{r})$ is a test function. Similarly, $1/|\mathbf{r} - \mathbf{r}_0|^2$ is an integrable singularity in 3D.

The Laplacian of $1/|\mathbf{r} - \mathbf{r}_0|$ in 3D is an important generalized function with applications in coherent imaging and tomography. A change of variables as in (2.139) allows us to set \mathbf{r}_0 to zero without loss of generality, and the Laplacian can be calculated in spherical coordinates as follows:

$$\nabla^2 \frac{1}{r} = \frac{1}{r^2} \frac{\partial}{\partial r} r^2 \frac{\partial}{\partial r} \frac{1}{r} = 0 \quad \text{if } r \neq 0. \quad (2.140)$$

To see the behavior at $r = 0$, we make use of the divergence theorem (Gauss's theorem), which states that

$$\int_S \mathbf{D} \cdot \hat{\mathbf{n}} da = \int_V \nabla \cdot \mathbf{D} d^3r, \quad (2.141)$$

where S is a closed surface surrounding volume V , da is the area element on S , $\hat{\mathbf{n}}$ is an outwardly directed unit normal to S , and \mathbf{D} is an arbitrary vector field. In the present problem, \mathbf{D} can be taken as the gradient of $1/r$, which is a vector directed radially away from the origin, and S can be taken as a sphere of radius R centered on the origin so that $\hat{\mathbf{n}}$ is in the same direction as $\nabla(1/r)$. Since $\nabla^2 f(\mathbf{r}) = \nabla \cdot \nabla f(\mathbf{r})$, we have

$$\int_V \nabla \cdot \nabla \frac{1}{r} d^3r = \int_S \hat{\mathbf{n}} \cdot \nabla \frac{1}{r} da = \int_S \left[\frac{\partial}{\partial r} \frac{1}{r} \right]_{r=R} da = -\frac{1}{R^2} \int_S da = -\frac{1}{R^2} 4\pi R^2 = -4\pi, \quad (2.142)$$

independent of R . Comparison of the first and last forms establishes that

$$\nabla^2 \frac{1}{r} = -4\pi \delta(\mathbf{r}), \quad \mathbf{r} \text{ a 3D vector}, \quad r = |\mathbf{r}|, \quad (2.143)$$

or, more generally,

$$\nabla^2 \frac{1}{|\mathbf{r} - \mathbf{r}_0|} = -4\pi \delta(\mathbf{r} - \mathbf{r}_0). \quad (2.144)$$

The same result can also be obtained more rigorously either by using a limiting representation of $1/r$ or by using distribution theory.

An analogous result in 2D is

$$\nabla^2 \ln |\mathbf{r} - \mathbf{r}_0| = 2\pi \delta(\mathbf{r} - \mathbf{r}_0), \quad \mathbf{r} \text{ a 2D vector}. \quad (2.145)$$

Both (2.144) and (2.145) have important applications in the theory of wave propagation and diffraction, and they show up in surprising ways in tomographic imaging as well.

2.4.7 Angular delta functions

So far in this chapter, the variable in the argument of a delta function has been a spatial variable in some number of dimensions, but it is also frequently useful to consider angular variables.

In 2D problems in polar coordinates, there is no difficulty in defining an angular delta function. We can simply define $\delta(\theta - \theta_0)$ by

$$\int_0^{2\pi} d\theta \delta(\theta - \theta_0) t(\theta) = t(\theta_0), \quad (2.156)$$

where $t(\theta)$ is a test function.

In 3D spherical coordinates, we need two angles; the usual choices are the colatitude θ , measured from the z axis, and the longitude or azimuth ϕ , defined as the rotation about the z axis as measured from the x axis. A unit vector $\hat{\mathbf{n}}$ in the direction determined by these angles is given by

$$\hat{\mathbf{n}} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta). \quad (2.157)$$

With these variables, we can define

$$\int_{4\pi} d\Omega_n \delta(\hat{\mathbf{n}} - \hat{\mathbf{n}}_0) t(\hat{\mathbf{n}}) = t(\hat{\mathbf{n}}_0), \quad (2.158)$$

where $d\Omega_n = \sin \theta d\theta d\phi$ is the element of solid angle associated with $\hat{\mathbf{n}}$, and $t(\hat{\mathbf{n}})$ is a test function in the angular variables.

3

Fourier Analysis

Jean Baptiste Joseph Fourier was born in a working-class French family in 1768. Orphaned at age eight, he entered the military school at Auxerre, where his aptitude for mathematics was evident. He was denied a commission in the artillery because of his low birth and decided instead to become a monk (Whitrow, 1965). He entered the Benedictine novitiate, but his plans were interrupted in 1789; the French Revolution changed both Fourier's life and the future of mathematics. Fourier was an early supporter of the revolution but an outspoken opponent of the Terror. He caught the eye of Napoleon and accompanied him to Egypt, where he became governor of lower Egypt. On his return to France in 1801 he became prefect of Isère, and during that time he conducted the investigations into heat flow that were to lead to the methodology that we now know as Fourier analysis.

Lord Kelvin called Fourier's *Théorie Analytique de la Chaleur* "a great mathematical poem," and Kelvin and P. G. Tait called Fourier's theorem "one of the most beautiful results of modern analysis ... an indispensable instrument in the treatment of nearly every recondite question in modern physics" (quoted in Bell, 1937).

Today, Fourier analysis is the cornerstone of many branches of science, engineering and mathematics. The modern field of image science can be traced to the turn-of-the century investigations of Ernst Abbé on the Fourier-transforming properties of lenses. Later work by P. M. Duffieux, Otto Schade, H. H. Hopkins, Edward O'Neill and others laid a firm foundation for the concepts of modulation transfer function and optical transfer function, which amount to analyzing an imaging system in terms of its Fourier decomposition. The full power of this approach to image science was evident by 1961 when Emmett Leith and Juris Upatnieks used Fourier methods to analyze holographic imaging systems.

The term Fourier analysis actually covers a diverse range of mathematical methods. We need to distinguish *Fourier series*, *Fourier transforms* and *discrete Fourier transforms*. The Fourier series is an expansion of a continuous function into a weighted sum of sines and cosines. We can view the Fourier-series

expansion as a continuous-to-discrete mapping; a function of a continuous variable is transformed into a discrete set of numbers. The Fourier transform, on the other hand, maps one function to another, so it is a continuous-to-continuous mapping or integral transform. The discrete Fourier transform (DFT), an often-used approximation to the Fourier integral, maps a discrete vector to another discrete vector, so it is a discrete-to-discrete mapping or matrix operator. Finally, the discrete-space Fourier transform, the spatial analog of the discrete-time Fourier transform often used in digital signal processing, maps an infinite sequence of data samples to a function, so it is a DC mapping. All four of these transforms are linear, so we can build on what we learned in Chap. 1 about linear operators.

Since Fourier analysis is all about sines and cosines, we begin in Sec. 3.1 with a short overview of some mathematical properties of these familiar trigonometric functions. Then in Sec. 3.2 we introduce the Fourier series and discuss its properties in some depth. In Secs. 3.3 and 3.4, the Fourier transform in one or several dimensions is developed as a generalization of the Fourier series, though it is also possible to go in the other direction and regard the Fourier series as a special case of the Fourier transform.

In Sec. 3.5 we discuss sampling, which can be viewed as a transformation from a function to a discrete set of numbers. Conditions under which this transformation is invertible and some specific inversion formulas are derived. In Sec. 3.6 we apply sampling theory and derive the discrete Fourier transform, which can be viewed either as an interesting matrix transformation in its own right or as an approximation to the continuous Fourier transform.

The available books on Fourier analysis tend to cluster into two classes. Engineering-oriented texts such as Gaskill (1978) and Bracewell (1965) are excellent compendia of practical properties of the transforms but spend little time discussing the underlying mathematical issues such as convergence and the applicability of the transforms to strange functions. At the opposite extreme, mathematical texts such as Champeney (1987) and Körner (1988) discuss these points at length but provide little guidance to the practitioner. To make matters worse, the mathematical literature itself is divided into two camps, depending on whether or not generalized functions are admitted.

In this chapter we attempt to take a middle ground. It is our hope that the chapter will indeed serve as a useful reference on practical properties of the transforms, but we also discuss conditions that must be imposed on the functions for the various results to hold in specified senses. Most importantly, we attempt to integrate generalized functions into the overall framework and to relate the transform theory to the Hilbert-space viewpoint that pervades this book.

As with the previous chapters, readers can skip over some of the more mathematical sections without loss of continuity. For example, any section with the word ‘convergence’ in its title can be skipped on a first reading. A few key results from these sections are used later, but they are called to the attention of the reader when needed.

3.1 SINES, COSINES AND COMPLEX EXPONENTIALS

3.1.1 Orthogonality on a finite interval

The basic building blocks of Fourier analysis are trigonometric functions of the form $\cos(2\pi nx/L)$ or $\sin(2\pi nx/L)$, where n is an integer and x is a real variable. The period of each of these functions is L/n , so the interval $-\frac{1}{2}L \leq x \leq \frac{1}{2}L$ contains exactly n cycles of both functions. The cosine is an even function of x on this interval and the sine is an odd function.

The reciprocal of the period, n/L , is the frequency associated with the periodic function $\cos(2\pi nx/L)$ or $\sin(2\pi nx/L)$. If x is a spatial variable, as it usually is in imaging applications, we shall refer to n/L as a spatial frequency and denote it ξ_n . Thus the functions $\{\cos(2\pi nx/L)\}$ and $\{\sin(2\pi nx/L)\}$ are sets of periodic functions with different spatial frequencies ξ_n indexed by the discrete parameter n . The numerical value of ξ_n is the number of cycles of $\cos(2\pi nx/L)$ or $\sin(2\pi nx/L)$ per unit length. For purposes of dimensional analysis, spatial frequency has dimensions $(\text{length})^{-1}$.

The following integrals involving these functions are well known from elementary calculus:

$$\frac{2}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \cos\left(\frac{2\pi nx}{L}\right) \cos\left(\frac{2\pi mx}{L}\right) = \delta_{mn}, \quad m \neq 0, \quad n \neq 0, \quad (3.1)$$

$$\frac{2}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \sin\left(\frac{2\pi nx}{L}\right) \sin\left(\frac{2\pi mx}{L}\right) = \delta_{mn}, \quad m \neq 0, \quad n \neq 0, \quad (3.2)$$

$$\int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \cos\left(\frac{2\pi nx}{L}\right) \sin\left(\frac{2\pi mx}{L}\right) = 0, \quad (3.3)$$

where m and n are integers and δ_{mn} is the Kronecker delta symbol, with value 1 if $n = m$ and 0 if $n \neq m$. The factor of 2 is required in (3.1) and (3.2) since, for $n = m \neq 0$, the integrals are L times the spatial averages of \sin^2 or \cos^2 over an integer number of periods. The average of \sin^2 or \cos^2 must be $\frac{1}{2}$ since the corresponding average of $\sin^2 + \cos^2$ is 1 and the average of \sin^2 must equal the average of \cos^2 over an integer number of periods.

The case $n = m = 0$ must be treated separately. The left-hand side of (3.1) is 2 in this case since both cosines are one, while the left-hand side of (3.2) is 0 since the sines are zero.

These sine and cosine functions are square-integrable over the interval $[-\frac{1}{2}L, \frac{1}{2}L]$, so they are vectors in the Hilbert space $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$. From the discussion in Chap. 1, the integrals in the three equations above will be recognized as scalar products in that space. Equations (3.1) and (3.2) say that $\{\sqrt{2/L} \cos(2\pi nx/L)\}$ and $\{\sqrt{2/L} \sin(2\pi nx/L)\}$ are two orthonormal sets in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$, while (3.3) says that any member of the first set is orthogonal to any member of the second.

We know from Chap. 1 that *complete* orthonormal sets are useful since they form a basis in terms of which any vector in the space can be expanded. The central question in Fourier analysis is whether the sets $\{\sqrt{2/L} \cos(2\pi nx/L)\}$ and $\{\sqrt{2/L} \sin(2\pi nx/L)\}$ are complete in that sense. This question is addressed in Sec. 3.2.

3.1.2 Complex exponentials

A more compact way to express the results of the last section uses complex exponentials. By DeMoivre's theorem (see App. B)

$$e^{i\theta} = \cos \theta + i \sin \theta. \quad (3.4)$$

Equation (3.4), like any equation involving complex variables, is really two equations, one for the real part and one for the imaginary part. These two simultaneous equations can be inverted to express the sine and cosine in terms of complex exponentials, with the result

$$\cos \theta = \frac{e^{i\theta} + e^{-i\theta}}{2}, \quad (3.5)$$

$$\sin \theta = \frac{e^{i\theta} - e^{-i\theta}}{2i}. \quad (3.6)$$

In terms of complex exponentials, the three orthogonality relations, (3.1)–(3.3), can be collapsed into a single equation:

$$\frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \exp\left(-\frac{2\pi inx}{L}\right) \exp\left(\frac{2\pi imx}{L}\right) = \delta_{mn}, \quad (3.7)$$

which is readily proved by separating real and imaginary parts and using (3.1)–(3.3). The ugly $\sqrt{2}$ has disappeared since the complex exponentials have modulus unity; if $n = m$, the integral is L . Also, it is no longer necessary to treat $n = 0$ or $m = 0$ separately.

In (3.7) we introduced a complex conjugate in the first exponential in keeping with the definition of a scalar product in \mathbb{L}_2 . If we denote $(1/\sqrt{L}) \exp(2\pi inx/L)$ as $u_n(x)$, (3.7) says that the $\{u_n(x)\}$ constitute an orthonormal set in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$. Again, the key question is whether they are a complete set.

3.1.3 Orthogonality on the infinite interval

In many applications of Fourier analysis, it is necessary to consider the infinite interval $-\infty < x < \infty$. If we simply let $L \rightarrow \infty$ in the treatment above, we run into difficulty because of the factor $1/\sqrt{L}$ in the definition of the orthonormal functions. Orthonormal functions with zero amplitude everywhere are of little use. A better approach is to designate the functions by a continuous index rather than a discrete one, so that n/L and m/L become the real continuous variables ξ and ξ' , respectively. Then the counterpart of (3.7) is

$$\int_{-\infty}^{\infty} dx \exp(-2\pi i\xi x) \exp(2\pi i\xi' x) = \delta(\xi - \xi'), \quad (3.8)$$

which is (2.45) in Chap. 2 with a notational change. In the limit $L \rightarrow \infty$, L times the Kronecker delta has become the Dirac delta.

Equation (3.8) says that the functions $\exp(2\pi i\xi x)$ and $\exp(2\pi i\xi' x)$ are orthogonal in the sense that their scalar product, defined appropriately for $\mathbb{L}_2(-\infty, \infty)$, vanishes if $\xi \neq \xi'$. If $\xi = \xi'$, however, the scalar product is infinite, so $\exp(2\pi i\xi x)$ is not itself a vector in $\mathbb{L}_2(-\infty, \infty)$. Nevertheless, we can expect from the discussions in Chap. 1 (see Sec. 1.1.6) that these complex exponentials will prove useful as a

basis for $\mathbb{L}_2(-\infty, \infty)$. Anticipating that result, we denote the set $\{\exp(2\pi i\xi x)\}$ as $\{u_\xi(x)\}$.

The corresponding orthogonality relations for sines and cosines are

$$2 \int_{-\infty}^{\infty} dx \cos(2\pi\xi x) \cos(2\pi\xi' x) = \delta(\xi + \xi') + \delta(\xi - \xi'), \quad (3.9)$$

$$2 \int_{-\infty}^{\infty} dx \sin(2\pi\xi x) \sin(2\pi\xi' x) = \delta(\xi - \xi') - \delta(\xi + \xi'). \quad (3.10)$$

Thus $\cos(2\pi\xi x)$ and $\cos(2\pi\xi' x)$ are orthogonal unless $\xi = \xi'$ or $\xi = -\xi'$, and similarly for the sines.

3.1.4 Discrete orthogonality

In the last section we converted the discrete index n in the function $\exp(2\pi i n x/L)$ into a continuous variable. We can also do the reverse and convert the continuous variable x into a discrete index k . In this case it is more convenient to work with the range $0 \leq x < L$ rather than the centered range used above. We get a discrete variable simply by dividing the range $[0, L)$ into K equal steps of size $\Delta x = L/K$ and defining

$$x_k = k\Delta x = \frac{kL}{K}, \quad k = 0, \dots, K-1. \quad (3.11)$$

The function $\exp(2\pi i n x/L)$ evaluated at $x = x_k$ is $\exp(2\pi i n k/K)$, which, for fixed n , is a set of K complex numbers or a $K \times 1$ vector. Of course, the index n specifies which $K \times 1$ vector we are considering. We denote by \mathbf{u}_n the vector for which the k^{th} component is given by $(1/\sqrt{K}) \exp(2\pi i n k/K)$. With the scalar product appropriate to the K -dimensional Euclidean space \mathbb{E}^K , we have the following orthogonality relation:

$$(\mathbf{u}_m, \mathbf{u}_n) = \frac{1}{K} \sum_{k=0}^{K-1} e^{2\pi i(m-n)k/K} = \delta_{mn}. \quad (3.12)$$

This result can be derived algebraically by recognizing the sum as a geometric series, with terms of the form t^k , where $t = \exp[2\pi i(m-n)/K]$. The usual expression for the sum of a geometric series then gives (3.12). A more intuitive view of the same result is given in the next section.

3.1.5 View from the complex plane

For fixed x , the function $u_n(x) = \exp(2\pi i n x/L)$ can be represented as a point on the unit circle in the complex plane or as a vector from the origin to that point. The axes in this complex representation are the real and imaginary parts of $u_n(x)$. The angle between the vector and the real axis is the phase, $2\pi n x/L$, which increases linearly as x increases. For this reason, the complex exponential is often referred to as a *linear phase factor*. The term *phasor* is also frequently encountered, especially in the electrical engineering literature.

A useful mental image is that there is a vector in the complex plane associated with each value of x , with the vector rotating linearly as x increases (see Fig. 3.1). The spatial frequency n/L specifies the rate of rotation.

Fig. 3.1 Illustration of a complex exponential or linear phase factor $\exp(2\pi i \xi_0 x)$.

This viewpoint can be used to give geometric interpretations of the various orthogonality relations derived above. Consider first (3.7). The integrand is the product of two complex exponentials, which is itself a complex exponential, $\exp[2\pi i(m-n)x/L]$. The resulting vector in the complex plane makes an angle $2\pi(m-n)x/L$ with the real axis. Again, this angle increases linearly as x varies, with the rate of rotation now specified by the *difference* in spatial frequencies, $(m-n)/L$. As x varies over the range of integration from $-\frac{1}{2}L$ to $\frac{1}{2}L$, the vector rotates through a total angle of $2\pi(m-n)$, which is an integer number of turns since $m-n$ is an integer. Each x in the range of integration is paired with another x such that the vector is oppositely directed. The integral, being just the sum of all these vectors, is zero unless $m=n$.

Similarly, in (3.12), the complex number $\exp[2\pi i(m-n)k/K]$ is a vector in the complex plane, making an angle $2\pi(m-n)k/K$ with the real axis. If $m=n$, the angles are zero for each k , and the sum is K , but if $m \neq n$, the vectors are uniformly spaced in angle and the vector sum is zero.

3.2 FOURIER SERIES

3.2.1 Basic concepts

Consider a one-dimensional (1D) function $f(x)$ defined on the interval $-\frac{1}{2}L \leq x < \frac{1}{2}L$. In the next section we shall be more precise about the requirements on $f(x)$, but for now we simply assume that it can be expanded in terms of sines and cosines in the form

$$f(x) = F_0 + \sum_{n=1}^{\infty} F_n^{(c)} \cos\left(\frac{2\pi n x}{L}\right) + \sum_{n=1}^{\infty} F_n^{(s)} \sin\left(\frac{2\pi n x}{L}\right). \quad (3.13)$$

Discussion of the validity of this form and the sense in which the series converges to $f(x)$ is postponed to the next section.

How do we find the coefficients of the expansion in (3.13)? The first term, F_0 , is found by integrating both sides of (3.13) from $-\frac{1}{2}L$ to $\frac{1}{2}L$, with the result

$$F_0 = \frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} f(x) dx, \quad (3.14)$$

since all other terms in (3.13) yield integrals of a sine or cosine over an integer number of periods and hence integrate to zero. Thus F_0 is simply the average of $f(x)$ over the interval. The coefficient F_0 is often referred to colloquially as the *DC term*; if x is a temporal variable and $f(x)$ is an electrical current, F_0 is the average or direct-current component, and the terminology has carried over to spatial variables as well.

To find the other coefficients, we multiply (3.13) by either $\cos(2\pi mx/L)$ or $\sin(2\pi mx/L)$, integrate over the same interval as before, and make use of the orthogonality relations, (3.1)–(3.3). The results are

$$F_n^{(c)} = \frac{2}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f(x) \cos\left(\frac{2\pi nx}{L}\right), \quad (3.15)$$

$$F_n^{(s)} = \frac{2}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f(x) \sin\left(\frac{2\pi nx}{L}\right). \quad (3.16)$$

It follows from these equations that $F_n^{(c)}$ and $F_n^{(s)}$ are real numbers if $f(x)$ is a real-valued function (or simply a real function for short).

If $f(x)$ is an even function, so that $f(-x) = f(x)$, then $F_n^{(s)} \equiv 0$ and only the cosine series is needed. Similarly, if $f(x)$ is odd, so that $f(-x) = -f(x)$, then $F_n^{(c)} \equiv 0$ and only the sine series is needed.

Fourier series in terms of complex exponentials A more compact way to state these results is by use of complex exponentials, so that the Fourier series takes the form

$$f(x) = \sum_{n=-\infty}^{\infty} F_n e^{2\pi inx/L}. \quad (3.17)$$

To find the coefficients $\{F_n\}$, we multiply both sides of (3.17) by $\exp(-2\pi imx/L)$ and integrate from $-\frac{1}{2}L$ to $\frac{1}{2}L$. With the orthogonality relation of (3.7), we find

$$\begin{aligned} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx e^{-2\pi imx/L} f(x) &= \sum_{n=-\infty}^{\infty} F_n \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx e^{-2\pi imx/L} e^{2\pi inx/L} \\ &= \sum_{n=-\infty}^{\infty} F_n L \delta_{mn} = LF_m. \end{aligned} \quad (3.18)$$

Solving for F_m and changing the dummy index m to n yields

$$F_n = \frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f(x) e^{-2\pi inx/L}. \quad (3.19)$$

Thus, if we know *a priori* that $f(x)$ can be expanded in the form of (3.17), the coefficients in the expansion are given by (3.19). The question of when $f(x)$ can be so represented will be treated in Sec. 3.2.2.

Periodicity We assumed above that $f(x)$ was defined on the interval $[-\frac{1}{2}L, \frac{1}{2}L]$, and of course the coefficients were fully determined by the values of $f(x)$ in this interval. It is, however, interesting to inquire about the behavior of the series outside that interval. Since the function $\exp(2\pi inx/L)$ is periodic with period L/n , where n is an integer, it is also periodic with period L . Since this is true for every term in the Fourier series, it is true for the sum as well (if the sum converges). That is,

$$f(x + mL) = f(x), \quad m = 0, \pm 1, \pm 2, \dots, \quad (3.20)$$

provided $f(x)$ is expressed by (3.17). We thus have two different ways of looking at the Fourier series. It is a representation of an arbitrary function on the interval $[-\frac{1}{2}L, \frac{1}{2}L]$, and it is a representation of a periodic function¹ with period L on the interval $(-\infty, \infty)$.

This view gives us alternative ways of expressing the Fourier coefficients. Since both factors in the integrand of (3.19) are periodic with period L , we can perform the integration over any period we choose. For example, it is straightforward to show that (3.19) is equivalent to

$$F_n = \frac{1}{L} \int_0^L dx f(x) e^{-2\pi inx/L} \quad (3.21)$$

if $f(x)$ has the periodic symmetry stated by (3.20).

Relation to the Laurent series For x real, the complex exponential $\exp(2\pi inx/L)$ lies on the unit circle in the complex plane. We can use this observation to relate the Fourier series to the Laurent series for functions of a complex variable (see App. B).

We define $w(x) \equiv \exp(2\pi ix/L)$, but we shall immediately drop the argument and write simply w for $w(x)$. Then the basic Fourier kernel is related to w by

$$\exp(2\pi inx/L) = w^n. \quad (3.22)$$

To get to the Laurent series, $f(x)$, must also be expressed in terms of w . To this end we define

$$f(x) = f_w(w) = f_w(e^{2\pi ix/L}). \quad (3.23)$$

The *Fourier* series for $f(x)$ is then the *Laurent* series for $f_w(w)$ around the point $w = 0$, *i.e.*,

$$f(x) = f_w(w) = \sum_{n=-\infty}^{\infty} F_n w^n. \quad (3.24)$$

The Laurent coefficients are identical to the Fourier coefficients. A change of variables from x to w in (3.19) allows us to write

$$F_n = \frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f(x) e^{-2\pi inx/L} = \frac{1}{2\pi i} \oint_C dw \frac{f_w(w)}{w^{n+1}}, \quad (3.25)$$

where the contour integral is around the unit circle, denoted C . Equation (3.25) is identical (except for notation) to the relation given in App. B for Laurent coefficients.

¹If the original definition of $f(x)$ on $[-\frac{1}{2}L, \frac{1}{2}L]$ does not have $f(-\frac{1}{2}L) = f(\frac{1}{2}L)$, then the corresponding periodic function on $(-\infty, \infty)$ will have periodically placed discontinuities.

A potential advantage of the Laurent series is that it would allow us to analytically extend $f(x)$ from a function of a real variable to a function of a complex variable, and the theory of Laurent series would enable us to make statements about convergence. Though we shall not have use for this extension, a related extension will prove useful when we discuss Fourier transforms in Sec. 3.3. For the remainder of the chapter, x will continue to denote a real variable.

3.2.2 Convergence of the Fourier series

In Sec. 3.2.1 we assumed that $f(x)$ could be represented by a Fourier series and used the orthogonality relations to derive expressions for the coefficients. In this section we pose the opposite question: Given the series and the coefficients, to what function does it converge?

To make this question more precise, we define

$$S_N(x) = \sum_{n=-N}^N F_n e^{2\pi i n x / L}, \quad (3.26)$$

where the $\{F_n\}$ are now *defined* by (3.19). This sum is called the N^{th} partial sum of the Fourier series of $f(x)$. For any finite N , $S_N(x)$ is a continuous, periodic function of x with period L (Champeney, 1987). We discuss below several ways in which S_N might converge to $f(x)$.

Pointwise convergence If $f(x)$ is smooth in some sense, there is no difficulty in showing that $S_N(x) \rightarrow f(x)$ for all x as $N \rightarrow \infty$. One way we could demonstrate this point is by use of the Laurent series introduced above. As we have used it, the Laurent series is convergent if $f_w(w)$ is analytic on the unit circle. As discussed in App. B, all derivatives of analytic functions exist. From this we can deduce that $S_N(x)$ converges to $f(x)$ at all x if all derivatives of $f_w(w)$ exist for w on the unit circle, which implies that all derivatives of $f(x)$ exist for real x . This result is of extremely limited usefulness.

A somewhat less restricted convergence statement is a classical theorem due to Dirichlet (Körner, 1988; Stakgold, 1979). If $f(x)$ is continuous and has a bounded continuous derivative on $(-\frac{1}{2}L, \frac{1}{2}L)$, except possibly at a finite number of points, then $S_N(x)$ converges to $f(x)$ for all points where $f(x)$ is continuous in that interval. This is an improvement over the previous paragraph, but it still does not encompass all of the functions for which we might want to construct a Fourier series. For more interesting functions, $S_N(x)$ may converge but not to $f(x)$, or it may not converge at all.

Consider two functions $f_1(x)$ and $f_2(x)$ that differ only at an isolated point x_0 . If the values of both functions at x_0 are finite, these functions have the same set of Fourier coefficients since the isolated point does not affect the integrals. Hence the two functions have the same $S_N(x)$ for all N , so $S_N(x)$, while it may converge, cannot converge to both functions at every point. A simple way to deal with this problem is to say that $f_1(x)$ and $f_2(x)$ are really the same function *almost everywhere*. This disclaimer, often abbreviated *a.e.*, allows us to disregard the isolated point. The isolated point (or any countable set of points) is, in mathematical jargon, a set of measure zero, which simply means it doesn't affect any integrals so we don't worry about it.

Having dismissed problems arising from isolated points, we turn next to discontinuities in $f(x)$. Consider a point x_0 where $f(x)$ is bounded but discontinuous and assume that the limit of $f(x)$ exists as $x \rightarrow x_0$ from both directions. Denote the

limit from above by $f(x_0^+)$ and from below by $f(x_0^-)$. A classical result (Stakgold, 1979) is that $S_N(x_0) \rightarrow \frac{1}{2}[f(x_0^+) + f(x_0^-)]$ as $N \rightarrow \infty$. A similar conclusion follows if $f(x)$ has a finite number of finite discontinuities. In other words, if we simply redefine $f(x)$ such that its value at every discontinuity is the average of its values on the two sides, we can say that $S_n(x)$ converges to $f(x)$ everywhere; without redefinition, we still need the *almost everywhere* disclaimer to exclude the discontinuity.

Many other theorems relate to the pointwise convergence of Fourier series (Champeney, 1987; Titchmarsh, 1948). The following theorem, quoted from Champeney, provides some useful guidelines:

Suppose that $f(x)$ is periodic of period L , defined and bounded on $[-\frac{1}{2}L, \frac{1}{2}L]$, and that at least one of the following four conditions is satisfied: (i) $f(x)$ is piecewise monotonic on $[-\frac{1}{2}L, \frac{1}{2}L]$; (ii) $f(x)$ has a finite number of maxima and minima on $[-\frac{1}{2}L, \frac{1}{2}L]$ and a finite number of discontinuities on $[-\frac{1}{2}L, \frac{1}{2}L]$; (iii) $f(x)$ is of bounded variation on $[-\frac{1}{2}L, \frac{1}{2}L]$; (iv) $f(x)$ is piecewise smooth on $[-\frac{1}{2}L, \frac{1}{2}L]$. Then the Fourier series coefficients can be defined by (3.19), using proper Riemann integrals, and the Fourier series given by (3.26) converges to $f(x)$ at each point of continuity of $f(x)$ and to the value $\frac{1}{2}[f(x_0^+) + f(x_0^-)]$ at all x .

While the conditions listed above allow considerable latitude in the function $f(x)$, clever mathematicians can always find pathological cases. Certain peculiar functions with a fractal character may be everywhere continuous but nowhere differentiable (Walker, 1991; Körner, 1988). These functions are not covered by the theorem above; for example, they have an infinite number of maxima and minima in a finite interval. In such cases, it is possible that the Fourier series for a periodic and everywhere continuous function can diverge for some x and even for a nondenumerable and dense set of x values. About all that can be proved unequivocally is that the Fourier series of a continuous function cannot diverge everywhere (Champeney, p. 157).

Uniform convergence After pointwise convergence, the next kind to consider is uniform convergence (Champeney, p. 26). Even though $S_N(x)$ may converge pointwise almost everywhere to $f(x)$, the rate of convergence may be different for different x , so that even at large N , $f(x) - S_N(x)$ may not be small for some x . A formal definition of uniform convergence is that the least upper bound of $|f(x) - S_N(x)|$ over any interval of x tends to 0 as N goes to ∞ .

One simple way to ensure uniform convergence of the Fourier series is to require that the function and its derivative be continuous (Stakgold, 1979). If the function is discontinuous, however, there is a well known failure of the condition of uniform convergence. As illustrated in Fig. 3.2, there is an oscillation and a significant overshoot near the point of discontinuity. As N gets larger, the spatial extent of the oscillation decreases, but the peak amplitude of the overshoot does not tend to zero. This finite limiting overshoot is known as the *Gibbs phenomenon* (after the American physicist J. Willard Gibbs). The Gibbs phenomenon does not contradict the fact that the Fourier series converges pointwise, but it does show that the convergence is not uniform in an interval surrounding the discontinuity (Stakgold, 1979, p. 135). A good discussion of the Gibbs phenomenon is given in Carslaw (1930).

Fig. 3.2 Illustration of the Gibbs phenomenon. The function $f(x)$ was a rect function, and the partial Fourier sum $S_N(x)$ from (3.26) is shown for three values of N . Though the oscillations become more rapid as N increases, the amount of overshoot error does not change.

Convergence in the \mathbb{L}_2 sense Another important kind of convergence is *convergence in the \mathbb{L}_2 sense*, which is often referred to in the literature as *convergence in the mean*. If we approximate $f(x)$ by $S_N(x)$, the mean-square error in the approximation is just $1/L$ times the square of the \mathbb{L}_2 norm of $f(x) - S_N(x)$. Convergence in the mean states that this mean-square error tends to zero as N tends to ∞ . To be precise, if we assume that $f(x)$ is in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$, then

$$\lim_{N \rightarrow \infty} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx |f(x) - S_N(x)|^2 = 0. \quad (3.27)$$

A formal proof of this theorem is given in Stakgold (1979), and a less formal one based on properties of delta functions is given below.

This kind of convergence says that if we use the Fourier series in place of the original function $f(x)$, the error we make is a function with zero length, in the sense of its \mathbb{L}_2 norm. In particular, if we form a scalar product with any function $h(x)$ in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$, it does not matter whether we use $f(x)$ or its Fourier-series representation, *i.e.*,

$$\int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx h^*(x) f(x) = \lim_{N \rightarrow \infty} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx h^*(x) S_N(x). \quad (3.28)$$

Equation (3.27) says that $f(x) - S_N(x)$ tends to the zero vector in \mathbb{L}_2 , and (3.28) is the extension that any scalar product with the zero vector is zero.

A proof of (3.27) and (3.28) based on properties of delta functions is instructive. If we use (3.26) for $S_N(x)$ and (3.19) for the coefficients, the right-hand side of (3.28) becomes

$$\lim_{N \rightarrow \infty} \frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx' h^*(x) f(x') \sum_{n=-N}^N e^{2\pi i n(x-x')/L}. \quad (3.29)$$

The sum is a geometric series with terms of the form $s^n = \exp(i\alpha n)$, where $\alpha = 2\pi(x - x')/L$. From (2.50) we know that

$$\lim_{N \rightarrow \infty} \sum_{n=-N}^N e^{2\pi i n(x-x')/L} = \text{comb} \left(\frac{x-x'}{L} \right). \quad (3.30)$$

As discussed in Chap. 2, the comb function is an infinite series of delta functions, but in the present problem only one of them lies in the range of integration, $(-\frac{1}{2}L, \frac{1}{2}L)$, so $\text{comb}(x)$ is equivalent to $\delta(x)$. Moreover, this delta function has the sifting property (2.24) not only for test functions but also for all functions in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$ if convergence in the mean is understood (Champeney, 1987, p. 35). Thus (3.29) becomes

$$\frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx' h^*(x) f(x') \delta\left(\frac{x-x'}{L}\right) = \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx h^*(x) f(x), \quad (3.31)$$

again establishing (3.28) and the conclusion that $S_N(x) - f(x)$ converges to the zero vector in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$.

Having established that $S_N(x)$ converges to $f(x)$ and recalling our previous discussion of orthogonality, we are now justified in claiming that the complex exponentials $\{(1/\sqrt{L}) \exp(2\pi i n x/L)\}$ form a complete, orthonormal basis in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$. This basis set is infinite but denumerable. Note that neither $\{\cos(2\pi n x/L)\}$ nor $\{\sin(2\pi n x/L)\}$ by itself is a complete basis (unless we restrict attention to even or odd functions). Both sines and cosines, or equivalently complex exponentials, are needed to expand an arbitrary function in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$.

Fourier series divergent at a point So far we have been discussing situations where $S_N(x)$ converges to *something* at all x , though not necessarily to $f(x)$. It is also possible that $S_N(x)$ does not converge at all for one or more values of x .

One way to deal with such situations is to treat the resulting series not as an ordinary function but as a generalized function. As discussed in Chap. 2, a generalized function is defined by multiplying it by a well behaved test function $t(x)$ and integrating. Thus, if we can assign a meaning to the integral

$$\int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx t(x) f(x) = \lim_{N \rightarrow \infty} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx t(x) \sum_{n=-N}^N F_n e^{2\pi i n x/L}, \quad (3.32)$$

then we shall have defined the generalized function $f(x)$ associated with the Fourier coefficients $\{F_n\}$, even if the series by itself does not converge.

As a simple example, consider the case where $F_n = 1$ for all n . The Fourier series diverges at $x = 0$, but the right-hand side of (3.32) can be written as

$$\lim_{N \rightarrow \infty} \sum_{n=-N}^N \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx t(x) e^{2\pi i n x/L} = \lim_{N \rightarrow \infty} L \sum_{n=-N}^N T_{-n} = \lim_{N \rightarrow \infty} L \sum_{n=-N}^N T_n = Lt(0), \quad (3.33)$$

where T_n is the well-defined Fourier coefficient of the continuous test function $t(x)$. Since exactly this same result would be obtained by integrating $Lt(x)\delta(x)$, we can say

$$\sum_{n=-\infty}^{\infty} e^{2\pi i n x/L} = \delta(x/L) = L\delta(x), \quad -\frac{1}{2}L < x < \frac{1}{2}L. \quad (3.34)$$

Furthermore, since any Fourier series is periodic, we can remove the restriction on x and write

$$\sum_{n=-\infty}^{\infty} e^{2\pi i n x/L} = \text{comb}(x/L). \quad (3.35)$$

Equation (3.30) provides another example of a divergent Fourier series. It can be regarded as a Fourier series with coefficients given by $F_n = \exp(-2\pi i n x'/L)$, where x' is a constant. The resulting Fourier series diverges if $x = x' + k/L$, where k is any integer, but it can be treated as the generalized function $\text{comb}[(x - x')/L]$. Some other examples will be introduced below when we discuss derivatives of a Fourier series.

Mollifying a divergent series A common trick in mathematical physics is to deal with a divergent sum or integral by introducing a *convergence factor* in the summand or integrand. This factor is chosen so that, in some limit, it becomes unity, but the new sum or integral nevertheless converges. Fortunately, there is a good mathematical justification for this trick, as we shall see here for the case of a divergent Fourier series.

Consider a function $f(x)$ with Fourier coefficients given by the usual integral, (3.19). For this integral to exist, it is sufficient for $f(x)$ to be absolutely integrable, *i.e.*, in $\mathbb{L}_1(-\frac{1}{2}L, \frac{1}{2}L)$. If that is the case, then F_n is bounded since

$$|F_n| = \frac{1}{L} \left| \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f(x) e^{-2\pi i n x} \right| \leq \frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx |f(x) e^{-2\pi i n x}| = \frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx |f(x)|. \quad (3.36)$$

This condition is not, however, sufficient to guarantee the convergence of the Fourier series, so it is not clear to what extent a function in $\mathbb{L}_1(-\frac{1}{2}L, \frac{1}{2}L)$ can be reconstructed from its Fourier coefficients. (A function in $\mathbb{L}_1(-\frac{1}{2}L, \frac{1}{2}L)$ need not be in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$, as shown by the example of a delta function.)

The key question is the following: Given a set of Fourier coefficients of a function in $\mathbb{L}_1(-\frac{1}{2}L, \frac{1}{2}L)$, can we recover the function even when the series diverges? Surprisingly, the answer to this question is yes. Consider two new partial sums defined by

$$S_N^{(C)}(x) = \sum_{n=-N}^N \left(1 - \frac{|n|}{N}\right) F_n e^{2\pi i n x/L}, \quad (3.37)$$

$$S_\lambda^{(A)}(x) = \sum_{n=-\infty}^{\infty} e^{-|n|/\lambda} F_n e^{2\pi i n x/L}. \quad (3.38)$$

The first of these sums was devised by Cesaro and the second by Abel, hence the superscripts. The additional factor in the summand in each case is the convergence factor. If $N \rightarrow \infty$ or $\lambda \rightarrow \infty$, these factors approach unity for any fixed, finite n , so they would not appear to influence the sums in the limit; in fact, they don't if the original Fourier series converges. The nice result, however, is that these partial sums can converge to $f(x)$ in some sense even when the Fourier series diverges, *i.e.*,

$$\lim_{N \rightarrow \infty} S_N^{(C)}(x) = f(x), \quad (3.39)$$

$$\lim_{\lambda \rightarrow \infty} S_\lambda^{(A)}(x) = f(x). \quad (3.40)$$

Convergence proofs can be found in Körner (1988) and Champeny (1987). For example, it can be shown that the sums in (3.37) and (3.38) converge in all of the

following senses (Champeney, p. 159):

- (a) To $f(x)$ almost everywhere;
- (b) To $f(x)$ at each point of continuity;
- (c) Uniformly to $f(x)$ on an interval $[a, b]$ whenever $f(x)$ is continuous on $[a-\epsilon, b+\epsilon]$ for some $\epsilon > 0$;
- (d) To $\frac{1}{2}[f(x^+) + f(x^-)]$ at each point where $f(x^+)$ and $f(x^-)$ exist, where $f(x^\pm) = \lim_{\epsilon \rightarrow 0} f(x \pm \epsilon)$;
- (e) As a limit in the mean in the L_1 sense over $(-\frac{1}{2}L, \frac{1}{2}L)$;
- (f) To the Lebesgue value of $f(x)$ at each Lebesgue point.

A Lebesgue value is simply the local average of $f(x)$ over some small region, where the average is defined by an integral in the Lebesgue sense (Champeney, p. 31). A Lebesgue point is one where such an integral exists.

The uniform convergence in point (c) is interesting. It says that the Gibbs phenomenon is eliminated by inclusion of the convergence factors.

The use of a convergence factor can be illustrated by returning to our example of a delta function, where $f(x) = \delta(x)$ and $F_n = 1/L$ for all n . In this case the limit of the Cesaro partial sum can be written

$$\lim_{N \rightarrow \infty} S_N^{(C)}(x) = \lim_{N \rightarrow \infty} \frac{1}{L} \sum_{n=-N}^N \left(1 - \frac{|n|}{N}\right) e^{2\pi i n x / L}. \quad (3.41)$$

Using results to be derived later [the Poisson summation formula (3.197) and the expression for the Fourier transform of a triangle function, (3.141)], we find

$$\begin{aligned} \lim_{N \rightarrow \infty} S_N^{(C)}(x) &= \lim_{N \rightarrow \infty} \frac{N}{L} \sum_{n=-N}^N \operatorname{sinc}^2 \left[\frac{N}{L}(x - nL) \right] \\ &= \sum_{n=-\infty}^{\infty} \delta(x - nL) = \frac{1}{L} \operatorname{comb} \left(\frac{x}{L} \right), \end{aligned} \quad (3.42)$$

where we have used (2.48) and (2.87). This is the correct answer since the function $f(x) = \delta(x)$ in $(-\frac{1}{2}L, \frac{1}{2}L)$ corresponds to $(1/L) \operatorname{comb}(x/L)$ when periodically extended.

The relation between this subsection and the previous one should not be overlooked. Above we didn't worry about the divergence of the Fourier series at a point but simply used the divergent series to define a generalized function. Here we fixed up the divergence with a convergence factor, arriving at a limiting representation for the same generalized function. Different choices of convergence factors lead to different limiting representations. For example, the reader may wish to show that the Abel convergence factor leads to (2.39).

3.2.3 Properties of the Fourier coefficients

Having found expressions for the Fourier coefficients and discussed the convergence properties of the series, we now examine some important practical properties of the coefficients.

Linearity The mapping from a function $f(x)$ to its Fourier coefficients is a linear operator, as defined in Chap. 1. If we define

$$h(x) = \alpha f(x) + \beta g(x), \quad (3.43)$$

where α and β are constants, then

$$H_n = \alpha F_n + \beta G_n, \quad (3.44)$$

where F_n , G_n , and H_n are Fourier coefficients of $f(x)$, $g(x)$ and $h(x)$, respectively.

Real functions Up until now, we have not imposed the requirement that $f(x)$ be real-valued; all of our results hold even if it is complex-valued. In practical applications, $f(x)$ will often be real, so of course its Fourier series must be real as well. By a change of variables, $x' = -x$, in (3.19), it can be seen that

$$F_n^* = F_{-n} \quad \text{if } f(x) \text{ is real.} \quad (3.45)$$

A consequence of this relation is that F_0 must be real if $f(x)$ is.

Equation (3.45) is sometimes referred to as the Hermiticity of the Fourier coefficients, and the series itself is said to be Hermitian. This terminology derives from properties of Hermitian matrices, where interchange of rows and columns followed by complex conjugation leaves the matrix element unchanged. Here we see that replacement of n with $-n$ followed by complex conjugation leaves F_n unchanged if it is a Fourier coefficient of a real function, so many writers use the term Hermitian to describe this symmetry. An unfortunate aspect of this terminology is that it is likely to foster the impression that we are dealing with Hermitian operators, which we are not.

Even and odd functions Additional restrictions on the Fourier coefficients arise from symmetry of $f(x)$. In Sec. 3.2.1, we noted that an even function could be described completely by a Fourier cosine series, while an odd function required only the sine series. In terms of the coefficients in the complex exponential series, this implies

$$F_n = F_{-n} \quad \text{if } f(x) = f(-x), \quad (3.46a)$$

$$F_n = -F_{-n} \quad \text{if } f(x) = -f(-x). \quad (3.46b)$$

Thus even (odd) functions have Fourier coefficients that are even (odd) when we replace n with $-n$.

Combining (3.45) and (3.46), we can make stronger statements: If $f(x)$ is real and even, its Fourier coefficients are also real and even, while if $f(x)$ is odd, its coefficients are pure imaginary and odd.

Asymptotic behavior It is of considerable importance to know how F_n behaves as n tends to $\pm\infty$. The answer depends on the properties of $f(x)$, but the following theorem, proved by Stakgold (1979) is often useful: If $f(x)$ is in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$ and the $\{F_n\}$ are defined by (3.19), then

$$\lim_{n \rightarrow \pm\infty} F_n = 0 \quad (3.47)$$

and the decay of F_n is sufficiently rapid so that

$$\sum_{n=-\infty}^{\infty} |F_n|^2 < \infty. \quad (3.48)$$

Moreover, the rate of decay is dependent on the smoothness of $f(x)$. If we know that $f(x)$ is continuous and has continuous derivatives up to at least order q , then (Stakgold, 1979)

$$\lim_{n \rightarrow \pm\infty} n^q F_n = 0. \quad (3.49)$$

We can understand these results intuitively by envisioning the real and imaginary parts of the integrand in (3.19). When a sine or cosine is multiplied by a smooth function, adjacent positive and negative half-cycles tend to cancel out. This cancellation becomes more complete as the frequency of the sine or cosine increases or as the function becomes smoother.

Parseval's relations Equation (3.48) says that the sum of squared moduli of the Fourier coefficients converges if $f(x)$ is in $L_2(-\frac{1}{2}L, \frac{1}{2}L)$. What it converges to is interesting. An important result called Parseval's identity states that

$$\sum_{n=-\infty}^{\infty} |F_n|^2 = \frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx |f(x)|^2. \quad (3.50)$$

This equation is a special case of a more general formula, known as the power theorem or generalized Parseval's theorem, which relates to products of two different functions, $f(x)$ and $g(x)$:

$$\sum_{n=-\infty}^{\infty} F_n^* G_n = \frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f^*(x) g(x). \quad (3.51)$$

There are several ways to derive these relations. A one-liner adapted from Marks (1991) starts by expressing $f^*(x)$ in (3.51) in terms of its Fourier series. From the complex conjugate of (3.17), we have

$$\frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f^*(x) g(x) = \frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \sum_{n=-\infty}^{\infty} F_n^* e^{-2\pi i n x / L} g(x). \quad (3.52)$$

Interchanging sum and integral and recognizing the integral as G_n completes the proof of (3.51), while setting $f(x) = g(x)$ establishes (3.50).

An alternative derivation of the generalized Parseval relation parallels the derivation given for (3.28). We begin with the left-hand side of (3.51) and insert the integral expressions for both Fourier coefficients. Regarding the infinite sum as the limit of partial sums, we obtain

$$\begin{aligned} \sum_{n=-\infty}^{\infty} F_n^* G_n &= \lim_{N \rightarrow \infty} \frac{1}{L^2} \sum_{n=-N}^N \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f^*(x) e^{2\pi i n x / L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx' g(x') e^{-2\pi i n x' / L} \\ &= \lim_{N \rightarrow \infty} \frac{1}{L^2} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx' f^*(x) g(x') \sum_{n=-N}^N e^{2\pi i n (x-x') / L}. \end{aligned} \quad (3.53)$$

By arguments identical to those used below (3.29), the sum becomes a delta function, and (3.51) follows.

Fourier series and unitary transformations Parseval's relations have an important interpretation in terms of scalar products. The right-hand side of (3.51) is $1/L$ times the \mathbb{L}_2 scalar product of $g(x)$ and $f(x)$, while the left-hand side can be interpreted as a scalar product in an infinite-dimensional Euclidean space \mathbb{E}^∞ . If we regard the process of constructing a Fourier series as a linear transformation from \mathbb{L}_2 to \mathbb{E}^∞ , the generalized Parseval relation says that the transformation preserves the scalar product except for the factor of $1/L$. Similarly, (3.50) says that the norm is preserved within $1/L$.

In Chap. 1 we saw that *unitary* transformations preserve norms and scalar products and that transformations based on orthonormal functions are unitary (see Sec. 1.4.5). The only reason the transformation from $f(x)$ to the set of Fourier coefficients $\{F_n\}$ is *not* unitary is that we did not define the coefficients with properly normalized orthonormal functions. As we have seen, the orthonormal set is $\{(1/\sqrt{L})\exp(2\pi inx/L)\}$, while the Fourier coefficients are defined with $1/L$ rather than $1/\sqrt{L}$. Except for the gratuitous factor of \sqrt{L} , the transformation from $f(x)$ to $\{F_n\}$ is unitary, and the Parseval relations follow.

Differentiation and integration of a Fourier series Suppose $f(x)$ is continuous and has a continuous derivative $f'(x)$ for some interval of x . Then both $f(x)$ and $f'(x)$ can be represented by Fourier series in this interval. Direct differentiation of the series for $f(x)$ yields

$$f'(x) = \sum_{n=-\infty}^{\infty} \frac{2\pi in F_n}{L} e^{2\pi inx/L}. \quad (3.54)$$

Hence the Fourier coefficients for $f'(x)$ are $\{2\pi in F_n/L\}$, where $\{F_n\}$ are the coefficients for $f(x)$.

Several comments about this result are in order. First, in spite of the factor of i , $f'(x)$ is real if $f(x)$ is real since replacing n with $-n$ and taking the complex conjugate leaves the product in unchanged [see (3.32)]. Second, if $f'(x)$ exists, the series in (3.54) will converge. Finally, if the series in (3.54) does not converge, we can nevertheless interpret it as a series representation of a generalized function.

For example, consider the function $f(x) = \text{rect}(2x/L)$ defined in (2.9). As discussed in Chap. 2, this function is discontinuous at $x = \pm L/4$, and its derivative, interpreted as a generalized function, has a delta function of weight $+1$ at $x = -L/4$ and another of weight -1 at $x = +L/4$. To show the same result in terms of Fourier series, we first expand $f(x)$ and then use (3.54). It follows that $F_0 = \frac{1}{2}$ and $F_n = (1/\pi n) \sin(\pi n/2)$ for $n \neq 0$. Hence the coefficients for $f'(x)$ are $(2i/L) \sin(\pi n/2)$ for all n . The series for $f'(x)$ does not converge at $x = \pm L/4$, but we can write

$$f'(x) = \sum_{n=-\infty}^{\infty} \frac{2i}{L} \sin(\pi n/2) e^{2\pi inx/L} = \delta(x + \frac{L}{4}) - \delta(x - \frac{L}{4}), \quad -\frac{1}{2}L \leq x < \frac{1}{2}L. \quad (3.55)$$

The validity of this form can be checked by multiplying by a test function and integrating. Starting with the right-hand side, we obtain

$$\int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx t(x) [\delta(x + \frac{L}{4}) - \delta(x - \frac{L}{4})] = t(-\frac{L}{4}) - t(\frac{L}{4}). \quad (3.56)$$

This result can be written in terms of the Fourier series for $t(x)$ evaluated at $x = \pm L/4$, with the result

$$t\left(-\frac{L}{4}\right) - t\left(\frac{L}{4}\right) = \sum_{n=-\infty}^{\infty} T_n \left[e^{-i\pi n/2} - e^{i\pi n/2} \right]. \quad (3.57)$$

The same result is obtained by multiplying the left-hand side of (3.55) by $t(x)$ and integrating, so (3.55) is a valid representation of the divergent series for the derivative of the rect function.

Integration of a Fourier series is much simpler than differentiation. A term-by-term indefinite integral introduces a factor of $1/(2\pi in)$, which can only help the convergence as $n \rightarrow \infty$. It can be proved that any Fourier series, whether convergent or not, can be integrated term by term between any limits. The integrated series converges to the integral of the periodic function corresponding to the original series (Sokolnikoff and Redheffer, 1958).

3.3 1D FOURIER TRANSFORM

3.3.1 Basic concepts

The Fourier series is an expansion of a function on a finite interval, or of a periodic function on the infinite interval. For many applications, it is necessary to have an expansion on the infinite interval without the requirement of periodicity. Development of such an expansion is the goal of this section.

Formal limit of a Fourier series The simplest route to this goal is the one travelled by Fourier himself, simply passing formally to the limit $L \rightarrow \infty$. In this limit, the spatial frequency n/L goes over to a continuous variable ξ . A change of one in n is equivalent to a change of ξ by an amount $\Delta\xi = 1/L$. The Fourier series thus limits to

$$\lim_{L \rightarrow \infty} \sum_{n=-\infty}^{\infty} F_n e^{2\pi i n x / L} = \lim_{L \rightarrow \infty} \frac{1}{\Delta\xi} \int_{-\infty}^{\infty} d\xi F_n e^{2\pi i \xi x}. \quad (3.58)$$

Now we simply define the limit of $F_n/\Delta\xi$ as $F(\xi)$, obtaining

$$F(\xi) \equiv \lim_{L \rightarrow \infty} \frac{F_n}{\Delta\xi} = \lim_{L \rightarrow \infty} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f(x) e^{-2\pi i \xi x} = \int_{-\infty}^{\infty} dx f(x) e^{-2\pi i \xi x}. \quad (3.59)$$

The function $F(\xi)$ is called the *Fourier transform* of $f(x)$. Using an operator notation similar to that introduced in Chap. 1, we denote this integral transform by the operator \mathcal{F} , with a subscript to denote the dimensionality of the integral. Hence, we write

$$F(\xi) = \mathcal{F}_1 \{f(x)\} = \int_{-\infty}^{\infty} dx f(x) e^{-2\pi i \xi x}. \quad (3.60)$$

The subscript will often be omitted when it is obvious from the context.

The limit in (3.58) suggests that the inverse transform is

$$f(x) = \mathcal{F}_1^{-1} \{F(\xi)\} = \int_{-\infty}^{\infty} d\xi F(\xi) e^{2\pi i \xi x}. \quad (3.61)$$

Showing that this operator \mathcal{F}_1^{-1} is indeed the inverse to \mathcal{F}_1 , and defining the sense in which the limits hold, requires a detailed discussion of convergence issues, which we give in Sec. 3.3.2.

Fourier integral theorem Before launching into a formal discussion of convergence, we present an alternative statement of the inverse Fourier transform. If the integral transform in (3.61) is indeed the inverse of the one in (3.60), we can write

$$f(x) = \int_{-\infty}^{\infty} d\xi e^{2\pi i \xi x} \left[\int_{-\infty}^{\infty} dx' f(x') e^{-2\pi i \xi x'} \right]. \quad (3.62)$$

This equation is commonly known as the *Fourier integral theorem*, though it is not yet a proper theorem since we have not stated the conditions that $f(x)$ must satisfy or the sense in which equality holds.

Taking a hint from the discussion above on Fourier series, we can also express the Fourier integral theorem using the limit of a finite integral rather than an infinite integral. We define

$$f_K(x) = \int_{-\frac{1}{2}K}^{\frac{1}{2}K} d\xi e^{2\pi i \xi x} \left[\int_{-\infty}^{\infty} dx' f(x') e^{-2\pi i \xi x'} \right]. \quad (3.63)$$

The advantage of this form is that, with a finite integral, we might be able to interchange order of integration and write

$$\begin{aligned} f(x) &= \lim_{K \rightarrow \infty} f_K(x) = \lim_{K \rightarrow \infty} \int_{-\infty}^{\infty} dx' f(x') \int_{-\frac{1}{2}K}^{\frac{1}{2}K} d\xi e^{2\pi i \xi (x-x')} \\ &= \lim_{K \rightarrow \infty} \int_{-\infty}^{\infty} dx' f(x') K \operatorname{sinc}[K(x-x')], \end{aligned} \quad (3.64)$$

which is plausible since $K \operatorname{sinc}[K(x-x')]$ is one of our limiting representations of $\delta(x-x')$. Proving the theorem in this form requires justifying the interchange of order of integration, stating the conditions under which $K \operatorname{sinc}[K(x-x')] \rightarrow \delta(x-x')$, and specifying the sense in which the right-hand side converges to $f(x)$. We undertake this enterprise in the next section.

3.3.2 Convergence issues

There is a vast literature on determination of conditions on $f(x)$ sufficient for one or more of the forms of the Fourier integral theorem to be valid. Papers and books on this subject can be divided into two categories, which we might call classical and distributional. The most influential book on the classical approach is, no doubt, Titchmarsh (1948), while the distributional approach was most forcefully advocated by Lighthill (1958).

The classical approach requires that we place restrictions on the function $f(x)$, just as we did with Fourier series. One possible restriction is that $f(x)$ be in one of the spaces $\mathbb{L}_p(-\infty, \infty)$, with $1 \leq p < \infty$. As we shall see, one immediate difficulty with this approach is that $f(x)$ and $F(\xi)$ need not be in the same space. Another problem is that some rather ordinary functions are not in a convenient \mathbb{L}_p space. For example, $\operatorname{sinc}(ax)$ is in $\mathbb{L}_p(-\infty, \infty)$ for $p > 1$, but is not in $\mathbb{L}_1(-\infty, \infty)$, while a

delta function, which we would certainly like to include in the theory, is absolutely integrable and hence can be regarded as a function in $\mathbb{L}_1(-\infty, \infty)$, but it is not in $\mathbb{L}_p(-\infty, \infty)$ for $p > 1$. The function $|x|^{-\frac{1}{2}}$ is not in $\mathbb{L}_p(-\infty, \infty)$ for *any* p . All of these problems will be circumvented by the use of distribution theory and generalized functions in Sec. 3.3.4.

Before proceeding, we need to make a distinction between the Hilbert space \mathbb{L}_p in which $f(x)$ is a vector and the domain of the function itself. The function $f(x)$ maps the real line (the x axis) to the complex plane. The Fourier transform $F(\xi)$ also maps the real line — this time the ξ axis — to the complex plane. Colloquially, $f(x)$ is often said to be a function in *real space* or *coordinate space*, while $F(\xi)$ is a function in *reciprocal space* or *frequency space*. Alternatively, the terms *space domain* and *Fourier domain* are often encountered for the x and ξ axes, respectively. All of these designations, however, refer merely to the real line \mathbb{R} . The space \mathbb{L}_p is not the same as either real space or frequency space.

Absolutely integrable functions Much of the classical literature on Fourier's theorem centers on functions in $\mathbb{L}_1(-\infty, \infty)$, the space of functions whose absolute value is integrable on the real line. The reason for this is simple; if $f(x)$ is in $\mathbb{L}_1(-\infty, \infty)$, then $F(\xi)$ is finite for all ξ :

$$|F(\xi)| = \left| \int_{-\infty}^{\infty} dx f(x) e^{-2\pi i \xi x} \right| \leq \int_{-\infty}^{\infty} dx |f(x) e^{-2\pi i \xi x}| = \int_{-\infty}^{\infty} dx |f(x)| < \infty. \quad (3.65)$$

Moreover, it can be shown that $F(\xi)$ is continuous everywhere and vanishes at infinity if $f(x)$ is in $\mathbb{L}_1(-\infty, \infty)$, *i. e.*,

$$\lim_{\xi \rightarrow \pm\infty} F(\xi) = 0. \quad (3.66)$$

This theorem, known as the Riemann-Lebesgue lemma, is proved in many books, such as Lang (1993).

Note, however, that having $f(x)$ an \mathbb{L}_1 function does not necessarily mean that $F(\xi)$ is also an \mathbb{L}_1 function. Since the maximum absolute value of a continuous function is its \mathbb{L}_∞ norm, all we can say about $F(\xi)$ so far is that it is in $\mathbb{L}_\infty(-\infty, \infty)$. In spite of the similarity of (3.60) and (3.61), we cannot be guaranteed that the integral in the inverse transform exists just because the forward one does.

To proceed, we need to rule out certain pathological functions that, while absolutely integrable and perhaps even differentiable everywhere, nevertheless vary arbitrarily rapidly. Such functions are said to be *of unbounded variation*. Roughly speaking, a function of bounded variation is one where the graph of the function has a finite length for any finite range of the variable (Strichartz, 1994, p. 39). Functions of unbounded variation include any function that goes to infinity as well as functions like $\cos(1/x)$ that oscillate infinitely rapidly. Differentiability and bounded variation are independent conditions, neither implying the other (Champeney, 1987).

For functions of bounded variation that are also in $\mathbb{L}_1(-\infty, \infty)$, there is a useful form of the Fourier integral theorem. Such functions cannot go to infinity and can have at most a finite number of discontinuities. These conditions are known as the *Dirichlet conditions*; if they hold, it can be shown that (Lang, 1993, pp. 289–290)

$$\lim_{K \rightarrow \infty} f_K(x) = \frac{1}{2}[f(x^+) + f(x^-)] = f(x), \quad (3.67)$$

where $f_K(x)$ is defined in (3.63) and $f(x^\pm)$ is defined below (3.40). The last form in (3.67) holds either if $f(x)$ is continuous at x or if we simply define $f(x)$ as the average of its values on either side of a finite discontinuity.

The reason that (3.67) works for \mathbb{L}_1 functions of bounded variation is that the interchange of order of integration in (3.64) is legal under these conditions. Basically, a double integral can be written in either order if both single integrals are absolutely convergent, which means that the integral of the absolute value of the integrand remains finite. An \mathbb{L}_1 function, by definition, is absolutely integrable, and any integral over a finite range is finite unless the integrand goes to infinity somewhere. Thus the twin conditions of an \mathbb{L}_1 function and bounded variation ensure that the interchange in (3.64) is allowed.

Comparison of (3.64) and (3.67) shows that it is legitimate to say that $K \operatorname{sinc}(Kx)$ limits to $\delta(x)$ when used in an integral with a function satisfying the Dirichlet conditions. Moreover, should that function happen to be discontinuous at $x = 0$, the interpretation of the delta function is that it sifts out the average of the two values on either side of the discontinuity, as in (2.62).

Square-integrable functions As discussed in Chap. 1, a Hilbert space has advantages over the more general Banach space, and \mathbb{L}_2 is a Hilbert space but \mathbb{L}_p for $p \neq 2$ is not. Thus we turn next to Fourier transforms of functions in $\mathbb{L}_2(-\infty, \infty)$, the space of square-integrable functions on the real line.

The theory of Fourier transforms of functions in $\mathbb{L}_2(-\infty, \infty)$ was developed by Plancherel in the early part of the twentieth century. Plancherel's main result is stated in terms of two limiting functions, $f_K(x)$ defined in (3.63) and $F_L(\xi)$, defined by

$$F_L(\xi) = \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f(x) e^{-2\pi i \xi x}. \quad (3.68)$$

Plancherel's theorem (Titchmarsh, 1948, p. 69) states that if $f(x)$ is in $\mathbb{L}_2(-\infty, \infty)$, then $F_L(\xi)$ converges in the mean to a function $F(\xi)$ that is also in $\mathbb{L}_2(-\infty, \infty)$, and conversely if $F(\xi)$ is in $\mathbb{L}_2(-\infty, \infty)$, $f_K(x)$ converges in the mean to a function $f(x)$ in $\mathbb{L}_2(-\infty, \infty)$. The limits $f(x)$ and $F(\xi)$ are related by the usual Fourier transform relations. Loosely speaking, \mathbb{L}_2 functions transform to \mathbb{L}_2 functions. There is now a satisfying symmetry between the transform and its inverse. The only catch is that some of the functions we might wish to transform are not in $\mathbb{L}_2(-\infty, \infty)$.

It is important to note that Plancherel's theory is couched in terms of convergence in the mean. The mean-square error we make in computing the inverse Fourier transform via (3.61) is a function with zero \mathbb{L}_2 norm. More precisely,

$$\lim_{K \rightarrow \infty} \int_{-\infty}^{\infty} dx |f_K(x) - f(x)|^2 = 0, \quad (3.69)$$

and similarly,

$$\lim_{L \rightarrow \infty} \int_{-\infty}^{\infty} d\xi |F_L(\xi) - F(\xi)|^2 = 0. \quad (3.70)$$

One way to look at these results is that the functions $\{\exp(2\pi i \xi x)\}$ form a continuous basis for $\mathbb{L}_2(-\infty, \infty)$. To expand an \mathbb{L}_2 function $f(x)$ in this basis, we write

$$f(x) = \int_{-\infty}^{\infty} d\xi F(\xi) u_\xi(x), \quad (3.71)$$

where $u_\xi(x) = \exp(2\pi i \xi x)$, so the expansion is precisely the *inverse* Fourier transform of $F(\xi)$. Similarly, an expansion of the \mathbb{L}_2 function $f(x)$ is given by

$$F(\xi) = \int_{-\infty}^{\infty} dx f(x) u_x(\xi), \quad (3.72)$$

where $u_x(\xi) = \exp(-2\pi i \xi x)$. The expansion is now just the Fourier transform of $f(x)$. Except for the minus sign, the same basis functions are used in both expansions. In (3.71) the basis function $\exp(2\pi i \xi x)$ can be viewed as a function of x indexed by the continuous index ξ , while in (3.72) the basis function $\exp(-2\pi i \xi x)$ can be viewed as a function of ξ indexed by x . Because of the continuous index, the basis functions are not themselves in the space \mathbb{L}_2 (see Chap. 1, Sec. 1.4.4).

Convergence factors While the picture of a Fourier transform as a mapping from $\mathbb{L}_2(-\infty, \infty)$ to $\mathbb{L}_2(-\infty, \infty)$ is appealing, there are many functions of practical interest that are not in $\mathbb{L}_2(-\infty, \infty)$. We can deal with such cases with a trick similar to the one used with Fourier series in (3.37) and (3.38); we can multiply the integrand by a convergence factor that tends to unity in some limit.

There are many theorems that justify this procedure, but we shall be content with stating just one of them here (Champeney, 1987, p. 63). Suppose two functions $f(x)$ and $F(\xi)$ are related almost everywhere as follows:

$$F(\xi) = \lim_{\lambda \rightarrow \infty} \int_{-\infty}^{\infty} dx f(x) e^{-|x|/\lambda} e^{-2\pi i \xi x}, \quad (3.73)$$

$$f(x) = \lim_{\lambda \rightarrow \infty} \int_{-\infty}^{\infty} d\xi F(\xi) e^{-|\xi|/\lambda} e^{2\pi i \xi x}. \quad (3.74)$$

If at least one of the functions $f(x)$ or $F(\xi)$ is in $\mathbb{L}_p(-\infty, \infty)$ for some p in the range $1 \leq p \leq 2$, then the other function will be in $\mathbb{L}_q(-\infty, \infty)$, where $p^{-1} + q^{-1} = 1$, and both integrals will be well behaved. The special case $p = q = 2$ gets us back to the statement that the Fourier transform of an \mathbb{L}_2 function is an \mathbb{L}_2 function, while $p = 1$, $q = \infty$ corresponds to the asymmetric situation where the transform of an \mathbb{L}_1 function is in \mathbb{L}_∞ , or conversely.

An important example of the use of this theorem is the delta function, $f(x) = \delta(x)$. Any limiting representation of the delta function is in \mathbb{L}_1 , and it follows from (3.73) and the definition of a delta function that $F(\xi) = 1$, which is a function in \mathbb{L}_∞ . We can also show that (3.74) is correct for this example. With $F(\xi) = 1$, (3.74) becomes

$$f(x) = \lim_{\lambda \rightarrow \infty} \int_{-\infty}^{\infty} d\xi e^{-|\xi|/\lambda} e^{2\pi i \xi x} = \lim_{\lambda \rightarrow \infty} \frac{2\lambda}{4\pi^2 x^2 \lambda^2 + 1}, \quad (3.75)$$

which is one of the limiting representations for a delta function, (2.39) with $\lambda = 1/(2\pi\epsilon)$.

Many different convergence factors can be used in similar theorems. When applied to $F(\xi) = 1$, they lead to different limiting representations of $\delta(x)$. In fact, (3.64) is analogous to (3.74) but with convergence factor $\text{rect}(\xi/K)$.

3.3.3 Unitarity of the Fourier operator

As discussed in the last section, if $f(x)$ is in $\mathbb{L}_2(-\infty, \infty)$, so is $F(\xi)$ except possibly for a function of zero \mathbb{L}_2 norm; thus the Fourier transform is an integral operator that maps \mathbb{L}_2 to itself. In Chap. 1 we discussed operators that map a Hilbert space \mathbb{U} to another Hilbert space \mathbb{V} , but here $\mathbb{U} = \mathbb{V} = \mathbb{L}_2$. Even though functions in the range and domain of the Fourier operator are denoted by different variables, the two spaces are really the same.

The Fourier mapping can be given in abstract operator form by

$$\mathbf{F} = \mathcal{F}\mathbf{f}, \quad (3.76)$$

where \mathbf{f} and \mathbf{F} are the \mathbb{L}_2 vectors corresponding to the functions $f(x)$ and $F(\xi)$, respectively. The operator \mathcal{F} transforms \mathbf{f} to \mathbf{F} .

The mapping properties of an integral transform are specified by its kernel function. The kernel of the Fourier transform is $\exp(-2\pi i\xi x)$ while the kernel of the inverse transform is $\exp(2\pi i\xi x)$. In Chap. 1 we saw that the kernel for the adjoint of an integral operator is obtained from the kernel for the operator itself by interchanging the variables and taking the complex conjugate. Here the variables are x and ξ , so the kernel for the adjoint is precisely the same as the kernel for the inverse. A unitary operator is one for which the adjoint equals the inverse, so the Fourier transform is a unitary operator. The analogous conclusion was found in Sec. 3.2.3 for a Fourier series.

Recall from Chap. 1 that an operator can be moved from one factor in a scalar product to the other if it is replaced by its adjoint (see Sec. 1.3.5). In the present context, that means

$$(\mathbf{F}_2, \mathcal{F}\mathbf{f}_1) = (\mathcal{F}^\dagger\mathbf{F}_2, \mathbf{f}_1), \quad (3.77)$$

where the first scalar product is an integral over ξ and the second is over x . Since \mathcal{F} is unitary, we have

$$(\mathbf{F}_2, \mathbf{F}_1) = (\mathcal{F}^{-1}\mathbf{F}_2, \mathbf{f}_1) = (\mathbf{f}_2, \mathbf{f}_1). \quad (3.78)$$

In other words, scalar products are preserved under unitary transformations.

Parseval's theorems Writing out (3.78) in terms of explicit integrals, we find

$$\int_{-\infty}^{\infty} d\xi [F_2(\xi)]^* F_1(\xi) = \int_{-\infty}^{\infty} dx [f_2(x)]^* f_1(x). \quad (3.79)$$

The special case where $f_1(x) = f_2(x)$ gives

$$\int_{-\infty}^{\infty} d\xi |F(\xi)|^2 = \int_{-\infty}^{\infty} dx |f(x)|^2. \quad (3.80)$$

The left-hand side of this equation is the \mathbb{L}_2 norm of $F(\xi)$ and the right-hand side is the \mathbb{L}_2 norm of $f(x)$.

Equation (3.80) is commonly called Parseval's theorem for Fourier transforms, while (3.79) is called the generalized Parseval theorem. Other terms such as Rayleigh's theorem or Plancherel's theorem are occasionally encountered, especially in the older literature. In essence, Parseval's theorems are just a statement of the unitarity of the Fourier operator and the fact that unitary transformations preserve norms and scalar products.

3.3.4 Fourier transforms of generalized functions

All of the Fourier theorems presented so far place restrictions on $f(x)$ and $F(\xi)$, often with different restrictions on each. It would be highly desirable to be able to choose a single class of functions broad enough to cover all functions of practical interest and their transforms. Fortunately, that goal can be reached by means of the theory of distributions and generalized functions.

Excellent pedagogical accounts of the distributional approach to Fourier transforms are given by Lighthill (1958), Strichartz (1994), and Richards and Youn (1990). For a much broader and more detailed treatment, see Zemanian (1965) and Zemanian (1987).

Tempered distributions The specific generalized functions we shall use are those corresponding to tempered distributions. Recall from Chap. 2 that tempered distributions are continuous, linear functionals acting on good functions, and that a good function is an open-support test function. More specifically, a good function is everywhere differentiable any number of times, and it and all of its derivatives vanish at infinity faster than $|x|^{-N}$ for all N . The space of good functions on the real line is sometimes called the Schwartz space and denoted $\mathbb{S}(-\infty, \infty)$ or simply \mathbb{S} . Note that good functions are necessarily square-integrable, so \mathbb{S} is a subspace of \mathbb{L}_2 .

The general form for a tempered distribution is

$$\Phi_g \{t(x)\} = \int_{-\infty}^{\infty} dx g(x)t(x), \quad (3.81)$$

where $t(x)$ is a good function and $g(x)$ is a generalized function, defined by specifying the number returned by the functional for each $t(x)$. For example, if $g(x) = \delta(x)$, $\Phi_g \{t(x)\} = t(0)$.

As its name implies, a good function is indeed very good as far as Fourier transforms are concerned. It can be shown that, if $t(x)$ is in \mathbb{S} , then its Fourier transform $T(\xi)$ is also in \mathbb{S} ; Fourier transforms of good functions are good functions (Strichartz, 1994, pp. 30–38). The same cannot be said of test functions in general; the transform of a function of compact support cannot have compact support, so it is important that we deal here with good functions and tempered distributions.

It might appear that this result is of little use since the conditions on good functions are so stringent. It would be much more interesting if we could make a similar statement about generalized functions. To do so, we must first define the Fourier transform of a generalized function.

Definition of Fourier transform The key to the definition of the Fourier transform of a generalized function is the unitary nature of the Fourier-transform operator. We note that the functional in (3.81) resembles a scalar product in \mathbb{L}_2 , even though $g(x)$ is almost never in \mathbb{L}_2 . Of course, the scalar product usually includes an asterisk indicating complex conjugate on the first factor in the integrand, but that is not needed since the generalized functions we consider are usually real. If $t(x)$ or $\mathcal{F}^{-1}\{T(\xi)\}$ is in \mathbb{S} , the functional $\Phi_g \{\mathcal{F}^{-1}T(\xi)\}$ is defined by

$$\Phi_g \{\mathcal{F}^{-1}[T(\xi)]\} = \int_{-\infty}^{\infty} dx g(x) [\mathcal{F}^{-1}\{T(\xi)\}], \quad (3.82)$$

which we can think of as the scalar product of $g(x)$ and the good function $\mathcal{F}^{-1}\{T(\xi)\}$. Since \mathcal{F} is a unitary operator in \mathbb{L}_2 and \mathbb{S} is a subspace of \mathbb{L}_2 , we can write

$$\Phi_g\{\mathcal{F}^{-1}[T(\xi)]\} = \int_{-\infty}^{\infty} dx g(x) [\mathcal{F}^\dagger\{T(\xi)\}] . \quad (3.83)$$

By analogy to scalar products in \mathbb{L}_2 , we now *define*

$$\Phi_g\{\mathcal{F}^{-1}[T(\xi)]\} \equiv \int_{-\infty}^{\infty} d\xi [\mathcal{F}\{g(x)\}]^* T(\xi) = \int_{-\infty}^{\infty} d\xi [G(\xi)]^* T(\xi) \equiv \Phi_G\{T(\xi)\} , \quad (3.84)$$

where $\mathcal{F}\{g(x)\} \equiv G(\xi)$, and the last distribution exists since $T(\xi)$ is a good function. In essence, the basic definition [for real $g(x)$] is

$$\int_{-\infty}^{\infty} dx g(x) t(x) = \int_{-\infty}^{\infty} d\xi [G(\xi)]^* T(\xi) . \quad (3.85)$$

Note that the complex conjugate on $G(\xi)$ is needed; even though $g(x)$ is real, its Fourier transform need not be.

We emphasize that (3.85) is a definition, but it is a reasonable one. As with other distributions defined in Chap. 2, this one holds for ordinary functions as well as generalized functions. If $g(x)$ were in \mathbb{L}_2 , the transition from (3.83) to (3.85) would follow from the definition of the adjoint (see Sec. 1.3.5 in Chap. 1). The definition in (3.85) is tantamount to asserting that the generalized Parseval theorem holds even for generalized functions.

Thus, so long as the action of the functional on any good function is defined, (3.85) provides a definition of the Fourier transform of the associated generalized function. Moreover, the Fourier transform of a generalized function defined this way is itself a generalized function, since $T(\xi)$ in (3.85) is a good function. So long as we deal with tempered distributions, *the Fourier transform of a generalized function always exists and is always a generalized function.*

This definition takes care of any doubts about the existence of the Fourier transform of a generalized function, but we still need an operational way to calculate it. To that end, we use the fact that a generalized function can always be written as the limit of a regular sequence of good functions (Lighthill, 1958). With the representation,

$$g(x) = \lim_{n \rightarrow \infty} g_n(x) , \quad (3.86)$$

we have

$$\int_{-\infty}^{\infty} dx g(x) t(x) = \lim_{n \rightarrow \infty} \int_{-\infty}^{\infty} dx g_n(x) t(x) = \lim_{n \rightarrow \infty} \int_{-\infty}^{\infty} d\xi [G_n(\xi)]^* T(\xi) , \quad (3.87)$$

where the interchange of limit and integral is allowed since the integrand is so well behaved (Lighthill, 1958, p. 18). Comparing (3.87) to (3.85) establishes the important result that

$$\mathcal{F}\{g(x)\} = \lim_{n \rightarrow \infty} \mathcal{F}\{g_n(x)\} = \lim_{n \rightarrow \infty} G_n(\xi) . \quad (3.88)$$

Example: Transform of the derivative of a delta function We have already seen that the Fourier transform of a delta function is unity (*i.e.*, the function $F(\xi) = 1$),

so we turn to a slightly more complicated example to illustrate the transform of a generalized function. Suppose $g(x) = \delta'(x)$, the derivative of a delta function as defined by [see (2.56)]

$$\Phi_{\delta'} \{t(x)\} = \int_{-\infty}^{\infty} dx \delta'(x) t(x) \equiv -t'(0). \quad (3.89)$$

From (3.82) and (3.84), we have

$$\begin{aligned} \int_{-\infty}^{\infty} d\xi [\mathcal{F}\{\delta'(x)\}]^* T(\xi) &= \int_{-\infty}^{\infty} dx \delta'(x) [\mathcal{F}^{-1}\{T(\xi)\}] \\ &= \int_{-\infty}^{\infty} dx \delta'(x) t(x) = -t'(0). \end{aligned} \quad (3.90)$$

But note that

$$-t'(0) = - \left[\frac{\partial}{\partial x} \int_{-\infty}^{\infty} d\xi T(\xi) e^{2\pi i \xi x} \right]_{x=0} = \int_{-\infty}^{\infty} d\xi (-2\pi i \xi) T(\xi), \quad (3.91)$$

where differentiation under the integral sign is legal since the good function $T(\xi)$ is so well behaved. Comparison of (3.90) and (3.91) allows us to write

$$\mathcal{F}\{\delta'(x)\} = 2\pi i \xi. \quad (3.92)$$

Since this function increases without bound as $\xi \rightarrow \infty$, it certainly isn't in any of the \mathbb{L}_p spaces, but as a generalized function corresponding to a tempered distribution, it is well defined.

The result in (3.92) could also be obtained from the limiting definition (3.88), along with any of the limiting representations of delta functions in Chap. 2.

3.3.5 Properties of the 1D Fourier transform

In this section we list several important properties of the Fourier transform. Many of these properties are implicit in the discussion above or follow from simple algebraic manipulation of the definitions, so we shall merely indicate the method of derivation without many details. Some comments will be made, however, on the extension of classical theorems to generalized functions.

Linearity The Fourier transform is a linear operator, so

$$\mathcal{F}\{\alpha f(x) + \beta g(x)\} = \alpha F(\xi) + \beta G(\xi), \quad (3.93)$$

where $F(\xi)$ and $G(\xi)$ are the Fourier transforms of $f(x)$ and $g(x)$, respectively.

Symmetry properties Fourier transforms have symmetry properties similar to those discussed in Sec. 3.2.3 for Fourier coefficients. It is straightforward to show from the definition of the transform that

$$F(-\xi) = [F(\xi)]^*, \quad \text{if } f(x) \text{ is real.} \quad (3.94)$$

As with Fourier coefficients, this relation is often referred to as Hermiticity, but note that the Fourier operator is unitary, not Hermitian.

Additional restrictions on the Fourier transform arise if $f(x)$ is an even or odd function. In particular,

$$F(\xi) = F(-\xi), \quad \text{if } f(x) = f(-x), \quad (3.95a)$$

$$F(\xi) = -F(-\xi), \quad \text{if } f(x) = -f(-x). \quad (3.95b)$$

Thus even (odd) functions have Fourier transforms that are even (odd). If $f(x)$ is real and even, its Fourier transform is also real and even, while if $f(x)$ is odd, its transform is pure imaginary and odd.

These results apply also to generalized functions. For example, $\delta(x)$ is real and even, so its Fourier transform, unity, is real and even. The derivative of a delta function is odd, and we have seen in (3.92) that its transform is pure imaginary and odd.

Derivatives To discover an expression for the Fourier transform of the first derivative of a function $f(x)$, we first represent the function in terms of its transform and then apply the derivative operator:

$$\frac{df}{dx} = \frac{d}{dx} \int_{-\infty}^{\infty} d\xi F(\xi) e^{2\pi i \xi x}. \quad (3.96)$$

If the derivative is bounded, it is legitimate to differentiate under the integral sign, yielding

$$\frac{df}{dx} = \int_{-\infty}^{\infty} d\xi F(\xi) 2\pi i \xi e^{2\pi i \xi x}. \quad (3.97)$$

Thus the Fourier transform of df/dx is $2\pi i \xi F(\xi)$. In operator form, we can write

$$\mathcal{F} \left\{ \frac{d}{dx} f(x) \right\} = 2\pi i \xi F(\xi). \quad (3.98)$$

In words, taking the derivative of a function is equivalent to multiplying its Fourier transform by $2\pi i \xi$.

We can repeat the process with impunity so long as the derivatives remain bounded, yielding

$$\mathcal{F} \left\{ \left(\frac{d}{dx} \right)^q f(x) \right\} = (2\pi i \xi)^q F(\xi). \quad (3.99)$$

In fact, the restriction to bounded derivatives is quite unnecessary. We have already seen in (3.92) that $\mathcal{F}\{\delta'(x)\} = 2\pi i \xi \mathcal{F}\{\delta(x)\} = 2\pi i \xi$, which is just (3.98) with $f(x) = \delta(x)$. Equations (3.98) and (3.99) can be derived from the definitions of derivatives and Fourier transforms of generalized functions, (2.18) and (3.85).

We can often discover useful dual relations by interchanging x and ξ and \mathcal{F} and \mathcal{F}^{-1} . For example, the dual to (3.99) is

$$\mathcal{F}^{-1} \left\{ \left(\frac{d}{d\xi} \right)^q F(\xi) \right\} = (-2\pi i x)^q f(x). \quad (3.100)$$

This relation can be derived for ordinary functions with bounded derivatives by differentiating under the integral sign; for generalized functions it follows from the definitions of derivatives and Fourier transforms.

Moments The q^{th} moment of a function $f(x)$ on $(-\infty, \infty)$ is defined by

$$m_q \equiv \int_{-\infty}^{\infty} dx x^q f(x). \quad (3.101)$$

This integral can be thought of as the Fourier transform of $x^q f(x)$ at zero frequency, *i.e.*,

$$m_q = \left[\int_{-\infty}^{\infty} dx x^q f(x) e^{-2\pi i \xi x} \right]_{\xi=0}. \quad (3.102)$$

From (3.100), we now have

$$m_q = (-2\pi i)^{-q} F^{(q)}(0), \quad (3.103)$$

where $F^{(q)}(\xi)$ is the q^{th} derivative of $F(\xi)$. Thus, except for a constant, the q^{th} moment of a function is the q^{th} derivative of its Fourier transform evaluated at the origin.

The special case $q = 0$ gives

$$m_0 = \int_{-\infty}^{\infty} dx f(x) = F(0). \quad (3.104)$$

This result is known as the *central-ordinate theorem* since a graph of $F(\xi)$ crosses the ordinate $\xi = 0$ at the value m_0 .

The dual theorem to (3.103) relates to moments of $F(\xi)$:

$$M_q \equiv \int_{-\infty}^{\infty} d\xi \xi^q F(\xi) = (2\pi i)^{-q} f^{(q)}(0). \quad (3.105)$$

The dual central-ordinate theorem is

$$M_0 = \int_{-\infty}^{\infty} d\xi F(\xi) = f(0). \quad (3.106)$$

Asymptotic behavior The asymptotic behavior of $F(\xi)$ as $\xi \rightarrow \infty$ is analogous to the behavior of a Fourier coefficient as $n \rightarrow \infty$. The classical Riemann-Lebesgue lemma, (3.66), states that if $f(x)$ is an ordinary function of bounded variation in $\mathbb{L}_1(-\infty, \infty)$ and $F(\xi)$ is its Fourier transform, then $F(\xi) \rightarrow 0$ as $|\xi| \rightarrow \infty$. Further, if $f(x)$ is continuous and has bounded derivatives up to at least order q , then (Stakgold, 1979)

$$\lim_{\xi \rightarrow \pm\infty} \xi^q F(\xi) = 0. \quad (3.107)$$

This result follows from the Riemann-Lebesgue lemma when we recognize that $\xi^q F(\xi)$ is just a constant times the Fourier transform of the q^{th} derivative of $f(x)$ [see (3.99)]. If that derivative is bounded and absolutely integrable, its Fourier transform must tend to zero as $\xi \rightarrow \infty$.

This time the condition of boundedness is important, however. We know that $\delta(x)$, though absolutely integrable, has a Fourier transform that does not vanish at infinity. Equation (3.107) is one of the few results in Fourier theory where it is really necessary to make a distinction between ordinary and generalized functions.

As an important example of this theorem, suppose $f(x)$ is a good function. Since all derivatives of a good function exist, (3.107) must hold for *all* q , which is equivalent to saying that $F(\xi)$ is also a good function.

Shifts and linear phase factors It follows readily from the definition of the Fourier transform that, for ordinary functions,

$$\mathcal{F}\{f(x - x_0)\} = e^{-2\pi i \xi x_0} F(\xi). \quad (3.108)$$

This equation holds also for generalized functions if we define shifted generalized functions in a sensible way [for example, by analogy to Eq. (2.52)].

Equation (3.108) shows that shifting a function by x_0 is equivalent to multiplying its Fourier transform by the complex exponential (or linear phase factor) $\exp(-2\pi i \xi x_0)$. This result can be understood by recalling the viewpoint presented in Sec. 3.1.5 and Fig. 3.1. When we express a function $f(x)$ in terms of its Fourier transform, we are resolving it into a sum of vectors, $F(\xi) \exp(2\pi i \xi x)$, in the complex plane. Replacing x by $x - x_0$ changes the angle of each vector by an amount $-2\pi \xi x_0$ linearly dependent on ξ . Since the angle of the vector is the phase of the complex number, this is equivalent to multiplying $F(\xi)$ by $\exp(-2\pi i \xi x_0)$.

The dual theorem is

$$\mathcal{F}\{e^{+2\pi i \xi_0 x} f(x)\} = F(\xi - \xi_0), \quad (3.109)$$

which can also be derived from basic definitions. Thus multiplying a function by a linear phase factor (this time linear in x) is equivalent to shifting its Fourier transform.

Scaled functions If a is a real number, $f(x/a)$ is a scaled version of the function $f(x)$. For $|a| > 1$, a graph of $f(x/a)$ is wider than a graph of $f(x)$, while for $|a| < 1$ it is narrower. Put another way, $f(x)$ takes on the same value at $x = x_0$ as $f(x/a)$ does at $x = ax_0$. Negative values of a correspond to reversal of the sense of the function along the x axis as well as scaling.

For ordinary functions, the Fourier transform of $f(x/a)$ is readily computed by a change of variables:

$$\mathcal{F}\{f(x/a)\} = \int_{-\infty}^{\infty} dx f(x/a) e^{-2\pi i \xi x} = |a| \int_{-\infty}^{\infty} dx' f(x') e^{-2\pi i \xi a x'}, \quad (3.110)$$

where $x' \equiv x/a$. The absolute value of a is needed since, for x negative, the direction of integration is reversed; if the integral is to always run from $-\infty$ to ∞ , we must write $dx = |a| dx'$. The right-hand side of this equation is recognized as a scaled version of $F(\xi)$,

$$\mathcal{F}\{f(x/a)\} = |a| F(a\xi). \quad (3.111)$$

Note that the scaling factor a appears in the numerator of the argument of $F(\xi)$, so a function that is scaled so that it becomes wider has its transform scaled so that it is narrower.

One way to understand the constant $|a|$ in (3.111) is via the central-ordinate theorem. The functions $|a|^{-1} f(x/a)$ and $f(x)$ have the same integral since the former has been increased in width by a and decreased in height by $1/a$ relative to the latter. The integral of both functions is given by $F(0)$ since $F(a \cdot 0) = F(0)$.

A derivation of (3.111) for generalized functions necessitates use of a scaled generalized function, which is defined such that

$$\int_{-\infty}^{\infty} dx g(x/a) t(x) = |a| \int_{-\infty}^{\infty} dx' g(x') t(ax'), \quad (3.112)$$

where $g(x)$ is a generalized function, $g(x/a)$ is its scaled counterpart and $t(x)$ is a good function. This definition is not directly applicable to the integral in (3.110) since the complex exponential is not a good function, but we can construct a good function such as $\exp[-2\pi i\xi x - (x/L)^2]$ and pass to the limit $L \rightarrow \infty$, yielding (3.111). Alternatively, we can get (3.111) from (3.112) by appealing to (3.87).

Powers of the Fourier operator Application of the inverse Fourier transform to $F(\xi)$ yields $f(x)$, but what happens if we take a Fourier *transform*, not the inverse transform, of $F(\xi)$? It is straightforward to show from basic definitions that

$$[\mathcal{F}\mathcal{F}](x) = [\mathcal{F}\mathcal{F}f](x) = f(-x). \quad (3.113)$$

Thus the square of the Fourier operator is the coordinate-inversion operator which maps $f(x)$ to $f(-x)$. If $f(x) = f(-x)$, there is no distinction between \mathcal{F} and \mathcal{F}^{-1} . Since coordinate inversion applied twice returns us to the original function, the fourth power of the Fourier operator is the identity operator.

3.3.6 Convolution and correlation

We briefly encountered the mathematical operation of convolution in Chap. 2 (Sec. 2.2.2), and we shall have many occasions to use it later in this book. As we shall see in Chap. 7, convolution is a common and fruitful model for imaging systems. Systems for which the input–output relation is a convolution are called *linear, shift-invariant systems*. In Chap. 7, we shall examine in detail the conditions under which the convolution model is applicable and develop alternative mathematical descriptions when it is not. Here we confine our attention to some basic mathematical properties of the convolution operation, especially its Fourier transform. Also included here is a brief discussion of the closely related operation of correlation.

Definition of convolution The convolution of two functions $f(x)$ and $h(x)$, denoted $[f * h](x)$ or simply $f * h$, is defined by

$$[f * h](x) = \int_{-\infty}^{\infty} dx' f(x') h(x - x') = \int_{-\infty}^{\infty} dx'' f(x - x'') h(x''). \quad (3.114)$$

The second form follows from the first by the change of variable $x' = x - x''$, so $[f * h](x) = [h * f](x)$.

It can be shown that $[f * h](x)$ is bounded for all x (*i.e.*, is in \mathbb{L}_∞) if $f(x)$ and $h(x)$ are both in $\mathbb{L}_2(-\infty, \infty)$. Moreover, if one function, say $f(x)$, is in $\mathbb{L}_1(-\infty, \infty)$ and the other is in $\mathbb{L}_p(-\infty, \infty)$, then $[f * h](x)$ is also in $\mathbb{L}_p(-\infty, \infty)$. In this sense, convolution with an \mathbb{L}_1 function or between two \mathbb{L}_2 functions is always possible (Richards and Youn, 1990, p. 128).

There are several ways to look at the operation of convolution. If we regard $h(x)$ as a fixed kernel, then convolution is a linear integral transform mapping $f(x)$ to a new function $[f * h](x)$. The problem with this view is that it overlooks the essential symmetry between $f(x)$ and $h(x)$. We could equally well fix $f(x)$ and regard the convolution as a transform mapping $h(x)$ to $[f * h](x)$. The convolution is really a *bilinear* transform with two inputs, $f(x)$ and $h(x)$, and one output, $[f * h](x)$. Still another way to look at convolution is as a linear functional mapping either $f(x)$ or $h(x)$ to a number, $[f * h](x)$, which happens to depend on the continuous variable x .

Fig. 3.3 Graphical interpretation of convolution.

To envision the dependence of $[f * h](x)$ on the variable x , it is useful to draw a graph of the factor $h(x - x')$ vs. x' as in Fig. 3.3. This graph looks like a graph of $h(x')$ but with the sense of the x' axis reversed and the origin shifted by x . It is this reversal or folding operation that gives rise to the term convolution. The value of $[f * h](x)$ for a particular x , say $x = x_0$, is obtained by integrating the product of the shifted and reversed function $h(x_0 - x')$ and $f(x')$. The full function $[f * h](x)$ is obtained by repeating the process for all values of the shift variable x . For a lucid introduction to convolution with copious examples, see Gaskill (1978).

Notation A common alternative notation for the convolution is $f(x) * h(x)$ instead of $[f * h](x)$. Since x is the shift variable, and hence the *only* variable of which $f * h$ is a function, the notation $f(x) * h(x)$ would appear to be redundant. Nevertheless, expressions of the form $f(x_1) * h(x_2)$ can often be useful. For example, suppose we wanted to convolve the shifted function $f(x - x_0)$ with $h(x)$. We could define $f_{x_0}(x) = f(x - x_0)$ and write the convolution as $[f_{x_0} * h](x)$ or $f_{x_0}(x) * h(x)$, but the more straightforward notation is $f(x - x_0) * h(x)$. In practice, this notation will not lead to difficulty since convolution commutes with translation [see (3.121) below].

Scale factors are a bit more problematical. If we wrote an expression like $f(x/a) * h(x/b)$, we would not know how to convert it to an integral. Is the shift variable x , x/a or x/b ? Even $f(x/a) * h(x/a)$ is inherently ambiguous and best avoided [see, *e.g.*, (3.143) below]. We shall, however, stipulate that expressions like $f(x) * h(x/b)$ are allowed and that the shift variable will be the unscaled one,

x rather than x/b . With these caveats, we shall use $f(x) * h(x)$ and $[f * h](x)$ interchangeably.

Correlation Correlation (sometimes called cross-correlation) is a bilinear transform like convolution but without the reversal. It is defined by

$$[f \star h](x) = \int_{-\infty}^{\infty} dx' f(x+x') h(x') = \int_{-\infty}^{\infty} dx'' f(x'') h(x''-x). \quad (3.115)$$

The notation $f(x) \star h(x)$ is also common. Note that, unlike convolution, the order of the functions matters in correlation, and $f \star h$ does not necessarily equal $h \star f$.

The relation between convolution and correlation is often written

$$f(x) \star h(x) = f(x) * h(-x), \quad (3.116)$$

but this notation must be used with caution. The right-hand side really means $[f * h_r](x)$, where $h_r(x) \equiv h(-x)$. The shift variable in the convolution is x , not $-x$.

Basic properties of convolutions As already stated, convolution is commutative and linear in both inputs, *i.e.*,

$$f * g = g * f, \quad (3.117)$$

$$f * [\alpha h_1 + \beta h_2] = \alpha f * h_1 + \beta f * h_2, \quad (3.118)$$

$$[\alpha f_1 + \beta f_2] * h = \alpha f_1 * h + \beta f_2 * h, \quad (3.119)$$

where α and β are arbitrary complex numbers. Convolution is also associative,

$$f * [g * h] = [f * g] * h, \quad (3.120)$$

which can be shown by writing out both sides as a double integral.

It is straightforward to show that convolution commutes with translation and differentiation (Richards and Youn, 1990, p. 23):

$$f(x-x_0) * h(x) = f(x) * h(x-x_0) = [f * h](x-x_0), \quad (3.121)$$

$$\frac{d}{dx} [f(x) * g(x)] = f'(x) * g(x) = f(x) * g'(x). \quad (3.122)$$

An interesting observation that follows from this last equation is that $f * g$ is differentiable if *either* f or g is differentiable. Convolution is a smoothing operation in this sense (Richards and Youn, 1990, pp. 23–24).

Convolutions involving generalized functions Convolutions are bilinear transforms with two input functions; in terms of distribution theory, either or both of these functions could be a test function, a good function or a generalized function. We shall examine each of these possibilities in turn.

If both f and g are test functions (infinitely differentiable functions of compact support), so is $f * g$. This statement follows from the comments above on differentiability and support; the differentiability of f or g ensures the differentiability of $f * g$, while the support of $f * g$ is the sum of the supports of f and g , so $f * g$ must be a function of compact support if f and g are. Thus the convolution of two test

functions is a test function. Likewise, the convolution of two good functions or a test function and a good function is a good function.

The convolution of a test function or a good function with an appropriate generalized function presents no special difficulties (see Richards and Youn, 1990, p. 25, or Strichartz, 1994, p. 52). If $t(x)$ is a test function and $g(x)$ is a generalized function as defined by (3.81), then

$$t(x) * g(x) = \int_{-\infty}^{\infty} dx' g(x') t(x - x') = \Phi_g \{t(x - x')\}. \quad (3.123)$$

Since $t(x - x')$ is a test function if $t(x)$ is, the distribution on the right is well defined. The analogous result holds for good functions and tempered distributions.

As a simple but important example, let $g(x) = \delta(x)$ and $t(x)$ be a good function. Then

$$t(x) * \delta(x) = \int_{-\infty}^{\infty} dx' \delta(x') t(x - x') = t(x). \quad (3.124)$$

Thus convolution with $\delta(x)$ is the identity operator. Similarly,

$$f(x) * \delta(x - x_0) = f(x - x_0), \quad (3.125)$$

so convolution of a good function with $\delta(x - x_0)$ produces a shifted version of the function. Equations (3.124) and (3.125) provide an illustration of the statement above that convolution commutes with translation.

Another important example of convolution with a generalized function involves the derivative of a delta function. Either from the definition of that generalized function or from (3.122) and (3.125), we see that

$$f(x) * \delta'(x - x_0) = \int_{-\infty}^{\infty} dx' f(x') \delta'(x - x_0 - x') = f'(x - x_0). \quad (3.126)$$

Note that there is no overall minus sign on the right-hand side, even though there is one in the basic sifting property of $\delta'(x)$; the minus sign disappears when we make a change of variables to put the integral in (3.126) into the form of (3.89).

Convolution of two generalized functions is a more delicate topic. To discuss it, we must introduce the idea of support of a generalized function (Richards and Youn, 1990, p. 25). The intuitive notion is that some generalized functions like the delta function are zero outside a compact set, while others like the step function are not. To get a more formal definition, consider a test function with support entirely *outside* the interval $[a, b]$. If the action of a distribution Φ_g on this test function is identically zero, we say that the generalized function $g(x)$ has support *inside* $[a, b]$. For example, for all test functions that vanish in $[-\epsilon, \epsilon]$, where ϵ is a small positive number, the distribution associated with $\delta(x)$ yields zero, so we can say that $\delta(x)$ has support $[-\epsilon, \epsilon]$. If the support defined this way is finite, we say that the generalized function has compact support.

An important property of generalized functions of compact support is that they can always be represented as the limit of a sequence of test functions, which allows us to define convolutions involving such functions. Richards and Youn (pp. 29–32) use this theorem as the starting point to show that all of the basic properties of convolutions discussed above, (3.117)–(3.122), hold even if both functions are generalized functions of compact support. For example,

$$\delta(x - x_1) * \delta(x - x_2) = \delta(x - x_1 - x_2) \quad (3.127)$$

and

$$\delta^{(m)}(x) * \delta^{(n)}(x) = \delta^{(m+n)}(x), \quad (3.128)$$

where $\delta^{(m)}(x)$ is the m^{th} derivative of a delta function.

Richards and Youn state (p. 29) that no one has yet given a definition of the convolution of two generalized functions that do not have compact support, and they speculate that there probably is none.

Fourier transforms of convolutions and correlations The Fourier transform of a convolution $[f * h](x)$ will turn out to play a pivotal role in the analysis of linear, shift-invariant imaging systems. We shall compute the transform indirectly by writing the convolution in a form that looks like the inverse transform of something.

Representing each of the functions $f(x)$ and $h(x)$ by its Fourier transform, we obtain

$$\begin{aligned} [f * h](x) &= \int_{-\infty}^{\infty} dx' f(x') h(x - x') \\ &= \int_{-\infty}^{\infty} dx' \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\xi' F(\xi) e^{2\pi i \xi x'} H(\xi') e^{2\pi i \xi' (x - x')}. \end{aligned} \quad (3.129)$$

We shall assume that $f(x)$ and $h(x)$ are sufficiently well behaved that we can interchange the order of integration. This assumption holds for test functions, good functions and L_2 functions, for example, but it also holds for generalized functions of compact support since they are the limit of a sequence of test functions. With this assumption, we can write

$$[f * h](x) = \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\xi' F(\xi) H(\xi') e^{2\pi i \xi' x} \int_{-\infty}^{\infty} dx' e^{2\pi i (\xi - \xi') x'}. \quad (3.130)$$

The integral over x' yields $\delta(\xi - \xi')$, so

$$\begin{aligned} [f * h](x) &= \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\xi' F(\xi) H(\xi') e^{2\pi i \xi' x} \delta(\xi - \xi') \\ &= \int_{-\infty}^{\infty} d\xi F(\xi) H(\xi) e^{2\pi i \xi x} = \mathcal{F}^{-1} \{F(\xi) H(\xi)\}. \end{aligned} \quad (3.131)$$

Thus

$$\mathcal{F}\{[f * h](x)\} = F(\xi) H(\xi). \quad (3.132)$$

This result is often referred to as the *convolution theorem*. In words, the Fourier transform of the convolution of two functions is the product of the transforms of the two functions. The functions in question can be any functions for which both sides of the equation are defined, so generalized functions of compact support are allowed. One of the two functions can even be a generalized function of infinite support, but problems arise if both are.

An interesting point follows by combining the convolution theorem with the central-ordinate theorem, (3.104). If $g(x) = [f * h](x)$, then its integral is given by

$$\int_{-\infty}^{\infty} dx g(x) = G(0) = F(0) H(0) = \int_{-\infty}^{\infty} dx f(x) \int_{-\infty}^{\infty} dx h(x). \quad (3.133)$$

Thus the infinite integral of a convolution is the product of the integrals of the two functions being convolved.

From (3.116) and (3.132), we find that the Fourier transform of a correlation is

$$\mathcal{F}\{[f \star h](x)\} = F(\xi) H(-\xi) = F(\xi) H^*(\xi), \quad (3.134)$$

where the last form is valid only if $h(x)$ is real [see (3.94)]. If $h(x)$ is even, there is no difference between correlation and convolution, and (3.132) and (3.134) are identical.

In incoherent optical imaging, the complex autocorrelation will turn out to be a very important function (Papoulis, 1968; Gaskill, 1978). It is defined by (3.115) with $h(x) = f^*(x)$, and its Fourier transform is given by

$$\mathcal{F}\{[f \star f^*](x)\} = |F(\xi)|^2. \quad (3.135)$$

3.3.7 Fourier transforms of some special functions

Useful tables of Fourier transforms are found in Campbell and Foster (1948), Magnus and Oberhettinger (1949), Erdélyi (1954), Papoulis (1962), Bracewell (1965), and Gaskill (1978). We discuss here a few transforms that we shall need frequently in this book. We shall also use the opportunity to discuss further the basic Fourier theorems given above.

Rect and sinc functions The rect and sinc functions were defined in Chap. 2 [see (2.9) and (2.43)]. An elementary integration shows that these functions form a Fourier transform pair and, in fact, we have already implicitly used this fact in (2.44) and (2.45). The explicit relations are:

$$\mathcal{F}\{\text{rect}(x/L)\} = L \text{sinc}(L\xi), \quad (3.136)$$

$$\mathcal{F}\{\text{sinc}(x/L)\} = L \text{rect}(L\xi). \quad (3.137)$$

This Fourier-transform pair provides a nice illustration of many of the properties of Fourier transforms discussed above. For example, note that both the transform and the inverse transform of a rect is a sinc, and vice versa. This symmetry between forward and inverse transforms holds because both the sinc and rect are real, even functions.

Note also that the rect function is discontinuous and hence its first derivative is not bounded. Its transform, the sinc function, falls off only as $1/\xi$ as $\xi \rightarrow \pm\infty$, in accordance with (3.107), which is valid for $q = 0$ but not $q = 1$.

The central-ordinate theorem of (3.104) can also be verified here. The integral of $\text{rect}(x/L)$ is trivially found to be L , and $L \text{sinc}(L\xi)$ evaluated at $\xi = 0$ is also L since $\sin(u)/u \rightarrow 1$ as $u \rightarrow 0$. Thus the integral of $f(x) = \text{rect}(x/L)$ is the same as $F(0)$ as required by (3.104).

One way to remember the normalizations of the rect and sinc functions is to note that $\text{rect}(x)$ and $\text{sinc}(x)$, without the scale factors of L , have unit integrals, *i.e.*,

$$\int_{-\infty}^{\infty} dx \text{rect}(x) = \int_{-\infty}^{\infty} dx \text{sinc}(x) = 1. \quad (3.138)$$

By a simple change of variables, the integrals of $\text{rect}(x/L)$ and $\text{sinc}(x/L)$ are each L , and the Fourier transform of each function evaluated at the origin is thus also L . Hence the normalized functions $L^{-1} \text{rect}(x/L)$ and $L^{-1} \text{sinc}(x/L)$ integrate to unity over $(-\infty, \infty)$ and their Fourier transforms are unity at the origin.

Triangle functions The triangle function is defined as

$$\operatorname{tri}\left(\frac{x}{L}\right) \equiv \begin{cases} 1 - |x|/L & \text{if } |x| \leq L \\ 0 & \text{if } |x| > L \end{cases}. \quad (3.139)$$

Like the *rect* and *sinc* functions, $\operatorname{tri}(x)$ without the $1/L$ scaling has unit integral when integrated from $-\infty$ to ∞ .

To find the Fourier transform of a triangle function, we recognize that it is the convolution of a *rect* with itself, *i.e.*,

$$\operatorname{tri}(x) = \operatorname{rect}(x) * \operatorname{rect}(x), \quad (3.140)$$

a relation that follows from the graphical interpretation of convolution. Hence, by (3.132) and (3.136),

$$\mathcal{F}\{\operatorname{tri}(x)\} = \operatorname{sinc}^2(\xi). \quad (3.141)$$

From the scaling property of Fourier transforms, (3.111), we have

$$\mathcal{F}\{\operatorname{tri}(x/L)\} = L \operatorname{sinc}^2(L\xi). \quad (3.142)$$

This development affords us an opportunity to comment on a potential pitfall with the shorthand notation for convolutions. It might be tempting to substitute x/L for x in (3.140), but it would not give the right answer. To discover the form for the convolution of $\operatorname{rect}(x/L)$ with itself, we define $r_L(x) \equiv \operatorname{rect}(x/L)$ and write

$$\begin{aligned} [r_L * r_L](x) &= \int_{-\infty}^{\infty} dx' r_L(x') r_L(x - x') \\ &= \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx' \operatorname{rect}\left[\frac{x - x'}{L}\right]. \end{aligned} \quad (3.143)$$

Note that $r_L(x - x')$ is just $\operatorname{rect}[\frac{x-x'}{L}]$, which results from the substitution of $x - x'$ for x in the definition of $r_L(x)$; it is not the same as $\operatorname{rect}[\frac{x}{L} - x']$ or $\operatorname{rect}[x - \frac{x'}{L}]$, neither of which is even dimensionally consistent.

Now the change of variable $x'' = x'/L$ gives

$$[r_L * r_L](x) = L \int_{-\frac{1}{2}}^{\frac{1}{2}} dx'' \operatorname{rect}\left(\frac{x}{L} - x''\right) = L [r_1 * r_1](x/L), \quad (3.144)$$

where r_1 is r_L for $L = 1$, or simply $\operatorname{rect}(x)$. Taking a Fourier transform of (3.144) gives

$$\mathcal{F}\{[r_L * r_L](x)\} = L \operatorname{sinc}^2(L\xi), \quad (3.145)$$

which is not the same as $\mathcal{F}\{\operatorname{tri}(x/L)\}$ in (3.142) because of the extra L . If we now insist on going back to the *rect* notation, we are forced to write (see Gaskill, 1978, p. 166)

$$\operatorname{rect}(x/L) * \operatorname{rect}(x/L) = L \operatorname{tri}(x/L). \quad (3.146)$$

This expression violates an elementary rule for functional equations: If $f(x) = g(x)$ for all x , then $f(x/L) = g(x/L)$. We can either say that a convolution is not a function and this rule doesn't apply or avoid convolution expressions with scale factors by defining auxiliary functions like r_L . We prefer the latter.

As a practical matter, if one has difficulty with scale factors in convolutions or Fourier transforms, dimensional analysis can be used. For example, in (3.145) above, if we assume that x has dimensions of length, then ξ must have dimensions of $(\text{length})^{-1}$ since the argument of a trigonometric function, and hence of a sinc function, must be dimensionless. Similarly, the argument of the rect function must be dimensionless, and hence L must have dimensions of length. The convolution and Fourier-transform operations are both integrals over x , and the dx contributes an additional factor of length. The asterisk $*$ and the Fourier operator \mathcal{F} have the same dimensions as x , at least in one dimension. Thus (3.146) is dimensionally consistent since both sides have dimensions of length, while both sides of (3.145) have dimensions of $(\text{length})^2$.

The central-ordinate theorem can also help resolve difficulties with scale factors. A graph of the function $\text{tri}(x/L)$ is an isosceles triangle with height unity and base $2L$, so its area is L . The central-ordinate theorem applied to (3.142) also shows that the integral of $\text{tri}(x/L)$ is L since $\text{sinc}^2(0) = 1$.

The asymptotic properties of the Fourier transform of a triangle function are worthy of note. While a rect function is discontinuous and has a transform that falls off as $1/\xi$, a triangle is continuous but has a discontinuous derivative. It can be differentiated once but not twice, and its transform falls off as $1/\xi^2$, consistent with (3.107) for $q = 1$. As noted above, a convolution is a smoothing operation which increases the differentiability of the function and thus the rate of decay of its transform.

Delta functions, sines and cosines We have discussed various Fourier transforms involving delta functions above, but the main results are collected here for ease of reference:

$$\mathcal{F}\{\delta(x)\} = 1, \quad (3.147)$$

$$\mathcal{F}\{\delta(x - x_0)\} = e^{-2\pi i x_0 \xi}, \quad (3.148)$$

$$\mathcal{F}\{\delta^{(k)}(x)\} = (2\pi i \xi)^k, \quad (3.149)$$

$$\mathcal{F}\{\delta^{(k)}(x - x_0)\} = (2\pi i \xi)^k e^{-2\pi i x_0 \xi}, \quad (3.150)$$

where $\delta^{(k)}(x)$ is the k^{th} derivative of $\delta(x)$.

Since a shifted delta function transforms into a linear phase factor (or complex exponential) as in (3.148), the converse also holds:

$$\mathcal{F}\{e^{2\pi i \xi_0 x}\} = \delta(\xi - \xi_0) \quad (3.151)$$

and

$$\mathcal{F}\{(-2\pi i x)^k e^{2\pi i \xi_0 x}\} = \delta^{(k)}(\xi - \xi_0). \quad (3.152)$$

A linear phase factor transforms to a single delta function, which can be paraphrased by saying it consists of a single spatial-frequency component.

The linear phase factors can be used to construct sines and cosines via (3.5) and (3.6), and the following transforms are obtained:

$$\mathcal{F}\{\cos(2\pi \xi_0 x)\} = \frac{1}{2} [\delta(\xi - \xi_0) + \delta(\xi + \xi_0)], \quad (3.153)$$

$$\mathcal{F}\{\sin(2\pi \xi_0 x)\} = \frac{1}{2i} [\delta(\xi - \xi_0) - \delta(\xi + \xi_0)]. \quad (3.154)$$

Sines and cosines transform to pairs of delta functions. First appearances aside, these functions consist of two spatial frequencies each; positive and negative frequencies must be considered distinct. For the cosine, the weights of the two delta functions are real and equal, while for the sine they are pure imaginary and differ by a minus sign.

Sines and cosines are infinitely differentiable and their transforms vanish identically at $\xi = \pm\infty$. Equation (3.107) holds for all q .

Comb function The comb function is defined as an infinite sum of delta functions in (2.48), but (2.50) shows that it is also an infinite sum of linear phase factors. Hence its Fourier transform is

$$\mathcal{F}\{\text{comb}(x)\} = \sum_{n=-\infty}^{\infty} \mathcal{F}\{e^{2\pi inx}\} = \sum_{n=-\infty}^{\infty} \delta(\xi - n) = \text{comb}(\xi). \quad (3.155)$$

Thus the Fourier transform of a comb is a comb. The scaled version of a comb function is

$$\text{comb}\left(\frac{x}{L}\right) = \sum_{n=-\infty}^{\infty} \delta\left(\frac{x}{L} - n\right) = L \sum_{n=-\infty}^{\infty} \delta(x - nL), \quad (3.156)$$

where the last step follows from (2.28). Thus $\text{comb}(x/L)$ is a sum of delta functions of weight L at the points $x = nL$, $n = 0, \pm 1, \pm 2, \dots, \pm\infty$. The Fourier transform of the scaled comb is

$$\mathcal{F}\{\text{comb}(x/L)\} = L \text{comb}(L\xi) = L \sum_{n=-\infty}^{\infty} \delta(L\xi - n) = \sum_{n=-\infty}^{\infty} \delta\left(\xi - \frac{n}{L}\right), \quad (3.157)$$

which is a sum of delta functions of unit weight at points $\xi = n/L$.

It is worth looking at these results from the viewpoint of dimensional analysis. In (3.155) x must be dimensionless since otherwise the exponent $2\pi inx$ would be meaningless. Hence ξ is also dimensionless, as are the delta functions, and dimensional analysis gets us nowhere. In (3.156) and (3.157) on the other hand, x and L can be physical lengths. In this case ξ has dimensions of $(\text{length})^{-1}$, $\delta(\xi - n/L)$ has dimensions of length and $\delta(x - nL)$ has dimensions of $(\text{length})^{-1}$. (See Sec. 2.4.3 for a discussion of dimensional analysis of delta functions.) All forms in (3.156) are thus dimensionless, while all forms in (3.157) have dimensions of length.

Step and signum functions In Sec. 2.3.2 we discussed two generalized functions related to the delta function, namely the step and signum functions. An important property of $\text{step}(x)$ is that its derivative is $\delta(x)$. Thus we know at once from (3.98) that

$$\mathcal{F}\left\{\frac{d}{dx} \text{step}(x)\right\} = 2\pi i\xi \mathcal{F}\{\text{step}(x)\} = \mathcal{F}\{\delta(x)\} = 1. \quad (3.158)$$

One might be tempted to conclude from this result that $\mathcal{F}\{\text{step}(x)\} = 1/(2\pi i\xi)$, but this is not correct. For one thing, we wouldn't know how to interpret the singularity $1/\xi$. For another, specifying the derivative of a function does not uniquely specify the function itself or its Fourier transform; we must account for the constant of integration.

To fix the constant, let us retreat to basic definitions. From (3.85), we have

$$\int_{-\infty}^{\infty} dx \text{step}(x) t(x) = \int_{-\infty}^{\infty} d\xi [\mathcal{F}\{\text{step}(x)\}]^* T(\xi), \quad (3.159)$$

where $t(x)$ is any good function and $T(\xi)$ is its Fourier transform. Expressing $t(x)$ on the left-hand side in terms of $T(\xi)$ and using the definition of the step function gives

$$\begin{aligned} \int_{-\infty}^{\infty} d\xi [\mathcal{F}\{\text{step}(x)\}]^* T(\xi) &= \int_0^{\infty} dx \int_{-\infty}^{\infty} d\xi T(\xi) e^{2\pi i \xi x} \\ &= \int_{-\infty}^{\infty} d\xi T(\xi) \int_0^{\infty} dx e^{2\pi i \xi x}, \end{aligned} \quad (3.160)$$

where the interchange of order of integration is legal since $T(\xi)$ is a good function. Comparison of the first and last integrals now reveals that

$$\mathcal{F}\{\text{step}(x)\} = \int_0^{\infty} dx e^{-2\pi i \xi x}, \quad (3.161)$$

which we might have written immediately if we had treated the step function as an ordinary function instead of defining it distributionally.

All that remains is to deal with the improper integral in (3.161), for which purpose we appeal to (3.88). Introducing the convergence factor $\exp(-x/L)$ in order to generate an integrable sequence, we find

$$\begin{aligned} \mathcal{F}\{\text{step}(x)\} &= \lim_{L \rightarrow \infty} \int_0^{\infty} dx e^{-2\pi i \xi x - x/L} = \lim_{L \rightarrow \infty} \frac{L}{1 + 2\pi i \xi L} \\ &= \lim_{L \rightarrow \infty} \frac{L}{1 + 4\pi^2 \xi^2 L^2} - \lim_{L \rightarrow \infty} \frac{2\pi i \xi L^2}{1 + 4\pi^2 \xi^2 L^2}. \end{aligned} \quad (3.162)$$

Letting $\epsilon = 1/(2\pi L)$ and comparing to (2.39), we recognize the first limit in (3.162) as $\frac{1}{2} \delta(\xi)$. The second limit is a representation of $\mathcal{P}\{1/(2\pi i \xi)\}$, where \mathcal{P} denotes Cauchy principal value [see (2.88)]. Thus we have, finally,

$$\mathcal{F}\{\text{step}(x)\} = \frac{1}{2} \delta(\xi) + \mathcal{P}\left\{\frac{1}{2\pi i \xi}\right\}. \quad (3.163)$$

Note that this result is consistent with (3.158) since $\xi \delta(\xi) = 0$. The constant of integration turned out to be $\frac{1}{2}$, which gave $\frac{1}{2} \delta(\xi)$ in the Fourier domain.

The Fourier transform of the signum function can now be derived. Since $\text{sgn}(x) = 2 \text{step}(x) - 1$ by (2.77), we have

$$\mathcal{F}\{\text{sgn}(x)\} = \mathcal{P}\left\{\frac{1}{i\pi\xi}\right\}. \quad (3.164)$$

We can verify this transform by taking the inverse, *i.e.*, by performing the integral

$$\mathcal{F}^{-1}\left\{\mathcal{P}\left(\frac{1}{i\pi\xi}\right)\right\} = \mathcal{P} \int_{-\infty}^{\infty} d\xi \frac{e^{2\pi i \xi x}}{i\pi\xi}. \quad (3.165)$$

This integral is a standard exercise in complex integration (see App. B), with the effect of the principal-value designation being that only half of the residue at $\xi = 0$ contributes (Friedman, 1991). The result is

$$\mathcal{F}^{-1}\left\{\mathcal{P}\left(\frac{1}{i\pi\xi}\right)\right\} = \text{sgn}(x), \quad (3.166)$$

as expected. The dual to this transform is

$$\mathcal{F}\left\{\mathcal{P}\left(\frac{1}{x}\right)\right\} = -i\pi \text{sgn}(\xi). \quad (3.167)$$

A derivation of this result by contour integration is given in App. B.

Powers and logarithms The generalized functions x^m (m an integer), $|x|^\alpha$ (α any real number not an integer) and $\ln|x|$ are defined in Sec. 2.3.3. These functions play an important role in tomographic imaging. Their Fourier transforms are derived from the basic definitions in Lighthill (1958). The results are

$$\mathcal{F}\{|x|^\alpha\} = \{2 \cos [\tfrac{1}{2}\pi(\alpha + 1)]\} \alpha! (2\pi|\xi|)^{-\alpha-1}, \quad \alpha \text{ real, noninteger,} \quad (3.168)$$

$$\mathcal{F}\{x^{-m}\} = -\pi i \frac{(-2\pi i \xi)^{m-1}}{(m-1)!} \operatorname{sgn}(\xi), \quad m > 0, \text{ integer,} \quad (3.169)$$

$$\mathcal{F}\{x^m\} = (-2\pi i)^{-m} \delta^{(m)}(\xi), \quad m \geq 0, \text{ integer,} \quad (3.170)$$

$$\mathcal{F}\{x^m \ln|x|\} = \pi i \frac{m!}{(2\pi\xi)^{m+1}} \operatorname{sgn}(\xi), \quad m \geq 0, \text{ integer.} \quad (3.171)$$

In these equations, $m!$ denotes the ordinary factorial function for the integer m , while $\alpha!$ is defined for noninteger α in terms of the gamma function [see Abramowitz and Stegun, 1965, or (C.123) in App. C] as $\alpha! = \Gamma(\alpha + 1)$. Transforms involving products of these generalized functions and signum and step functions can be found in Lighthill.

An interesting special case of (3.168) is

$$\mathcal{F}\{|x|^{-\frac{1}{2}}\} = |\xi|^{-\frac{1}{2}}. \quad (3.172)$$

Thus $|x|^{-\frac{1}{2}}$ is its own Fourier transform.

Gaussians and quadratic phase factors The Gaussian function is important in probability theory and as a model for the point spread function of imaging systems. It is also the prototype of a good function (see Sec. 2.1.2). One convenient form for the Gaussian is (Gaskill, 1978)

$$\operatorname{gaus}(x) \equiv \exp(-\pi x^2). \quad (3.173)$$

An advantage of this definition is that

$$\int_{-\infty}^{\infty} dx \operatorname{gaus}(x) = 1. \quad (3.174)$$

One way to derive this result, which will be important below, is to compute not the integral, denoted I , but its square:

$$I^2 = \left[\int_{-\infty}^{\infty} dx \operatorname{gaus}(x) \right]^2 = \int_{-\infty}^{\infty} dx e^{-\pi x^2} \int_{-\infty}^{\infty} dy e^{-\pi y^2} = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy e^{-\pi(x^2+y^2)}. \quad (3.175)$$

In this form the double integral can be interpreted as a 2D integral over the infinite plane. This integral can be performed in polar coordinates; letting $r^2 = x^2 + y^2$, we find

$$I^2 = 2\pi \int_0^{\infty} r dr e^{-\pi r^2} = \int_0^{\infty} du e^{-u} = 1, \quad (3.176)$$

confirming (3.174).

The Fourier transform of $\operatorname{gaus}(x)$ is given by

$$\mathcal{F}\{\operatorname{gaus}(x)\} = \int_{-\infty}^{\infty} dx e^{-2\pi i \xi x - \pi x^2}. \quad (3.177)$$

The integral will be evaluated by forcing it to look like (3.174). To do so, we complete the square by adding and subtracting $\pi\xi^2$ in the exponent, yielding

$$\mathcal{F}\{\text{gaus}(x)\} = e^{-\pi\xi^2} \int_{-\infty}^{\infty} dx e^{-\pi(x+i\xi)^2} = e^{-\pi\xi^2} \int_{C_1} dz e^{-\pi z^2}. \quad (3.178)$$

where z is a complex variable and the (open) contour integral is along the path C_1 parallel to the real axis and displaced upward by $i\xi$; for points on this contour, $z = x + i\xi$. Note, however, that $\exp(-\pi z^2)$ is entire (analytic for all finite z) and vanishes at infinity on both C_1 and the real axis. We can thus deform the contour to be the real axis, denoted C_2 , without changing the value of the integral (see App. B), so

$$\mathcal{F}\{\text{gaus}(x)\} = e^{-\pi\xi^2} \int_{C_2} dz e^{-\pi z^2} = e^{-\pi\xi^2} \int_{-\infty}^{\infty} dx e^{-\pi x^2} = e^{-\pi\xi^2}, \quad (3.179)$$

where the last step follows from (3.174). Like the function $|x|^{-\frac{1}{2}}$ encountered above, $\text{gaus}(x)$ and its Fourier transform have the same form.

By the scaling theorem, (3.111), we now have

$$\mathcal{F}\{|a|^{-1} \text{gaus}(x/a)\} = e^{-\pi a^2 \xi^2}, \quad (3.180)$$

where a is real. It follows from this equation and the central ordinate theorem that $|a|^{-1} \text{gaus}(x/a)$ integrates to unity over $(-\infty, \infty)$.

Closely related to the Gaussian is the quadratic phase factor $\exp(i\pi\beta x^2)$, where β is real. In fact, one might be tempted to regard this as a Gaussian of the form $\text{gaus}(bx)$, where $b = \sqrt{i\beta}$, but that view is dangerous. While $\text{gaus}(bx)$ for b real is very well behaved (in fact, the prototype of a good function), $\exp(i\pi\beta x^2)$ for β real is not even in $\mathbb{L}_1(-\infty, \infty)$. A safer procedure is to regard the quadratic phase factor as a generalized function and compute its transform from first principles.

As in (3.88), we shall regard the generalized function $\exp(i\pi\beta x^2)$ as the limit of a sequence of good functions. A convenient form for the good functions is $\exp(i\pi\beta x^2 - \pi\alpha x^2)$, where α is real and positive. We then have

$$\mathcal{F}\{e^{i\pi\beta x^2}\} = \lim_{\alpha \rightarrow 0} \int_{-\infty}^{\infty} dx e^{i\pi\beta x^2 - \pi\alpha x^2 - 2\pi i\xi x}. \quad (3.181)$$

As above, the approach is to complete the square. A little algebra yields

$$\mathcal{F}\{e^{i\pi\beta x^2}\} = \lim_{\alpha \rightarrow 0} e^{\pi b^2} \int_{-\infty}^{\infty} dx e^{-\pi(\gamma x + b)^2}, \quad (3.182)$$

where $b = i\xi/\gamma$ and $\gamma = \sqrt{\alpha - i\beta}$. Note that γ is a complex number with phase $\phi_\gamma = \frac{1}{2} \tan^{-1}(-\beta/\alpha)$, which approaches $\pi/4$ as $\alpha \rightarrow 0$. The change of variables $z = \gamma x + b$ allows us to write

$$\mathcal{F}\{e^{i\pi\beta x^2}\} = \lim_{\alpha \rightarrow 0} e^{\pi b^2} \frac{1}{\gamma} \int_C dz e^{-\pi z^2}, \quad (3.183)$$

where the contour C makes an angle ϕ_γ to the real axis. The key point, however, is that there are no singularities of the integrand anywhere between C and the real

axis, and the integrand vanishes rapidly at infinity along both C and the real axis. Therefore, we can again deform the contour to the real axis and write

$$\mathcal{F}\{e^{i\pi\beta x^2}\} = \lim_{\alpha \rightarrow 0} e^{\pi b^2} \frac{1}{\gamma} \int_{-\infty}^{\infty} dx e^{-\pi x^2} = \lim_{\alpha \rightarrow 0} e^{\pi b^2} \frac{1}{\gamma}. \quad (3.184)$$

Passing to the limit, we have, finally

$$\mathcal{F}\{e^{i\pi\beta x^2}\} = \sqrt{\frac{i}{\beta}} e^{-i\pi\xi^2/\beta}. \quad (3.185)$$

The exponents in this expression are the same as we would have obtained by use of (3.180) with complex a , but that *ad hoc* approach would have left us unsure how to handle the factor $|a|$.

The quadratic phase factor and its Fourier transform play a crucial role in diffraction theory (see Chap. 9) and radar signal processing (Chap. 18). Additional properties are discussed in Sec. 4.3.

3.3.8 Relation between Fourier series and Fourier transforms

Most treatments of Fourier analysis introduce the Fourier series as a way of representing a periodic function by a discrete sum of complex exponentials. The Fourier transform is then used to represent a general, nonperiodic function by a continuous superposition or integral of complex exponentials. In a classical approach it would not be possible to use the Fourier transform for a periodic function which cannot be in $\mathbb{L}_1(-\infty, \infty)$. The use of generalized functions, however, frees us of that restriction and makes it possible to look at the Fourier *transform* of a periodic function.

Consider a periodic function $f(x)$ of bounded variation and period L , so that $f(x + mL) = f(x)$, where m is any integer. Let $f_0(x)$ be identical with $f(x)$ for x in $(-\frac{1}{2}L, \frac{1}{2}L)$ and zero outside this interval, *i.e.*,

$$f_0(x) = f(x) \operatorname{rect}(x/L). \quad (3.186)$$

Since $f_0(x)$ has bounded support, it is either a test function or the limit of a sequence of test functions. Then we can write $f(x)$ as

$$f(x) = \sum_{n=-\infty}^{\infty} f_0(x - nL) = f_0(x) * \sum_{n=-\infty}^{\infty} \delta(x - nL), \quad (3.187)$$

where we have used (3.125) and the linearity of the convolution operation. With some trepidation, we rewrite this equation in terms of the shorthand notation for the convolution as

$$f(x) = f_0(x) * \left[\frac{1}{L} \operatorname{comb}\left(\frac{x}{L}\right) \right]. \quad (3.188)$$

Recall that we stipulated in Sec. 3.3.6 that, in expressions of this form with one unscaled variable and one scaled one, the shift variable in the convolution would be the unscaled one. Thus the interpretation of $f_0(x) * L^{-1} \operatorname{comb}(x/L)$ is that it is the same thing as $f_0(x) * c_L(x)$, where $c_L(x) = L^{-1} \operatorname{comb}(x/L)$.

With this notation, we can now take the Fourier transform of $f(x)$ by use of the convolution theorem, (3.132), along with (3.157) for the Fourier transform of a comb. The result is

$$F(\xi) = \mathcal{F}\{f(x)\} = \mathcal{F}\left\{f_0(x) * \left[\frac{1}{L} \text{comb}\left(\frac{x}{L}\right)\right]\right\} = F_0(\xi) \text{comb}(L\xi), \quad (3.189)$$

where $F_0(\xi)$ is the Fourier transform of $f_0(x)$. To be more explicit,

$$F(\xi) = F_0(\xi) \sum_{n=-\infty}^{\infty} \delta(\xi L - n) = \frac{1}{L} \sum_{n=-\infty}^{\infty} F_0\left(\frac{n}{L}\right) \delta\left(\xi - \frac{n}{L}\right), \quad (3.190)$$

where the last form has made use of (2.25) and (2.28).

Equation (3.190) says that the Fourier transform of a periodic function is defined for all ξ but is zero unless $\xi = n/L$, where n is an integer. The behavior at these discrete frequencies is that of a delta function, and the weight of the delta function at $\xi = n/L$ is given by $F_0(\xi)$ sampled (evaluated) at this discrete value. The key point is that the *periodicity of the function $f(x)$ restricts its Fourier transform to a discrete set of frequencies*.

An interesting result is obtained by simply taking the inverse transform of (3.190). We find

$$f(x) = \frac{1}{L} \sum_{n=-\infty}^{\infty} F_0\left(\frac{n}{L}\right) e^{2\pi i n x / L}, \quad (3.191)$$

which we recognize as a Fourier *series* with coefficients $L^{-1}F_0(n/L)$. In other words, the *Fourier coefficients of a periodic function are sampled values of the Fourier transform of one period of the function*. Of course, the Fourier-series representation inherently has only a discrete set of frequencies present, and these are the same frequencies, n/L , as selected by the comb of delta functions in the Fourier transform.

Poisson summation formula The starting point for the discussion above was the representation of a periodic function $f(x)$ as the convolution of its values in one period, $f_0(x)$, with a comb function. Now let us consider a slightly different problem. Consider a function $g(x)$ that is *not* periodic and does not necessarily have bounded support. From this function we can *create* a periodic function $g_p(x)$ of period L by forming all possible translated replicas of the original function and adding them together. Mathematically, we define

$$g_p(x) = \sum_{n=-\infty}^{\infty} g(x - nL) = g(x) * \frac{1}{L} \text{comb}\left(\frac{x}{L}\right). \quad (3.192)$$

The important difference between this equation and (3.188) is that here the different terms can overlap spatially.

The new function $g_p(x)$ is periodic with period L and hence can be expanded in a Fourier series:

$$g_p(x) = \sum_{k=-\infty}^{\infty} C_k e^{2\pi i k x / L}. \quad (3.193)$$

The coefficients are given by

$$C_k = \frac{1}{L} \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \sum_{n=-\infty}^{\infty} g(x-nL) e^{-2\pi i k x/L}. \quad (3.194)$$

The change of variables $x' = x - nL$ leads to

$$C_k = \frac{1}{L} \sum_{n=-\infty}^{\infty} \int_{-\frac{1}{2}L-nL}^{\frac{1}{2}L-nL} dx' g(x') e^{-2\pi i k x'/L} e^{-2\pi i n k}. \quad (3.195)$$

The last exponential is identically one since nk is an integer, and the sum of integrals over contiguous intervals of width L is equivalent to one integral over $(-\infty, \infty)$.

Thus we have

$$C_k = \frac{1}{L} \int_{-\infty}^{\infty} dx' g(x') e^{-2\pi i k x'/L} = \frac{1}{L} G\left(\frac{k}{L}\right), \quad (3.196)$$

where, as usual, $G(\xi)$ is the Fourier transform of $g(x)$. Note that, in contrast to (3.190) or (3.191), the transform that appears here is not the transform of one period of a periodic function but rather of the original, nonperiodic function from which we constructed the periodic one, g_p .

Combining (3.192), (3.193) and (3.196), we obtain the *Poisson summation formula*,

$$\sum_{n=-\infty}^{\infty} g(x-nL) = \frac{1}{L} \sum_{k=-\infty}^{\infty} G\left(\frac{k}{L}\right) \exp\left(\frac{2\pi i k x}{L}\right). \quad (3.197)$$

The special case $x = 0$ gives

$$\sum_{n=-\infty}^{\infty} g(nL) = \frac{1}{L} \sum_{k=-\infty}^{\infty} G\left(\frac{k}{L}\right). \quad (3.198)$$

This remarkable theorem says that, with suitable scale factors, *the sum of the samples of any function $g(x)$ equals the sum of the samples of its Fourier transform*. Note that L is now simply the sample spacing in x , not a period. The sample spacing in ξ is $1/L$.

If $g(x)$ has compact support, the Poisson summation formula takes a familiar form. Suppose $g(x)$ vanishes outside the range $-\frac{1}{2}L < x < \frac{1}{2}L$. Then the left-hand side of (3.197) is a sum of periodically repeated replicas of $g(x)$, while on the right side, the sampled Fourier transform $G(k/L)$ is identical to G_k , the k^{th} Fourier coefficient of $g(x)$. Thus, when $g(x)$ has support $(-\frac{1}{2}L, \frac{1}{2}L)$, (3.197) is just the usual Fourier-series representation. As it stands, however, (3.197) places no restriction on $g(x)$.

A practical advantage of the Poisson summation formula is that it converts a slowly converging series into a rapidly converging one (Kanwal, 1983). For example, if $g(x)$ is a Gaussian, we find (Strichartz, 1994)

$$\sum_{k=-\infty}^{\infty} e^{-4\pi^2 t k^2} = \frac{1}{\sqrt{4\pi t}} \sum_{n=-\infty}^{\infty} e^{-n^2/4t}. \quad (3.199)$$

The left-hand side converges rapidly for large t , while the right-hand side does so for small t .

3.3.9 Analyticity of Fourier transforms

Up until now, the spatial frequency ξ has been a real variable, but it is also of interest to consider complex frequencies. For this purpose, we write

$$\xi = \xi_r + i\xi_i, \quad (3.200)$$

where subscripts r and i denote real and imaginary parts, respectively. The Fourier transform is still defined by (3.60), which now reads

$$F(\xi) = \int_{-\infty}^{\infty} dx f(x) e^{-2\pi i \xi_r x} e^{2\pi \xi_i x}. \quad (3.201)$$

It is not obvious that $F(\xi)$ exists for all complex ξ . For example, if $\xi_i > 0$, the factor $\exp(2\pi \xi_i x)$ in the integrand blows up exponentially as $x \rightarrow \infty$. This problem is avoided, however, if $f(x)$ is square-integrable and has compact support. In that case, as we shall now show, $F(\xi)$ is an analytic function of the complex variable ξ .

Suppose the support of $f(x)$ is $(-\frac{1}{2}L, \frac{1}{2}L)$ and denote $F(\xi)$ by

$$F(\xi) = F_r(\xi_r, \xi_i) + iF_i(\xi_r, \xi_i), \quad (3.202)$$

where, if $f(x)$ is real,

$$F_r(\xi_r, \xi_i) = \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f(x) \cos(2\pi \xi_r x) e^{2\pi \xi_i x}; \quad (3.203)$$

$$F_i(\xi_r, \xi_i) = - \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f(x) \sin(2\pi \xi_r x) e^{2\pi \xi_i x}. \quad (3.204)$$

To demonstrate the analyticity of $F(\xi)$, we must show that the Cauchy-Riemann conditions are satisfied (see App. B). If $f(x)$ is in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$, there is no problem in differentiating under the integral sign, so

$$\frac{\partial F_r}{\partial \xi_r} = \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx f(x) (-2\pi x) \sin(2\pi \xi_r x) e^{2\pi \xi_i x} = \frac{\partial F_i}{\partial \xi_i}, \quad (3.205)$$

verifying the first of the Cauchy-Riemann conditions; the second one follows similarly. The conclusion is that $F(\xi)$ is *entire* (analytic for all finite ξ) if $f(x)$ is square-integrable and has compact support. This statement is frequently referred to as the *Paley-Wiener theorem* (Paley and Wiener, 1934).

The Paley-Wiener theorem can also be derived if $f(x)$ is a generalized function of compact support (Strichartz, 1994), though in this case $F(\xi)$ might grow exponentially as $\xi \rightarrow \infty$. The general statement of the theorem is that the Fourier transform of a function or generalized function of compact support is an entire function of exponential type.

The Paley-Wiener theorem should not be surprising when we recall the relation between the smoothness of a function and the asymptotic behavior of its Fourier transform. Compact support is the ultimate in decay at infinity and analyticity is the ultimate in smoothness (Strichartz, 1994).

An interesting consequence of the Paley-Wiener theorem is that the Fourier transform of a function of compact support cannot itself have compact support. That is the case since an analytic function that is zero over any finite region of the complex plane must be zero everywhere (see App. B).

3.3.10 Related transforms

Fourier cosine transform We saw in (3.95) that the Fourier transform of an even function is an even function. If the function is also real, then

$$F(\xi) = F(-\xi) = 2 \int_0^{\infty} dx f(x) \cos(2\pi\xi x), \quad f(x) \text{ real and even.} \quad (3.206)$$

Even if $f(x)$ is not even, however, we can use this form as the definition of the *Fourier cosine transform* of $f(x)$. Denoting this transform by $F_c(\xi)$, we write

$$F_c(\xi) \equiv 2 \int_0^{\infty} dx f(x) \cos(2\pi\xi x). \quad (3.207)$$

Since the cosine is an even function, it follows at once that

$$F_c(\xi) = F_c(-\xi). \quad (3.208)$$

Since $F_c(x)$ is computed from knowledge of $f(x)$ for $x \geq 0$, and negative x values never enter into (3.207), we cannot expect to recover $f(x)$ for $x < 0$ from $F_c(\xi)$. The inversion formula for $x \geq 0$ follows from (3.153), with the result

$$f(x) = 2 \int_0^{\infty} d\xi F_c(\xi) \cos(2\pi\xi x), \quad x \geq 0. \quad (3.209)$$

This result is valid for $x \geq 0$ without any assumptions about the symmetry of $f(x)$. On the other hand, should we ignore the condition on x and evaluate the right-hand side of (3.209) for negative x , we would find that we had a representation of an even function. The situation is analogous to a Fourier series, which can be viewed as a representation of a periodic function for $-\infty \leq x \leq \infty$ or of an arbitrary function for $-\frac{1}{2}L \leq x \leq \frac{1}{2}L$. Equation (3.209) is a representation of an even function for $-\infty \leq x \leq \infty$ or of an arbitrary function for $x \geq 0$.

Fourier sine transform The Fourier sine transform is defined as

$$F_s(\xi) \equiv 2 \int_0^{\infty} dx f(x) \sin(2\pi\xi x). \quad (3.210)$$

Since the sine is an odd function,

$$F_s(\xi) = -F_s(-\xi), \quad (3.211)$$

no matter the symmetry of $f(x)$. The inversion formula, which follows from (3.154), is

$$f(x) = 2 \int_0^{\infty} d\xi F_s(\xi) \sin(2\pi\xi x), \quad x \geq 0. \quad (3.212)$$

Again, this result is valid for $x \geq 0$ without any assumptions about the symmetry of $f(x)$, but the right-hand side of the equation is an odd function of x . Equation (3.212) is a representation of an odd function for $-\infty \leq x \leq \infty$ or an arbitrary function for $x \geq 0$.

3.4 MULTIDIMENSIONAL FOURIER TRANSFORMS

3.4.1 Basis functions

One-dimensional (1D) Fourier analysis involves the complex-exponential basis function $u_\xi(x) = \exp(2\pi i \xi x)$. To perform a similar analysis for a 2D or 3D function, we must construct 2D and 3D complex exponentials. In 2D a reasonable generalization of $u_\xi(x)$ is

$$u_{\xi\eta}(x, y) \equiv \exp[2\pi i(\xi x + \eta y)]. \quad (3.213)$$

Regarded as a function of x for fixed y , this function is periodic with period $1/\xi$, and as a function of y for fixed x it is periodic with period $1/\eta$ (see Fig. 3.4). Thus ξ is the spatial frequency for the x variation and η is the spatial frequency for the y variation.

Fig. 3.4 Illustration of the 2D basis function, $\exp[2\pi i(\xi_0 x + \eta_0 y)]$.

Vector notation It is convenient to think of ξ and η as Cartesian coordinates of a 2D vector $\boldsymbol{\rho}$. Similarly, x and y are the components of a 2D spatial-position vector \mathbf{r} . We can then recognize the exponent in (3.213) as a simple 2D scalar product and write

$$u_{\boldsymbol{\rho}}(\mathbf{r}) = \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \quad (3.214)$$

In the same fashion, we can define a 3D complex-exponential basis function by

$$u_{\xi\eta\zeta}(x, y, z) \equiv \exp[2\pi i(\xi x + \eta y + \zeta z)]. \quad (3.215)$$

Now ξ , η and ζ are the spatial frequencies for variation along x , y and z , respectively. We shall usually use the same notation in 3D as in 2D; that is, $\boldsymbol{\rho}$ is now a 3D spatial-frequency vector with Cartesian components (ξ, η, ζ) while \mathbf{r} is a 3D spatial position vector with Cartesian components (x, y, z) . With these conventions, (3.214) is valid in 3D as well as 2D. In fact, it holds in any number of dimensions.

Sometimes we shall encounter 2D and 3D vectors in the same problem and must make a notational distinction between them. In such cases, we shall reserve $\boldsymbol{\rho}$ and \mathbf{r} for the 2D vectors and use $\boldsymbol{\sigma}$ and \mathbf{r} for the 3D ones. For the remainder of this chapter, however, that distinction is not needed and dimensionality will be determined by context.

Orthonormality and completeness The orthonormality and completeness properties of the multidimensional basis functions follow from their 1D counterparts. The statement of orthonormality in two dimensions is [cf. (3.8)]

$$\begin{aligned} & \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy [u_{\xi\eta}(x, y)]^* u_{\xi'\eta'}(x, y) \\ &= \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy \exp[-2\pi i(\xi x + \eta y)] \exp[2\pi i(\xi' x + \eta' y)] \\ &= \delta(\xi - \xi') \delta(\eta - \eta'). \end{aligned} \quad (3.216)$$

A similar expression holds in 3D, but it is much cleaner to use the vector notation. In any number of dimensions we can write

$$\int_{\infty} d^n r [u_{\boldsymbol{\rho}'}(\mathbf{r})]^* u_{\boldsymbol{\rho}}(\mathbf{r}) = \int_{\infty} d^n r \exp[-2\pi i(\boldsymbol{\rho} - \boldsymbol{\rho}') \cdot \mathbf{r}] = \delta(\boldsymbol{\rho} - \boldsymbol{\rho}'). \quad (3.217)$$

See Sec. 2.4.1 for a review of notational conventions in n D and Sec. 2.4.2 for a discussion of n D delta functions.

The closure or completeness integral in n D is

$$\int_{\infty} d^n \rho [u_{\boldsymbol{\rho}}(\mathbf{r})]^* u_{\boldsymbol{\rho}'}(\mathbf{r}') = \int_{\infty} d^n \rho \exp[-2\pi i\boldsymbol{\rho} \cdot (\mathbf{r} - \mathbf{r}')] = \delta(\mathbf{r} - \mathbf{r}'). \quad (3.218)$$

Thus the n D complex exponentials form a complete orthonormal set in any of the senses that their 1D counterparts do. In particular, they are complete in $\mathbb{L}_2(\mathbb{R}^n)$ if convergence in the mean is understood.

3.4.2 Definitions and elementary properties

Definitions The 2D Fourier transform of a suitably well behaved function in Cartesian coordinates is defined as

$$F(\xi, \eta) = \mathcal{F}_2 \{f(x, y)\} = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy f(x, y) e^{-2\pi i(\xi x + \eta y)}. \quad (3.219)$$

We can look at this equation as two consecutive 1D transforms, first on y then on x . In operator notation,

$$\mathcal{F}_2 = \mathcal{F}_{1(x \rightarrow \xi)} \mathcal{F}_{1(y \rightarrow \eta)}. \quad (3.220)$$

These operators commute so long as both integrals remain finite. To obtain the inverse of the 2D transform, we simply perform two consecutive 1D inverse transforms (in either order), giving

$$f(x, y) = \mathcal{F}_2^{-1} \{F(\xi, \eta)\} = \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\eta F(\xi, \eta) e^{2\pi i(\xi x + \eta y)}. \quad (3.221)$$

This result is valid in any circumstance where both of the individual 1D operations are valid.

A similar argument holds in any number of dimensions; the n D Fourier transform in Cartesian coordinates can always be decomposed into n consecutive 1D

transforms, and the inverse transform has the expected form so long as all of the constituent 1D operations are legal.

In vector form, the general n D expressions for the Fourier transform and its inverse are

$$F(\boldsymbol{\rho}) = \mathcal{F}_n\{f(\mathbf{r})\} = \int_{\infty} d^n r f(\mathbf{r}) \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}), \quad (3.222)$$

$$f(\mathbf{r}) = \mathcal{F}_n^{-1}\{F(\boldsymbol{\rho})\} = \int_{\infty} d^n \rho F(\boldsymbol{\rho}) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \quad (3.223)$$

Multidimensional tempered distributions Multidimensional test functions and good functions were defined in Sec. 2.4.1. By decomposing the n D transform of a good function into n 1D transforms as above, it can be shown that the Fourier transform of a good function is a good function in any number of dimensions (Strichartz, 1994). From this result we can define the n D Fourier transform of a generalized function analogously to (3.85). Let $g(\mathbf{r})$ be a generalized function corresponding to an n D tempered distribution, $t(\mathbf{r})$ be an n D good function and $T(\boldsymbol{\rho})$ be its n D Fourier transform. Then the defining equation for $G(\boldsymbol{\rho})$ is

$$\int_{\infty} d^n r g(\mathbf{r}) t(\mathbf{r}) = \int_{\infty} d^n \rho [G(\boldsymbol{\rho})]^* T(\boldsymbol{\rho}). \quad (3.224)$$

Both sides of this equation have the look and feel of a scalar product in $\mathbb{L}_2(\mathbb{R}^n)$, but of course they are not since $g(\mathbf{r})$ is not necessarily in that space.

From this definition we can derive n D counterparts of most of the Fourier theorems developed in 1D with the assurance that they are valid for generalized functions as well as ordinary ones. In particular, (3.222) and (3.223) work for generalized functions so long as we interpret any improper integrals by expressing the generalized function as the limit of good functions.

Below we present the n D extensions of several other theorems from Sec. 3.3. Derivations are omitted, but in most cases they involve little more than the notational change, $x \rightarrow \mathbf{r}$ and $\xi \rightarrow \boldsymbol{\rho}$, in the corresponding 1D derivation. Except as noted, all theorems given are valid for generalized functions associated with n D tempered distributions (Strichartz, 1994).

Multidimensional Parseval's relations If both $f(\mathbf{r})$ and $F(\boldsymbol{\rho})$ are in $\mathbb{L}_2(\mathbb{R}^n)$, then the n D Fourier transformation is a unitary operator in that space. Since unitary transformations preserve norms and scalar products, we can write at once

$$\int_{\infty} d^n r [f_1(\mathbf{r})]^* f_2(\mathbf{r}) = \int_{\infty} d^n \rho [F_1(\boldsymbol{\rho})]^* F_2(\boldsymbol{\rho}), \quad (3.225)$$

$$\int_{\infty} d^n r |f(\mathbf{r})|^2 = \int_{\infty} d^n \rho |F(\boldsymbol{\rho})|^2, \quad (3.226)$$

provided both $f_1(\mathbf{r})$ and $f_2(\mathbf{r})$ are in $\mathbb{L}_2(\mathbb{R}^n)$. If one of these functions is an n D good function and the other is a generalized function, (3.225) also holds, virtually by definition [see (3.224)]. Note, however, that (3.226) may not work since the square of a generalized function is not necessarily defined.

Symmetry All of the 1D symmetry properties derived in Sec. 3.3.5 carry over to n D essentially unchanged. Directly from the definition we have the so-called Hermiticity property:

$$F(-\boldsymbol{\rho}) = [F(\boldsymbol{\rho})]^* \quad \text{if } f(\mathbf{r}) \text{ is real.} \quad (3.227)$$

To clarify the notation, let us consider specifically the 2D case. If $F(\boldsymbol{\rho})$ is a shorthand for $F(\xi, \eta)$, then $F(-\boldsymbol{\rho})$ signifies $F(-\xi, -\eta)$. If we represent $F(\boldsymbol{\rho})$ as a gray-scale image, then $F(-\boldsymbol{\rho})$ is the same image with the ξ and η axes inverted.

Even (odd) functions transform to even (odd) functions in n D, *i.e.*,

$$F(\boldsymbol{\rho}) = \pm F(-\boldsymbol{\rho}) \quad \text{if } f(\mathbf{r}) = \pm f(-\mathbf{r}). \quad (3.228)$$

Central-ordinate and central-slice theorems The central-ordinate theorems in n D follow directly from the definitions of the transform and its inverse. The Fourier kernel $\exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) = 1$ if either $\boldsymbol{\rho} = \mathbf{0}$ or $\mathbf{r} = \mathbf{0}$ (but note that these are vector equations, so *all* components must be zero). Thus

$$F(\mathbf{0}) = \int_{-\infty}^{\infty} d^n r f(\mathbf{r}), \quad (3.229)$$

$$f(\mathbf{0}) = \int_{-\infty}^{\infty} d^n \rho F(\boldsymbol{\rho}). \quad (3.230)$$

As in 1D, these relations are very useful for checking the constants in a Fourier calculation.

An important generalization of the central-ordinate theorem ensues if we use Cartesian coordinates and set some but not all of the corresponding frequency variables to zero. For example, if we write $f(\mathbf{r}) = f(x, y)$ and $F(\boldsymbol{\rho}) = F(\xi, \eta)$ in 2D, we find that

$$F(0, \eta) = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy f(x, y) e^{-2\pi i \eta y}; \quad (3.231)$$

$$F(\xi, 0) = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy f(x, y) e^{-2\pi i \xi x}. \quad (3.232)$$

These equations are special cases of the *central-slice theorem*, which plays a key role in the theory of tomographic imaging. This theorem is explored further in Chap. 4, but to get a glimmering of its content we rewrite (3.231) as

$$F(0, \eta) = \int_{-\infty}^{\infty} dy \left[\int_{-\infty}^{\infty} dx f(x, y) \right] e^{-2\pi i \eta y}. \quad (3.233)$$

The quantity in square brackets is a 1D function of y obtained by integrating $f(x, y)$ along lines parallel to the x axis. This 1D function is called the *line-integral projection* (or simply *projection*) of $f(x, y)$, with the projection direction being parallel to the x axis. The remaining integral in (3.233) is just a 1D Fourier transform with respect to y . Thus (3.233) says that the 1D Fourier transform of a projection of a 2D function is the same as the 2D Fourier transform of the function, but evaluated along a line through the origin ($\xi = 0$) in the 2D frequency domain.

Derivatives The Fourier transform of the derivative of a function is essentially the same thing in 1D and n D, except that in n D we must distinguish the various possible partial derivatives. For example, the rationale that led to (3.98) shows also that

$$\mathcal{F}_n \left\{ \frac{\partial}{\partial x} f(\mathbf{r}) \right\} = 2\pi i \xi F(\boldsymbol{\rho}). \quad (3.234)$$

Here ξ is the x -component of the spatial-frequency vector in any number of dimensions. Similar results hold for other components, higher derivatives and mixed partial derivatives.

On the other hand, there is an additional richness to the subject of derivatives in higher dimensions. Since $f(\mathbf{r})$ is a scalar function, we can compute its gradient, which is a vector in the direction of maximum rate of change of $f(\mathbf{r})$. Proceeding from the expression for a gradient in Cartesian components and using (3.234), we can show that

$$\mathcal{F}_n \{ \nabla f(\mathbf{r}) \} = 2\pi i \boldsymbol{\rho} F(\boldsymbol{\rho}). \quad (3.235)$$

Since $\nabla f(\mathbf{r})$ is a vector, so is its Fourier transform; (3.235) is really n equations, one for each component of the vector. The Fourier transform of a gradient always points in the same direction as $\boldsymbol{\rho}$.

Similarly, the Fourier transform of a Laplacian (divergence of the gradient) is given by

$$\mathcal{F}_n \{ \nabla^2 f(\mathbf{r}) \} = (2\pi i \rho)^2 F(\boldsymbol{\rho}), \quad (3.236)$$

where $\rho = |\boldsymbol{\rho}|$ is the magnitude of the spatial frequency vector. For example, in 3D, $\rho = \sqrt{\xi^2 + \eta^2 + \zeta^2}$. Since the Laplacian is a scalar, so is its Fourier transform.

Shifts and linear phase factors Just as in 1D, multiplying an n D function by a linear phase factor produces a translation or shift of its Fourier transform, and vice versa. It follows from the definition of the n D transform that

$$\mathcal{F}_n \{ \exp(+2\pi i \boldsymbol{\rho}_0 \cdot \mathbf{r}) f(\mathbf{r}) \} = F(\boldsymbol{\rho} - \boldsymbol{\rho}_0). \quad (3.237)$$

$$\mathcal{F}_n \{ f(\mathbf{r} - \mathbf{r}_0) \} = \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}_0) F(\boldsymbol{\rho}). \quad (3.238)$$

Scaled functions In 2D, $f(\mathbf{r})$ is the vector notation for the function $f(x, y)$. We shall use the notation $f(\mathbf{r}/a)$ (with a real) to mean $f(x/a, y/a)$; the extension to any number of dimensions is straightforward. By a change of variables in the definition of the n D transform, we find, analogously to (3.111),

$$\mathcal{F}_n \{ f(\mathbf{r}/a) \} = |a|^n F(a\boldsymbol{\rho}). \quad (3.239)$$

This is one of the few Fourier theorems where the number of dimensions n enters explicitly.

A consequence of this result and the central-ordinate theorem is that the integral of $f(\mathbf{r})$ and $|a|^{-n} f(\mathbf{r}/a)$ are the same. In n D, if we wish to scale all n coordinate axes of a function by a factor a , we must scale its amplitude by $|a|^{-n}$ to maintain a constant integral.

3.4.3 Multidimensional convolution and correlation

The vector notation makes it simple to generalize the definitions of convolution and correlation to n D. An n D convolution is defined by [cf. (3.114)]

$$[f * h](\mathbf{r}) = f(\mathbf{r}) * h(\mathbf{r}) = \int_{\infty} d^n r' f(\mathbf{r}') h(\mathbf{r} - \mathbf{r}') = \int_{\infty} d^n r'' f(\mathbf{r} - \mathbf{r}'') h(\mathbf{r}''). \quad (3.240)$$

Explicitly in 2D, we have

$$[f * h](x, y) = \int_{-\infty}^{\infty} dx' \int_{-\infty}^{\infty} dy' f(x', y') h(x - x', y - y'). \quad (3.241)$$

Similarly, the n D correlation is given by [cf. (3.115)]

$$[f \star h](\mathbf{r}) = \int_{\infty} d^n r' f(\mathbf{r} + \mathbf{r}') h(\mathbf{r}') = \int_{\infty} d^n r'' f(\mathbf{r}'') h(\mathbf{r}'' - \mathbf{r}). \quad (3.242)$$

The n D Fourier transforms of the convolution and correlation are, respectively,

$$\mathcal{F}_n\{[f * h](\mathbf{r})\} = F(\boldsymbol{\rho}) H(\boldsymbol{\rho}), \quad (3.243)$$

$$\mathcal{F}_n\{[f \star h](\mathbf{r})\} = F(\boldsymbol{\rho}) H(-\boldsymbol{\rho}) = F(\boldsymbol{\rho}) [H(\boldsymbol{\rho})]^*, \quad (3.244)$$

where the last step in (3.244) is valid if $h(\mathbf{r})$ is real.

An important special case of (3.244) occurs when $h(\mathbf{r}) = f^*(\mathbf{r})$. The correlation is referred to as a complex autocorrelation in that case, and we have

$$\mathcal{F}_n\{[f \star f^*](\mathbf{r})\} = |F(\boldsymbol{\rho})|^2, \quad (3.245)$$

which is the generalization of (3.135). This equation will prove to be essential in discussing the properties of incoherent optical systems.

3.4.4 Rotationally symmetric functions

So far we have discussed n D Fourier transforms as n -fold integrals in Cartesian coordinates, but if the function being transformed has symmetry properties, other coordinate systems could be preferable. Consider, for example, a 2D function with rotational symmetry about the origin. The natural coordinate system is polar coordinates (r, θ) , with $r = |\mathbf{r}|$ being the distance from the origin and θ being the angle measured from the x axis. In these coordinates, $f(\mathbf{r})$ is independent of θ and can be written as $f(r)$.

In 2D polar coordinates, $\boldsymbol{\rho} \cdot \mathbf{r} = \rho r \cos(\theta - \theta_\rho)$, where (ρ, θ_ρ) are the polar coordinates of $\boldsymbol{\rho}$, and we can write

$$\mathcal{F}_2\{f(r)\} = \int_0^{\infty} r dr f(r) \int_0^{2\pi} d\theta e^{-2\pi i \rho r \cos(\theta - \theta_\rho)}. \quad (3.246)$$

Since $f(r)$ is independent of θ , the integral over θ can be done once and for all. A well known integral (and a very important one in optics) is

$$J_k(z) = \frac{i^{-k}}{\pi} \int_0^{\pi} d\theta e^{iz \cos \theta} \cos(k\theta), \quad (3.247)$$

where $J_k(z)$ is the Bessel function of the first kind of order k (Abramowitz and Stegun, 1965). This integral is often used as the definition of this Bessel function.

With a little algebra, the integral in (3.246) can be put into the form of (3.247) with $k = 0$, yielding

$$\mathcal{F}_2 \{f(r)\} = 2\pi \int_0^\infty r dr J_0(2\pi\rho r) f(r). \quad (3.248)$$

This form is often referred to as the *Hankel transform of zeroth order*, but we emphasize that it is also the 2D *Fourier transform* of a function with rotational symmetry.

A similar calculation applies in 3D for spherically symmetric functions. The natural coordinate system is spherical polar coordinates (r, θ, ϕ) , where θ is the colatitude, measured from the z axis, and ϕ is the azimuth or longitude. A spherically symmetric function $f(\mathbf{r})$ is independent of θ and ϕ , so we can write $f(\mathbf{r}) = f(r)$, where $r = |\mathbf{r}|$. The exponent in the Fourier kernel is simplified, without loss of generality, by taking the z axis to be parallel to $\boldsymbol{\rho}$, so that $\boldsymbol{\rho} \cdot \mathbf{r} = \rho r \cos \theta$. We then have

$$\mathcal{F}_3 \{f(r)\} = \int_0^\infty r^2 dr f(r) \int_0^{2\pi} d\phi \int_0^\pi d\theta \sin \theta \exp(-2\pi i \rho r \cos \theta), \quad (3.249)$$

and some algebra gives

$$\mathcal{F}_3 \{f(r)\} = 4\pi \int_0^\infty r^2 dr \operatorname{sinc}(2\rho r) f(r). \quad (3.250)$$

The constants in (3.248) and (3.250) can be checked by the central-ordinate theorem; since $J_0(0) = \operatorname{sinc}(0) = 1$, $F(\mathbf{0})$ is given by the integral of the function in both cases.

3.4.5 Some special functions and their transforms

Delta functions The definitions of the n D delta function and the n D Fourier transform show at once that

$$\mathcal{F}_n \{\delta(\mathbf{r})\} = 1, \quad (3.251)$$

$$\mathcal{F}_n \{\delta(\mathbf{r} - \mathbf{r}_0)\} = \exp(-2\pi i \mathbf{r}_0 \cdot \boldsymbol{\rho}). \quad (3.252)$$

The transforms of various n D derivatives of the delta function follow from these results and (3.234)–(3.236). For example,

$$\mathcal{F}_n \{\nabla^2 \delta(\mathbf{r})\} = -4\pi^2 \rho^2. \quad (3.253)$$

Complex exponentials, sines and cosines A modest change of variables in the expression for the n D Fourier transform shows that

$$\mathcal{F}_n \{\exp(2\pi i \boldsymbol{\rho}_0 \cdot \mathbf{r})\} = \delta(\boldsymbol{\rho} - \boldsymbol{\rho}_0). \quad (3.254)$$

From this result and (3.5) and (3.6), we find

$$\mathcal{F}_n \{\cos(2\pi \boldsymbol{\rho}_0 \cdot \mathbf{r})\} = \frac{1}{2} [\delta(\boldsymbol{\rho} - \boldsymbol{\rho}_0) + \delta(\boldsymbol{\rho} + \boldsymbol{\rho}_0)], \quad (3.255)$$

$$\mathcal{F}_n \{\sin(2\pi \boldsymbol{\rho}_0 \cdot \mathbf{r})\} = \frac{1}{2i} [\delta(\boldsymbol{\rho} - \boldsymbol{\rho}_0) - \delta(\boldsymbol{\rho} + \boldsymbol{\rho}_0)]. \quad (3.256)$$

As in 1D, sines and cosines transform to pairs of delta functions. These delta functions are located at $\boldsymbol{\rho} = \pm \boldsymbol{\rho}_0$, two points oppositely displaced from the origin in the n D frequency space.

Cylinders and besincs A convenient special function in 2D is the cylinder function, which is unity inside a disc of diameter D and zero outside:

$$\text{cyl}\left(\frac{r}{D}\right) \equiv \begin{cases} 1 & \text{if } r < D/2 \\ 0 & \text{if } r > D/2 \end{cases} . \quad (3.257)$$

Note that r is $|\mathbf{r}|$, where \mathbf{r} is a 2D vector, so $\text{cyl}(r/D)$ is specifically a 2D function. The name cylinder evokes a surface relief plot of the function, which looks like a cylinder (see Fig. 3.5). The cylinder function is a useful representation of a circular aperture in optics.

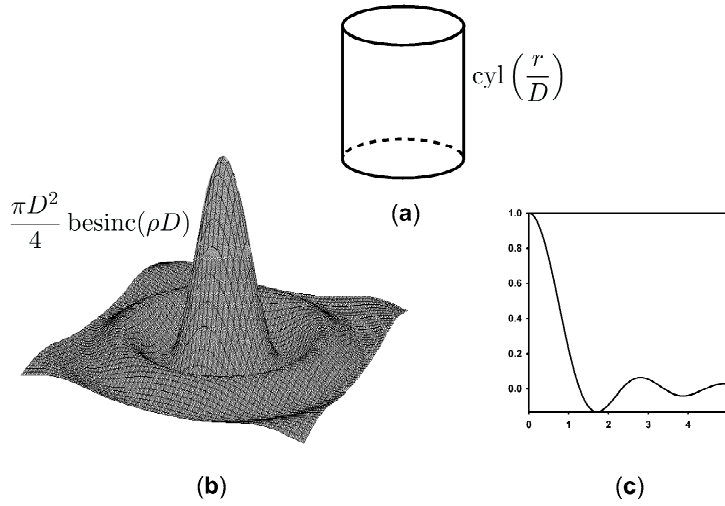

Fig. 3.5 (a) The cylinder function $\text{cyl}(r)$; (b) The 2D Fourier transform of the cylinder, $\text{besinc}(\rho)$ presented as a relief plot; (c) Radial profile of the 2D function in (b).

Since the cylinder function is rotationally symmetric, its Fourier transform can be found from (3.248):

$$\mathcal{F}_2\{\text{cyl}(r/D)\} = 2\pi \int_0^{\frac{1}{2}D} r \, dr \, J_0(2\pi\rho r) = \frac{\pi D^2}{4} \cdot \frac{2J_1(\pi\rho D)}{\pi\rho D}, \quad (3.258)$$

where $J_1(\cdot)$ is the first-order Bessel function of the first kind (Abramowitz and Stegun, 1965). A succinct way to write this equation is

$$\mathcal{F}_2\{\text{cyl}(r/D)\} = \frac{\pi D^2}{4} \text{besinc}(\rho D), \quad (3.259)$$

where

$$\text{besinc}(t) \equiv \frac{2J_1(\pi t)}{\pi t}. \quad (3.260)$$

The besinc function, also referred to as a jinc or sombrero function, is the 2D counterpart of the sinc function. It is plotted in Fig. 3.5. Since $\text{besinc}(0) = 1$, the factor of $\pi D^2/4$ in (3.259) is in accord with the 2D central-ordinate theorem; the area of the disc is the integral of the cylinder function.

Gaussians and quadratic phase factors The n D Gaussian is just a product of 1D Gaussians. For example, in 3D,

$$\text{gaus}\left(\frac{\mathbf{r}}{a}\right) = e^{-\pi(x^2+y^2+z^2)/a^2} = e^{-\pi x^2/a^2} e^{-\pi y^2/a^2} e^{-\pi z^2/a^2}. \quad (3.261)$$

Since the n D function factors into a product of n 1D functions, it follows that

$$\mathcal{F}_n\{\text{gaus}(\mathbf{r}/a)\} = |a|^n e^{-\pi a^2 \rho^2} = |a|^n \text{gaus}(a\rho), \quad (3.262)$$

where we have used (3.180) and (3.239).

By the same argument, an n D quadratic phase factor is a product of n 1D ones, and we have [cf. (3.185)]

$$\mathcal{F}_n\{e^{i\pi\beta r^2}\} = \left(\frac{i}{\beta}\right)^{\frac{1}{2}n} e^{-i\pi\rho^2/\beta}. \quad (3.263)$$

3.4.6 Multidimensional periodicity

Comb functions Consider the 2D function $\text{comb}(\mathbf{r}/a)$ defined by

$$\text{comb}(\mathbf{r}/a) \equiv \text{comb}(x/a) \text{comb}(y/a) = \sum_{k=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} \delta\left(\frac{x}{a} - k\right) \delta\left(\frac{y}{a} - m\right). \quad (3.264)$$

Regarded as a 2D function, $\delta(x/a - k)$ is a line mass (see Sec. 2.4.4) located at $x = ka$. The product $\delta(x/a - k) \delta(y/a - m)$ is the intersection of two line masses or a point mass located at $(x, y) = (ka, ma)$, so $\text{comb}(\mathbf{r}/a)$ is a set of 2D delta functions located on a square lattice. Similarly, in n D, $\text{comb}(\mathbf{r}/a)$ is a product of n 1D combs or a set of delta functions on a regular lattice in \mathbb{R}^n .

Since the n D comb function is a product of n 1D functions, we have

$$\mathcal{F}_n\{\text{comb}(\mathbf{r}/a)\} = |a|^n \text{comb}(a\rho). \quad (3.265)$$

If the lattice has different spacings in different directions, the n D comb function can be expressed in product form and transformed one dimension at a time. For example, in 2D,

$$\mathcal{F}_2\{\text{comb}(x/a) \text{comb}(y/b)\} = |ab| \text{comb}(a\xi) \text{comb}(b\eta). \quad (3.266)$$

The delta functions in frequency space are now spaced by $1/a$ along ξ and $1/b$ along η .

If the lattice is not orthogonal, more care is needed. Consider a 2D lattice of delta functions located at the points $\mathbf{r} = m_1\mathbf{a} + m_2\mathbf{b}$, where \mathbf{a} and \mathbf{b} are arbitrary noncollinear vectors and m_1 and m_2 are integers. An array of delta functions on these points can be written

$$\sum_{m_1=-\infty}^{\infty} \sum_{m_2=-\infty}^{\infty} \delta(\mathbf{r} - m_1\mathbf{a} - m_2\mathbf{b}). \quad (3.267)$$

A more compact way of writing this expression (and one more easily generalized to higher dimensions) makes use of a matrix \mathbf{P} , defined by

$$\mathbf{P} = \begin{bmatrix} a_x & b_x \\ a_y & b_y \end{bmatrix}, \quad (3.268)$$

and a column vector $\mathbf{m} = (m_1, m_2)^t$, called a *multi-index*. With this notation,

$$\sum_{m_1=-\infty}^{\infty} \sum_{m_2=-\infty}^{\infty} \delta(\mathbf{r} - m_1\mathbf{a} - m_2\mathbf{b}) = \sum_{\mathbf{m}} \delta(\mathbf{r} - \mathbf{P}\mathbf{m}), \quad (3.269)$$

where the sum over \mathbf{m} implies the double sum over m_1 and m_2 from $-\infty$ to ∞ . This matrix-vector form can be generalized to nD , in which case \mathbf{P} becomes an $n \times n$ matrix and \mathbf{m} an $n \times 1$ column vector of integers. With this notation, it can be shown that (Marks, 1991)

$$\mathcal{F}_n \left\{ |\det(\mathbf{P})| \sum_{\mathbf{m}} \delta(\mathbf{r} - \mathbf{P}\mathbf{m}) \right\} = \sum_{\mathbf{m}} \delta(\boldsymbol{\rho} - \mathbf{Q}\mathbf{m}), \quad (3.270)$$

where $\mathbf{Q}^t = \mathbf{P}^{-1}$, and $\det(\cdot)$ denotes determinant.

This equation shows that the Fourier transform of a general nD comb of delta functions on the nonorthogonal lattice $\mathbf{P}\mathbf{m}$ is a similar comb on the *reciprocal lattice* $\mathbf{Q}\mathbf{m}$. The reciprocal lattice is an important tool in solid-state physics (see, for example, Ashcroft and Mermin, 1976).

In 2D, the points $\mathbf{Q}\mathbf{m}$ are located at $\boldsymbol{\rho} = m_1\mathbf{A} + m_2\mathbf{B}$, where \mathbf{A} and \mathbf{B} are the basis vectors for the reciprocal lattice, defined such that $\mathbf{a} \cdot \mathbf{A} = \mathbf{b} \cdot \mathbf{B} = 1$ and $\mathbf{a} \cdot \mathbf{B} = \mathbf{b} \cdot \mathbf{A} = 0$. Equation (3.266) is the special case of (3.270) for diagonal matrices \mathbf{P} and \mathbf{Q} , in which case $\mathbf{a} \perp \mathbf{b}$ and $\mathbf{A} \perp \mathbf{B}$.

Multidimensional periodic functions An nD function $f(\mathbf{r})$ satisfies the periodicity condition

$$f(\mathbf{r} + \mathbf{P}\mathbf{m}) = f(\mathbf{r}), \quad (3.271)$$

where \mathbf{P} is some $n \times n$ matrix \mathbf{P} and \mathbf{m} is again an $n \times 1$ vector of integers. As a simple example, consider $n = 3$ and $\mathbf{P} = L\mathbf{I}_3$, where \mathbf{I}_3 is the 3×3 unit matrix. With this choice, (3.271) becomes

$$f(x + m_1L, y + m_2L, z + m_3L) = f(x, y, z). \quad (3.272)$$

Since m_1, m_2 and m_3 are integers, this equation describes a 3D function that is periodic on a cubic lattice of spacing L . It will be useful to keep this simple example in mind, but the remainder of this section will use the more general formula (3.271).

To proceed, we need to define a *unit cell*, just as in solid state physics (Ashcroft and Mermin, 1976). One definition of a unit cell is that it is the set of points that lies closer to the origin than to any other point in the lattice. This particular choice is known as the *Wigner-Seitz unit cell*. A geometrical method to construct a Wigner-Seitz unit cell is shown in Fig. 3.6.

By analogy to (3.188), the periodic function of (3.271) can be expressed as

$$f(\mathbf{r}) = f_0(\mathbf{r}) * \sum_{\mathbf{m}} \delta(\mathbf{r} - \mathbf{P}\mathbf{m}), \quad (3.273)$$

where

$$f_0(\mathbf{r}) = \begin{cases} f(\mathbf{r}) & \text{if } \mathbf{r} \text{ is in unit cell} \\ 0 & \text{otherwise} \end{cases}. \quad (3.274)$$

Fig. 3.6 Method of constructing the Wigner-Seitz unit cell in 2D. The perpendicular bisector is constructed for each line connecting the origin to another point in the lattice, and the unit cell is the smallest area bounded by all of these lines. Hence points in the unit cell lie closer to the origin than to any other lattice point.

We can now take the Fourier transform of $f(\mathbf{r})$ by use of (3.243) and (3.270). The result is [cf. (3.189)]

$$F(\boldsymbol{\rho}) = \mathcal{F}_n\{f(\mathbf{r})\} = F_0(\boldsymbol{\rho}) \frac{1}{|\det(\mathbf{P})|} \sum_{\mathbf{m}} \delta(\boldsymbol{\rho} - \mathbf{Q}\mathbf{m}), \quad (3.275)$$

where $\mathbf{Q}^t = \mathbf{P}^{-1}$ and $F_0(\boldsymbol{\rho})$ is the Fourier transform of $f_0(\mathbf{r})$. Thus, just as in the 1D case, the Fourier transform of a periodic function is the Fourier transform of its values in the unit cell times a sum of delta functions. Again the periodicity of the function restricts its Fourier transform to a discrete set of frequencies. Here the discrete frequencies are the points of the reciprocal lattice. In fact, it is precisely this property that gives rise to the term reciprocal lattice; many books refer to Fourier space as *reciprocal space*.

Still pursuing the analogy to the 1D case, we take the inverse transform of (3.275), yielding [cf. (3.191)]

$$f(\mathbf{r}) = \frac{1}{|\det(\mathbf{P})|} \sum_{\mathbf{m}} F_0(\mathbf{Q}\mathbf{m}) \exp[2\pi i(\mathbf{Q}\mathbf{m}) \cdot \mathbf{r}]. \quad (3.276)$$

This is the n D Fourier series for the periodic function $f(\mathbf{r})$. As in the 1D case, the Fourier coefficients of a periodic function are sampled values of the Fourier transform of one period (unit cell) of the function.

As noted in Sec. 3.2.1, there are two ways to view a Fourier series. It is a representation of a periodic function in all space or a representation of an arbitrary function in a finite region. We now investigate the latter view in the multidimensional case.

Consider a function $f(\mathbf{r})$ that vanishes identically unless \mathbf{r} is in a region \mathbf{S}_f of the n D space. We choose an arbitrary lattice, defined by a matrix \mathbf{P} , with no restrictions except that \mathbf{S}_f must fit entirely within the Wigner-Seitz unit cell of the lattice. We define a *support function* $S_f(\mathbf{r})$ via

$$S_f(\mathbf{r}) = \begin{cases} 1 & \text{if } \mathbf{r} \text{ is in } \mathbf{S}_f \\ 0 & \text{otherwise} \end{cases}. \quad (3.277)$$

Then an exact representation of $f(\mathbf{r})$, valid in all space, is²

²The possibility of an exact representation like (3.278) is a consequence of sampling theory, a topic to be introduced in the next section. The requirement that the function fit within the unit cell

$$f(\mathbf{r}) = \frac{1}{|\det(\mathbf{P})|} \sum_{\mathbf{m}} F(\mathbf{Qm}) \exp[2\pi i(\mathbf{Qm}) \cdot \mathbf{r}] S_f(\mathbf{r}). \quad (3.278)$$

Without the support function, the series in (3.278) would represent an infinite set of replicas of $f(\mathbf{r})$, but the presence of $S_f(\mathbf{r})$ sets all replicas but one to zero.

A suggestive way to rewrite (3.278) is:

$$f(\mathbf{r}) = \sum_{\mathbf{m}} F(\mathbf{Qm}) \Phi_{\mathbf{m}}(\mathbf{r}), \quad (3.279)$$

where $\Phi_{\mathbf{m}}(\mathbf{r})$ is a basis function defined by

$$\Phi_{\mathbf{m}}(\mathbf{r}) \equiv \frac{1}{|\det(\mathbf{P})|} \exp[2\pi i(\mathbf{Qm}) \cdot \mathbf{r}] S_f(\mathbf{r}). \quad (3.280)$$

These basis functions can thus be used to represent exactly an arbitrary function of compact support.

3.5 SAMPLING THEORY

So far we have considered Fourier expansions of functions of a continuous variable x , and most of our results have been couched in terms of integrals with respect to this variable. When it comes time to perform real calculations, however, we often must have recourse to a digital computer, and computers usually deal with discrete sets of numbers. It is straightforward to convert a continuous function $f(x)$ to such a discrete set — we can simply evaluate it at a discrete set of points. The resulting numbers $f_j \equiv f(x_j)$ are referred to as *samples* of $f(x)$, and the process of evaluation is called *sampling*. We shall express this operation via the *sampling operator* \mathcal{S} , a continuous-to-discrete operator that derives sample values from a function. The inverse process — determination of a continuous function from its discrete samples — is more difficult and in fact impossible without placing stringent conditions on the function. If there were no restrictions, the function could vary in an arbitrary manner between the samples and we would have no way of knowing it. Some sort of smoothness constraint is required.

3.5.1 Bandlimited functions

One way of saying that a function is smooth is to say that its Fourier transform vanishes identically outside a finite interval; such a function is said to be *bandlimited*. One way to construct a bandlimited function, at least in principle, is to start with an arbitrary function and pass it through an ideal low-pass filter. As we shall see in Chap. 9, certain kinds of optical systems act as low-pass filters with a sharp cutoff, so the image with such systems is bandlimited; its Fourier transform has compact support. As we noted in Sec. 3.3.9, however, the Fourier transform of a function of compact support cannot itself have compact support, so the output of

is equivalent to saying that the reciprocal lattice satisfies the Nyquist condition for sampling in frequency space. See Sec. 3.5.4.

an ideal low-pass filter must in principle have infinite spatial extent. If we truncate the spatial function (*e.g.*, record the image on a piece of film of finite size), we induce higher spatial frequencies, so the image is no longer strictly bandlimited.

Nevertheless, the Fourier transform may drop to an insignificant level for $|\xi|$ larger than some frequency ξ_{max} , in which case we can proceed as if the function were bandlimited, recognizing that the resulting interpolation formula will be only approximate. In practice, if we go through the two-step procedure of low-pass filtering and truncation, an appropriate value for ξ_{max} will be just slightly greater than the cutoff frequency of the filter.

Paley-Wiener space A more formal way of discussing bandlimited functions makes use of the Paley-Wiener theorem (see Sec. 3.3.9) and a reproducing-kernel Hilbert space (see Sec. 1.8) called *Paley-Wiener space*.

The Paley-Wiener theorem shows that the Fourier transform of a function with compact support is an entire function of exponential type. Similarly, if the Fourier transform $F(\xi)$ has compact support, the function $f(x)$ itself, regarded as a function of a complex variable, is entire. That means that a bandlimited function is continuous, differentiable and expandable in a complex Taylor series (see App. B). We won't have need for complex x , but all of these nice properties hold for real x as well. Bandlimited functions of a real variable are said to be in Paley Wiener space.

Ideal low-pass filtering with a cutoff at $\xi = \pm\xi_{max}$ corresponds to convolution with $B \text{sinc}(Bx)$ in the spatial domain, where $B = 2\xi_{max}$. Equivalently, this convolution corresponds to multiplication in the frequency domain by the Fourier transform of the sinc. Since

$$\mathcal{F}_1\{B \text{sinc}(Bx)\} = \text{rect}(\xi/B), \tag{3.281}$$

subsequent convolution with $B \text{sinc}(Bx)$ has no further effect. (A rect function raised to any power is still the same rect function.) Thus bandlimited functions containing only frequencies for which $|\xi| \leq B/2$ must satisfy

$$\int_{-\infty}^{\infty} dx' B \text{sinc}[B(x - x')] f(x') = f(x). \tag{3.282}$$

From the discussion in Sec. 1.8, (3.282) will be recognized as the condition for Paley-Wiener space to be a reproducing-kernel Hilbert space. The operator \mathcal{B} used in Sec. 1.8 here corresponds to convolution with $B \text{sinc}(Bx)$. All functions in Paley-Wiener space are invariant to this operator, and \mathcal{B} is simply the unit operator in the reproducing-kernel space (or, equivalently, the projection operator from $\mathbb{L}_2(\mathbb{R})$ to the space). Thus Paley-Wiener space is a reproducing-kernel Hilbert space with a sinc function as the kernel (Walter, 1994; Daubechies, 1992). As noted in Sec. 1.8, a function in a reproducing-kernel Hilbert space is smooth in a certain sense; the smoothness of bandlimited functions will be exploited below.

3.5.2 Reconstruction of a bandlimited function from uniform samples

Bandlimited functions are so smooth that their behavior between samples can be predicted exactly from the sample values, provided the samples are sufficiently close together. In other words, there exists an exact interpolation formula, usually referred to as the *Whittaker-Shannon sampling theorem*, for reconstruct-

ing a bandlimited function from its samples. Other names for this theorem include the *Whittaker-Shannon-Kotel'nikov theorem*, the *Whittaker-Shannon-Kotel'nikov-Kramer theorem*, the *sampling theorem*, and the *cardinal series* (Marks, 1991). We shall derive this important theorem in two different ways below.

Shannon's derivation The first derivation of the sampling theorem that we present is the one given originally by Shannon and discussed in Jerri (1977).

A bandlimited function can be represented by the truncated inverse Fourier transform,

$$f(x) = \int_{-\frac{1}{2}B}^{\frac{1}{2}B} d\xi F(\xi) \exp(2\pi i \xi x). \quad (3.283)$$

The truncation of the range of integration to $(-\frac{1}{2}B, \frac{1}{2}B)$ entails no error since $F(\xi)$ vanishes identically outside this range. The full range B , including positive and negative frequencies, is called the *bandwidth* of the function. (Caution: In engineering texts, the term bandwidth often refers to the maximum frequency present in a signal, which is our $\frac{1}{2}B$.)

Another consequence of the bandlimited character is that $F(\xi)$ can be exactly represented on $(-\frac{1}{2}B, \frac{1}{2}B)$ by the Fourier series,

$$F(\xi) = \sum_{k=-\infty}^{\infty} C_k \exp(-2\pi i \xi k/B). \quad (3.284)$$

This expression is essentially the same as (3.17) but with $x \rightarrow \xi$ and $L \rightarrow B$. The coefficients in (3.284) are given by [cf. (3.191)]

$$C_k = \frac{1}{B} \int_{-\frac{1}{2}B}^{\frac{1}{2}B} d\xi F(\xi) \exp(2\pi i \xi k/B) = \frac{1}{B} f\left(\frac{k}{B}\right). \quad (3.285)$$

Plugging (3.285) into (3.284) and the result into (3.283), we find

$$f(x) = \int_{-\frac{1}{2}B}^{\frac{1}{2}B} d\xi \sum_{k=-\infty}^{\infty} \frac{1}{B} f\left(\frac{k}{B}\right) \exp(-2\pi i \xi k/B) \exp(2\pi i \xi x). \quad (3.286)$$

Interchanging sum and integral and performing an integration yields

$$f(x) = \sum_{k=-\infty}^{\infty} f\left(\frac{k}{B}\right) \operatorname{sinc}(Bx - k). \quad (3.287)$$

This is the desired interpolation formula, the Whittaker-Shannon sampling theorem. We can see that the right-hand side of (3.287) exactly reproduces $f(x)$ at the sample points as follows: If $x = j/B$ (j an integer), then $\operatorname{sinc}(Bx - k) = \operatorname{sinc}(j - k) = \delta_{jk}$, so the equation reads $f(j/B) = f(j/B)$. The interpolation function has the nice property that it is unity at one of the sampling points and zero at all others.

Of course, giving the right answer at the sample points is not sufficient for an interpolation formula; it must also work for all x . Linear or spline interpolants, for example, could reproduce $f(x)$ at $x = j/B$, but only the sinc function gives the exact values for $f(x)$ at all intermediate points, and then only if $f(x)$ is bandlimited to bandwidth B .

In spite of their approximate character, linear interpolants and splines do have one practical advantage over the Whittaker-Shannon theorem; determination of $f(x)$ at some point x requires knowledge of the sample values at only the adjacent sample points. Equation (3.287) shows that knowledge of $f(j/B)$ for *all* j is required to determine $f(x)$ for *any* x other than a sampling point.

Alternative derivation In this section, we present an alternative derivation of the Whittaker-Shannon sampling theorem based on comb functions. This derivation, found in many modern texts (*e.g.*, Marks, 1991 or Gaskill, 1978), makes it clearer what the sampling rate must be and what happens if it is not large enough.

Suppose the continuous-to-discrete operator \mathcal{S} acts on $f(x)$ to give a set of sample values $\{f(j\Delta x)\}$, $j = 0, \pm 1, \pm 2, \dots, \pm\infty$, where for the moment Δx is arbitrary. We can use the adjoint operator \mathcal{S}^\dagger to construct an auxiliary function $f_s(x)$, formed by using the sample values as weights for an infinite set of delta functions. Thus $f_s(x)$ is defined by

$$f_s(x) = \mathcal{S}^\dagger \mathcal{S} f(x) = \sum_{j=-\infty}^{\infty} f(j\Delta x) \delta(x - j\Delta x). \quad (3.288)$$

This function and others encountered in this derivation are illustrated in Fig. 3.7.

Fig. 3.7 Functions encountered in a derivation of the Whittaker-Shannon sampling theorem. (a) The original function $f(x)$, illustrated by a sinc^2 function plus a narrow Gaussian. The narrow Gaussian keeps $f(x)$ from being bandlimited. (b) The Fourier transform of $f(x)$. (c) The sampled function $f_s(x)$; the spikes represent delta functions. (d) The Fourier transform of $f_s(x)$, showing the replication induced by sampling.

Since $f(x) \delta(x - j\Delta x) = f(j\Delta x) \delta(x - j\Delta x)$ [see (2.25)], we can also write

$$f_s(x) = \sum_{j=-\infty}^{\infty} f(x) \delta(x - j\Delta x) = f(x) \sum_{j=-\infty}^{\infty} \delta(x - j\Delta x) = f(x) \frac{1}{\Delta x} \text{comb} \left(\frac{x}{\Delta x} \right). \quad (3.289)$$

Reconstructing $f(x)$ from the set of samples $\{f(j\Delta x)\}$ is equivalent to finding an operator that maps $f_s(x)$ to $f(x)$. To ferret out such an operator, we take the Fourier transform of $f_s(x)$, with the result

$$F_s(\xi) = \mathcal{F}_1\{f_s(x)\} = F(\xi) * \text{comb}(\Delta x\xi) = \frac{1}{\Delta x} \sum_{j=-\infty}^{\infty} F\left(\xi - \frac{j}{\Delta x}\right), \quad (3.290)$$

where we have used (3.125), (3.132) and (3.157).

Thus, as illustrated in Fig. 3.7, the Fourier transform of $f_s(x)$ is a set of displaced replicas of the Fourier transform of $f(x)$. There is no overlap of the replicas if $f(x)$ is bandlimited to bandwidth B and the sample interval Δx satisfies

$$\Delta x \leq 1/B. \quad (3.291)$$

This important condition is known as the *Nyquist sampling condition* (Nyquist, 1928a). If it is satisfied, we can use a simple rect function to isolate a single replica,

$$F(\xi) = \frac{1}{B} \text{rect} \frac{\xi}{B} F_s(\xi). \quad (3.292)$$

Thus, provided the Nyquist condition holds, the operator that maps $F_s(\xi)$ to $F(\xi)$ is nothing more than multiplication by a rect.

The corresponding operator in the space domain is convolution with a sinc; an inverse transform of (3.292) gives

$$\begin{aligned} f(x) &= \text{sinc}(Bx) * f_s(x) = \text{sinc}(Bx) * \left[\sum_{j=-\infty}^{\infty} f(j\Delta x) \delta(x - j\Delta x) \right] \\ &= \sum_{j=-\infty}^{\infty} f(j\Delta x) \text{sinc}[B(x - j\Delta x)]. \end{aligned} \quad (3.293)$$

This result is a valid interpolation formula provided $B\Delta x \leq 1$; the special case $B\Delta x = 1$ gives us back (3.287).

How many samples are needed? If we really had a bandlimited function, it could not be strictly spatially limited, so an infinite number of samples spaced at the Nyquist interval would be needed to specify the function. In many practical situations however, the function is spatially limited, and we regard it as approximately bandlimited to a bandwidth of B . If this approximation is adequate and we sample at an interval of $\Delta x = 1/B$, then a function of spatial extent L requires $L/\Delta x = LB$ samples. The product LB , known as the *space-bandwidth product* measures the number of *degrees of freedom* of the function, or the number of independent parameters needed to specify it.

Generalizations of Whittaker-Shannon There are many generalizations and extensions of the sampling theorem. The reader who wishes to delve further is referred to Jerri (1977), Butzer (1983), Jerri (1986), Marks (1991) and Zayed (1993). Topics treated in these references include nonuniform sampling, sampling of random processes, non-bandlimited functions, implicit sampling and sampling for general integral transforms.

A very powerful generalization of the sampling theorem uses the idea of a *sampling basis* in a reproducing-kernel Hilbert space (Zayed, 1993). Consider a space of functions $f(x)$ with reproducing kernel $h(x, x')$. A basis $\{s_n(x)\}$ in this space is called a sampling basis if there exists a set of points x_n along the real line such that

$$f(x) = \sum_n f(x_n) s_n(x). \quad (3.294)$$

For simplicity, we consider only orthonormal bases. It is proved in Zayed (1993) that an orthonormal basis is a sampling basis if and only if it is generated from the reproducing kernel by

$$s_n(x) = h(x, x_n). \quad (3.295)$$

Paley-Wiener space satisfies this condition with the kernel being a sinc function, and (3.294) is just the Whittaker-Shannon sampling theorem in this case.

3.5.3 Aliasing

A crucial assumption in the derivation of the Whittaker-Shannon sampling theorem above is that there is no overlap of the displaced replicas of $F(\xi)$ in (3.290). If there is overlap, there is no way to distinguish a particular frequency ξ_0 from the frequencies $\xi_0 \pm n/\Delta x$. Such frequencies are said to be *aliased* since they produce identical sets of samples, as illustrated in Fig. 3.8.

Fig. 3.8 Illustration of aliasing. The two cosines differ in frequency by the reciprocal of the sampling interval, so they agree exactly at the sample points.

One way to think about aliasing is that it results from heterodyning. In the temporal domain, heterodyne detection is the multiplication of a signal, say $\cos(2\pi\nu_1 t)$, with a local oscillator at a different frequency, say $\cos(2\pi\nu_2 t)$. By elementary trigonometry, the product has terms at the sum and difference frequencies, $\cos[2\pi(\nu_1 \pm \nu_2)t]$. Exactly the same argument holds in the spatial domain; multiplication of $\cos(2\pi\xi_1 x)$ and $\cos(2\pi\xi_2 x)$ yields terms in $\cos[2\pi(\xi_1 \pm \xi_2)x]$. In (3.289), the function $f(x)$ is sampled by multiplying it by the comb function, which contains all harmonics of the fundamental sampling frequency $1/\Delta x$. In the multiplication each frequency component ξ in $f(x)$ is heterodyned to a set of new frequencies $\xi \pm \frac{n}{\Delta x}$, as seen in (3.290).

Another way to think about aliasing is in terms of null functions of the sampling operator \mathcal{S} which maps $f(x)$ to its samples $\{f(j\Delta x)\}$. Since $\cos(2\pi\xi x)$ and $\cos[2\pi(\xi \pm \frac{n}{\Delta x})x]$ yield exactly the same samples, the difference function $\cos(2\pi\xi x) - \cos[2\pi(\xi \pm \frac{n}{\Delta x})x]$ is a null function of \mathcal{S} .

The reader has, no doubt, seen examples of aliasing in everyday experience. A television image is sampled by the raster lines, and the moiré pattern seen in a TV image of empty seats in a football stadium or a performer's striped coat is due to aliasing. Here the coat or stadium is multiplied by the raster function, generating a multitude of new frequencies. An interesting point in this case is that the spatial frequencies are vectors, and heterodyning produces vector sum and difference frequencies. Both the raster pattern and the coat might correspond to very high spatial frequencies, but if the vector difference is small, it is easily seen in the TV image.

There are two ways to avoid significant aliasing in practice. One is simply to use a very fine sampling interval small (small Δx) to ensure that the Nyquist condition is satisfied. If the function being sampled is not truly bandlimited, it would be desirable to choose Δx small compared to $1/(2\xi_{max})$, where $F(\xi)$ has dropped to some very small value by $\xi = \pm\xi_{max}$.

The second way to avoid aliasing is to prefilter the function with a low-pass *anti-aliasing* filter before sampling. In the TV example above, the camera lens might constitute such a filter. If the lens cannot pass the high spatial frequencies in the performer's coat, they cannot heterodyne with the raster pattern. Some information has been lost by the low-pass filter, but the effect is usually less deleterious than aliasing.

3.5.4 Sampling in frequency space

The sampling theorem (3.293) and the Nyquist condition (3.291) are applicable when $f(x)$ is a bandlimited function, which means that its Fourier transform has finite support. Two dual relations hold if $f(x)$ itself has finite support. In that case we can reconstruct its Fourier transform $F(\xi)$ from samples taken according to a different Nyquist condition.

Suppose $f(x)$ is zero outside $(-\frac{1}{2}L, \frac{1}{2}L)$ and that $F(\xi)$ is sampled at $\xi_j = j\Delta\xi$, $j = 0, \pm 1, \pm 2, \dots, \pm\infty$. Under what circumstances can $F(\xi)$ be recovered from $\{F(j\Delta\xi)\}$ and what is the explicit interpolation formula? We can answer these questions by little more than a change of notation in the derivation above. The spatial variable x becomes the frequency variable ξ , $f(x)$ becomes $F(\xi)$, the sample interval Δx becomes $\Delta\xi$, and the bandlimit B is replaced by the space limit L . The new Nyquist condition is, by analogy to (3.291),

$$\Delta\xi \leq 1/L, \quad (3.296)$$

and the interpolation formula analogous to (3.293) is

$$F(\xi) = \sum_{j=-\infty}^{\infty} F(j\Delta\xi) \operatorname{sinc} \left(\frac{\xi}{\Delta\xi} - j \right). \quad (3.297)$$

3.5.5 Multidimensional sampling

If samples are acquired in Cartesian coordinates, the Whittaker-Shannon sampling theorem extends trivially to higher dimensions. Suppose, for example, we sample a 2D function $f(x, y)$ at $x = ja$, $y = ka$, where j and k are integers, and that $F(\xi, \eta) = 0$ unless $-\frac{1}{2}B \leq \xi, \eta \leq \frac{1}{2}B$, with $aB \leq 1$. Under these circumstances,

(3.293) generalizes to

$$f(x, y) = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} f(ja, ka) \operatorname{sinc}\left(\frac{x}{a} - j\right) \operatorname{sinc}\left(\frac{y}{a} - k\right). \quad (3.298)$$

But there are many other possible sampling theorems in two or more dimensions. The sampling need not be on a square lattice, and the support of the Fourier transform of $f(x, y)$ need not be a simple product of rects. Rather than enumerate some subset of these theorems, we shall present a single general formula from which they can all be derived. The treatment parallels the ‘alternative derivation’ of the 1D sampling theorem above.

Consider an n D function $f(\mathbf{r})$ with Fourier transform $F(\boldsymbol{\rho})$. Consider also a function $S(\boldsymbol{\rho})$ that takes on the value 1 within the support of $F(\boldsymbol{\rho})$ and 0 outside it, so that

$$F(\boldsymbol{\rho}) = F(\boldsymbol{\rho}) S(\boldsymbol{\rho}). \quad (3.299)$$

Using the notation of Sec. 3.4.6 and following the development in Marks (1991), we presume that $f(\mathbf{r})$ is sampled on the points $\mathbf{r} = \mathbf{P}\mathbf{m}$, where \mathbf{P} is an $n \times n$ matrix and \mathbf{m} is an $n \times 1$ column vector with all elements given by integers ranging from $-\infty$ to ∞ . The samples of $f(\mathbf{r})$ are thus the set of numbers $\{f(\mathbf{P}\mathbf{m})\}$. As in (3.288), we can use the samples to define an auxiliary function $f_s(\mathbf{r})$, given by

$$f_s(\mathbf{r}) = \sum_{\mathbf{m}} f(\mathbf{P}\mathbf{m}) \delta(\mathbf{r} - \mathbf{P}\mathbf{m}) = f(\mathbf{r}) \sum_{\mathbf{m}} \delta(\mathbf{r} - \mathbf{P}\mathbf{m}). \quad (3.300)$$

An n D Fourier transform and use of (3.270) yields [cf. (3.290)]

$$\begin{aligned} F_s(\boldsymbol{\rho}) &= F(\boldsymbol{\rho}) * \mathcal{F}_n \left\{ \sum_{\mathbf{m}} \delta(\mathbf{r} - \mathbf{P}\mathbf{m}) \right\} = \frac{1}{|\det(\mathbf{P})|} F(\boldsymbol{\rho}) * \sum_{\mathbf{m}} \delta(\boldsymbol{\rho} - \mathbf{Q}\mathbf{m}) \\ &= \frac{1}{|\det(\mathbf{P})|} \sum_{\mathbf{m}} F(\boldsymbol{\rho} - \mathbf{Q}\mathbf{m}), \end{aligned} \quad (3.301)$$

where $\mathbf{Q}^t = \mathbf{P}^{-1}$. As discussed in Sec. 3.4.6, the points $\mathbf{Q}\mathbf{m}$ define the reciprocal lattice.

As in the corresponding 1D derivation, we now have a set of shifted replicas of $F(\boldsymbol{\rho})$; here the replicas are centered on the reciprocal lattice points $\mathbf{Q}\mathbf{m}$. If these replicas do not overlap, we can multiply $F_s(\boldsymbol{\rho})$ by the support function $S(\boldsymbol{\rho})$ to isolate a single replica, giving [cf. (3.292)]

$$F(\boldsymbol{\rho}) = |\det(\mathbf{P})| S(\boldsymbol{\rho}) F_s(\boldsymbol{\rho}). \quad (3.302)$$

An inverse transform now gives

$$\begin{aligned} f(\mathbf{r}) &= |\det(\mathbf{P})| s(\mathbf{r}) * f_s(\mathbf{r}) = |\det(\mathbf{P})| s(\mathbf{r}) * \left[\sum_{\mathbf{m}} f(\mathbf{P}\mathbf{m}) \delta(\mathbf{r} - \mathbf{P}\mathbf{m}) \right] \\ &= |\det(\mathbf{P})| \left[\sum_{\mathbf{m}} f(\mathbf{P}\mathbf{m}) s(\mathbf{r} - \mathbf{P}\mathbf{m}) \right]. \end{aligned} \quad (3.303)$$

This is the desired multidimensional generalization of the Whittaker-Shannon sampling theorem. The interpolation function is, within a constant, the inverse Fourier

transform of the support function $S(\boldsymbol{\rho})$. There is no simple statement of the Nyquist condition except to say that there must be no overlap of the replicas of $F(\boldsymbol{\rho})$ centered on the reciprocal-lattice points. For many special cases and applications of this formula, see Marks (1991).

3.5.6 Sampling with a finite aperture

So far we have considered only point sampling as the operator \mathcal{S} . In one dimension, \mathcal{S} transforms the function $f(x)$ into a discrete set of numbers $\{f(x_j)\}$. There are, however, many other possible forms for the sampling operator. We can, for example, define \mathcal{S} as a normalized integral of the function over a small region, so that

$$f_j = \mathcal{S} f(x) = \frac{1}{\epsilon} \int_{x_j - \frac{1}{2}\epsilon}^{x_j + \frac{1}{2}\epsilon} dx f(x). \quad (3.304)$$

If we take $x_j = j\Delta x$ and $\Delta x = \epsilon$, then the regions are contiguous pixels. On the other hand we can also take $x_j = j\Delta x$ but pass to the limit $\epsilon \rightarrow 0$. In this case, if $f(x)$ is continuous at $x = x_j$, we have

$$\lim_{\epsilon \rightarrow 0} f_j = f(x_j) = f(j\Delta x). \quad (3.305)$$

A general way of describing these transformations is in terms of continuous-to-discrete mappings as discussed in Sec. 1.2.4. By analogy to (1.30), we can write

$$f_j = \int_{-\infty}^{\infty} dx f(x) a(x_j - x), \quad (3.306)$$

where $a(x)$ is called the *sampling function* or *aperture function*. The latter designation is suggestive of instruments such as scanning microdensitometers where an optical aperture is placed at a sequence of locations in an image plane.

To get back to (3.304) from this general form, we take

$$a(x) = \epsilon^{-1} \text{rect}(x/\epsilon), \quad (3.307)$$

while point sampling is recovered by taking $a(x) = \delta(x)$.

It is interesting to inquire whether there exists a counterpart of the Whittaker-Shannon theorem for the more general kind of sampling defined in (3.306). To answer this question, note that (3.306) can also be written as

$$f_j = [f * a](x_j), \quad (3.308)$$

where $[f * a](x)$ denotes the convolution of $f(x)$ and $a(x)$ (see Sec. 3.3.6). Thus sampling a function with a finite aperture is equivalent to first convolving it with an aperture function, then performing point sampling on the result.

Since convolution corresponds to multiplication in the frequency domain, $[f * a](x)$ is bandlimited to $(-\frac{1}{2}B, \frac{1}{2}B)$ if $f(x)$ is. Thus $[f * a](x)$ can be recovered from its samples $\{f_j\}$ if $x_j = j\Delta x$ and Δx satisfies the Nyquist condition, $B\Delta x = 1$. From (3.293), we have immediately that

$$[f * a](x) = \sum_{j=-\infty}^{\infty} f_j \text{sinc}\left(\frac{x}{\Delta x} - j\right). \quad (3.309)$$

Of course, all this says is that we can recover $[f * a](x)$; we would really like to recover $f(x)$ itself. To see when that is possible, we take the Fourier transform of the convolution, yielding

$$\mathcal{F}_1\{[f * a](x)\} = F(\xi) A(\xi), \quad (3.310)$$

where, as usual, functions with capital letters are the Fourier transforms of the corresponding lower-case functions. If $A(\xi)$ does not vanish in the interval $-\frac{1}{2}B < \xi < \frac{1}{2}B$, we can find $F(\xi)$ in that interval by dividing through by $A(\xi)$. Since $F(\xi)$ is assumed to vanish outside that interval, an inverse Fourier transform then yields the desired $f(x)$.

As an example, let $a(x)$ be given by (3.307). Then, by (3.136), $A(\xi) = \text{sinc}(\epsilon\xi)$, which does not vanish in $(-\frac{1}{2}B, \frac{1}{2}B)$ provided $\epsilon < 2B^{-1}$. If the Nyquist condition is exactly satisfied, so that $B\Delta x = 1$, $A(\xi)$ will not vanish in the interval of interest if $\epsilon < 2\Delta x$. Since the usual pixel sampling corresponds to $\epsilon = \Delta x$, there is no problem in recovering $f(x)$ from its samples on contiguous pixels if the Nyquist condition is satisfied. It will be left as an exercise for the reader to develop an explicit interpolation formula for this case.

3.6 DISCRETE FOURIER TRANSFORM

3.6.1 Motivation and definitions

Though many Fourier transforms can be found analytically, there are also many circumstances where numerical methods are needed. In image processing, for example, we usually do not have an analytical description of the image, so analytical determination of its Fourier transform is out of the question. In other circumstances we might have an analytic expression for the function but not be able to express its Fourier transform in closed form.

In such cases, we are forced to represent the function to be transformed by a discrete set of numbers and to approximate the Fourier integral by a sum. One way to do so is:

$$F(\xi) \simeq \Delta x \sum_{k=-\infty}^{\infty} f(k\Delta x) \exp(-2\pi i \xi k \Delta x). \quad (3.311)$$

This form is still not amenable to numerical computation for two reasons: For each ξ an infinite sum is required, and there are an infinite number of values of ξ .

To restrict the sum to a finite number of terms, we must presume that $f(x)$ vanishes, at least approximately, outside some finite interval. As in Sec. 3.1.4, we take that interval as $[0, L)$ and divide it into N equal steps of size $\Delta x = L/N$, so that the samples are at $x = x_k = k\Delta x = kL/N$, $k = 0, \dots, N-1$. Since $f(x)$ now has finite support, $F(\xi)$ can be represented exactly by its samples at $\xi = \xi_n = n\Delta\xi$, provided these samples in frequency space satisfy the dual Nyquist condition (3.296), $\Delta\xi \leq 1/L$. We choose the inequality to be an equality. The samples $F(n\Delta\xi)$ can be approximated by $\Delta x F_n$, where

$$F_n \equiv \sum_{k=0}^{N-1} f_k \exp(-2\pi i kn/N), \quad (3.312)$$

and $f_k = f(k\Delta x)$. In the limit as $N \rightarrow \infty$ (or equivalently, $\Delta x \rightarrow 0$), $\Delta x F_n \rightarrow F(n\Delta\xi)$.

Though motivated as an approximation to the Fourier integral, (3.312) is an important linear transformation in its own right. Known as the *discrete Fourier transform* or *DFT*, it transforms the N -dimensional vector \mathbf{f} with components $\{f_k\}$ to another N -dimensional vector \mathbf{F} with components $\{F_n\}$. The exact inverse to this transform can be established from the orthogonality relation (3.12), yielding

$$f_k = \frac{1}{N} \sum_{n=0}^{N-1} F_n \exp(2\pi i kn/N). \quad (3.313)$$

Another way to express these results is to recognize that $\exp(-2\pi i/N)$, which we can denote as W_N , is an N^{th} root of unity (see Sec. B.1.5), *i.e.*,

$$[W_N]^N = [\exp(-2\pi i/N)]^N = \exp(-2\pi i) = 1. \quad (3.314)$$

In terms of W_N , the DFT is

$$F_n = \sum_{k=0}^{N-1} f_k W_N^{kn}, \quad (3.315)$$

and its inverse is

$$f_k = \frac{1}{N} \sum_{n=0}^{N-1} F_n W_N^{-kn}. \quad (3.316)$$

We shall return to the question of how well the DFT approximates the Fourier transform in Sec. 3.6.3, but first we establish some basic properties of the DFT itself.

3.6.2 Basic properties of the DFT

The DFT has many properties analogous to those of the Fourier series and Fourier transform as discussed in Secs. 3.2 and 3.3. The one exception is that there is no need to discuss convergence since finite sums of finite values are necessarily finite.

Linearity Like its kin, the DFT is a linear transformation. If \mathbf{f} and \mathbf{g} are N -dimensional vectors with DFTs \mathbf{F} and \mathbf{G} , respectively, and we define

$$\mathbf{h} = \alpha\mathbf{f} + \beta\mathbf{g}, \quad (3.317)$$

where α and β are constants, then

$$\mathbf{H} = \alpha\mathbf{F} + \beta\mathbf{G}, \quad (3.318)$$

where \mathbf{H} is the DFT of \mathbf{h} .

Periodicity and folding Since W_N is an N^{th} root of unity, raising it to a power that is an integer multiple of N leaves it invariant. From this observation it follows that

$$W_N^{kn} = W_N^{k(n+N)}. \quad (3.319)$$

Plugging this result into (3.315) reveals that

$$F_{n+N} = F_n. \quad (3.320)$$

In other words, regardless of the sequence $\{f_k\}$, its DFT is periodic with period N . Though we are free to evaluate F_n for any n , there are only N independent values. It is conventional to choose $n = 0, 1, \dots, N-1$, but we could equally well choose any other range of N contiguous integers.

Furthermore, if all of the $\{f_k\}$ are real, there is an additional constraint on the $\{F_n\}$. It is straightforward to show in this case that

$$F_n = F_{-n}^* \quad \text{if } f_k \text{ is real for all } k. \quad (3.321)$$

This result is the DFT analog of the Hermiticity condition for Fourier series or transforms, (3.45) or (3.94). Combining (3.320) and (3.321), we also have

$$F_{\frac{1}{2}N+n} = F_{\frac{1}{2}N-n}^* \quad \text{if } f_k \text{ is real for all } k. \quad (3.322)$$

Thus if we choose the basic range of n to run from 0 to $N-1$ and all of the $\{f_k\}$ are real, there is a folding point at $n = \frac{1}{2}N$. The real part of F_n is symmetric about this point while the imaginary part is antisymmetric. These relations are illustrated in Fig. 3.9.

Fig. 3.9 Illustration of symmetry properties of the DFT of a real sequence. (a) A 32-point real sequence $\{f_n, n = 0, \dots, 31\}$; (b) Real part of the DFT of this sequence plotted over five periods; (c) Imaginary part of the DFT of this sequence plotted over five periods.

The same symmetry relations apply to the inverse DFT. We can regard (3.313) as a representation of our original sequence for $n = 0, 1, \dots, N-1$, but given the representation, we can plug in any n whatsoever. Doing so shows that the representation is periodic with period N . Like the Fourier series, an inverse DFT is a representation of an arbitrary function on a finite interval or of a periodic function on the infinite interval.

Shifted sequences In discussing Fourier transforms, we found that shifting the function was equivalent to multiplying its transform by a linear phase factor [see (3.108)]. A similar result holds for the DFT, but we must be careful how we define a shift.

Given a sequence $\{f_k, k = 0, \dots, N-1\}$, let us define a new sequence $\{y_k, k = 0, \dots, N-1\}$ by

$$y_k = f_{k-m}. \quad (3.323)$$

The problem with this definition is that $k-m$ may not be in the range 0 to $N-1$. When this occurs, we have two options: we can either take f_{k-m} to be zero or

we can assume that the original sequence $\{f_k\}$ is defined for all k by periodically repeating the original N values. This latter view is the one that is consistent with the periodicity properties of the DFT as discussed above, and it is the choice we shall make. Thus, if $k - m$ in (3.323) lies outside $[0, N - 1]$, we must add or subtract a multiple of N to get it back into this range. Technically, the index of f is $k - m$, modulo N , but to keep the notation simple we do not explicitly show the modulo convention. Shifting modulo N is also referred to as *cyclic shifting*.

The DFT of the (cyclically) shifted sequence is

$$Y_n = \exp(-2\pi imn/N) F_n. \quad (3.324)$$

Again, as in (3.108), shifting the input to the transform operation has the effect of multiplying the output by a linear phase factor, here linear in n .

Kronecker deltas Suppose the sequence $\{f_k\}$ consists of all zeros except for a one in the m^{th} position, *i.e.*,

$$f_k = \delta_{km}, \quad (3.325)$$

where δ_{km} is the Kronecker delta. The DFT of this particular sequence is

$$F_n = \sum_{k=0}^{N-1} \delta_{km} \exp(-2\pi ikn/N) = \exp(-2\pi imn/N). \quad (3.326)$$

This result is the DFT analog of (3.148); again a delta function transforms to a linear phase factor.

Since $\exp(-2\pi imn/N)$ is periodic in n with period N , we have a simple example of the general periodicity condition (3.320). Equation (3.326) is also an illustration of the shift theorem (3.324) since $F_n = 1$ for all n if $f_k = \delta_{k0}$.

Now consider a sequence $\{f_k\}$ defined by

$$f_k = \exp(2\pi ikm/N). \quad (3.327)$$

The DFT yields

$$F_n = N \delta_{mn}, \quad (3.328)$$

where we have used (3.12). This is the analog of (3.151); a linear phase factor transforms to a delta function. Here it is a Kronecker delta times a factor of N .

Discrete convolution and correlation A discrete implementation of the convolution equation $g(x) = [f * h](x)$ is [*cf.* (3.114)]

$$g_n = \frac{1}{N} \sum_{k=0}^{N-1} f_k h_{n-k}, \quad n = 0, 1, 2, \dots, N - 1, \quad (3.329)$$

where, as above, the shift is interpreted modulo N . The factor of $1/N$, corresponding to the dx in a convolution integral, should not be overlooked.

The DFT counterpart of the convolution theorem, (3.132), is

$$G_n = F_n H_n. \quad (3.330)$$

The proof follows from the definition of the DFT and (3.12). The factor of $1/N$ in the definition of discrete convolution, (3.329), eliminates the factor of N that comes

from the discrete orthogonality relation, (3.12).

Discrete correlation can be defined similarly:

$$g_n = \frac{1}{N} \sum_{k=0}^{N-1} f_k h_{n+k}, \quad n = 0, 1, 2, \dots, N-1, \quad (3.331)$$

and a DFT gives the analog of (3.134),

$$G_n = F_n H_n^*. \quad (3.332)$$

Parseval's relation Parseval's relation, the analog of (3.51) or (3.79), is

$$\sum_{k=0}^{N-1} f_k h_k^* = \frac{1}{N} \sum_{n=0}^{N-1} F_n H_n^*. \quad (3.333)$$

The left-hand side of this equation is the Euclidean scalar product of the N -dimensional vectors \mathbf{f} and \mathbf{h} , while the right-hand side is $1/N$ times the similar scalar product of \mathbf{F} and \mathbf{H} . Had we defined the DFT with a factor of $1/\sqrt{N}$ in both the forward and inverse transforms, this extra factor of $1/N$ would not have appeared and we would be able to say that discrete Fourier transformation was unitary. The situation is completely analogous to Fourier series, where we have an asymmetric factor of $1/L$ (see Sec. 3.2.3).

3.6.3 Relation between discrete and continuous Fourier transforms

We return now to the question of how a DFT is related to a continuous Fourier transform. Our goal in this section is not only to show the mathematical relation but also to offer some practical suggestions to anyone who wishes to use the DFT to compute an approximation to a continuous transform.

The formal mathematical connection between the discrete and continuous transforms rests on two concepts: sampling and periodic replication. We saw in Sec. 3.5 that sampling a function in the space domain, as in (3.289), produces a periodic function in the frequency domain, (3.290). Conversely, periodically replicating a function as in (3.192) yields a Fourier transform that is sampled in the sense that it contains only a discrete set of frequencies. The DFT of any sequence is both discrete (sampled) and periodic, so we might suspect that it corresponds in some sense to a continuous Fourier transform from one periodic, sampled function to another.

To make this argument more precise, we begin with an arbitrary continuous function $f(x)$ and consider the sequence of steps needed to create from it a periodic, sampled function (Hayes, 1992; Hakimashhadi, 1988). The steps involved are illustrated in Fig. 3.10.

The first step is to sample the function at points $x_n = n\Delta x$. As in (3.289) we can then define the auxiliary function $f_s(x)$ in terms of the sample values by

$$f_s(x) = f(x) \frac{1}{\Delta x} \text{comb} \left(\frac{x}{\Delta x} \right) = \sum_{n=-\infty}^{\infty} f(n\Delta x) \delta(x - n\Delta x). \quad (3.334)$$

From (3.290) and Fig. 3.7, we know that this operation has the effect of periodically replicating the Fourier transform $F(\xi)$. If $F(\xi)$ does not have finite support or the

Nyquist condition is not satisfied, there is aliasing or overlap of the various replicas.

Since we do not wish to assume that the original $f(x)$ itself has finite support, we now impose a finite support by multiplying $f_s(x)$ by a window function that selects $0 \leq x < L$. The appropriate window function is

$$w(x) = \text{rect} \left[\frac{x - \frac{1}{2}L + \epsilon}{L} \right], \quad (3.335)$$

where ϵ is a positive number less than Δx which ensures that the point at $x = 0$ is included in the window while the one at $x = L$ is not. We define $N = L/\Delta x$ so that exactly N points are included in the window; the index n thus ranges from 0 to $N - 1$. The resulting function after sampling and windowing is

$$f_{sw}(x) = f_s(x) w(x) = \sum_{n=0}^{N-1} f(n\Delta x) \delta \left(x - \frac{nL}{N} \right). \quad (3.336)$$

The (continuous) Fourier transform of this function is

$$F_{sw}(\xi) = F_s(\xi) * W(\xi). \quad (3.337)$$

The next (and last) step is periodic replication. As defined in (3.192), this operation is described mathematically by convolution with $L^{-1} \text{comb}(x/L)$, where L is the period. (Note that we take the period to be identical to the width of the window function.) The resulting sampled, windowed and periodically replicated function is given by³

$$f_{swp}(x) = f_{sw}(x) * \frac{1}{L} \text{comb} \left(\frac{x}{L} \right). \quad (3.338)$$

Substituting (3.336) into (3.338) and performing the convolution by means of (3.127), we find

$$\begin{aligned} f_{swp}(x) &= \sum_{n=0}^{N-1} f(n\Delta x) \delta \left(x - \frac{nL}{N} \right) * \sum_{m=-\infty}^{\infty} \delta(x - mL) = \\ &= \sum_{m=-\infty}^{\infty} \sum_{n=0}^{N-1} f(n\Delta x) \delta \left(x - \frac{nL}{N} - mL \right). \end{aligned} \quad (3.339)$$

Now it is straightforward to take the Fourier transform of $f_{swp}(x)$, with the result

$$F_{swp}(\xi) = \sum_{m=-\infty}^{\infty} \sum_{n=0}^{N-1} f(n\Delta x) \exp[-2\pi i \xi (nL/N + mL)]. \quad (3.340)$$

By (2.50) we can also write

$$F_{swp}(\xi) = \frac{1}{L} \sum_{m=-\infty}^{\infty} \left[\sum_{n=0}^{N-1} f(n\Delta x) \exp(-2\pi i n m/N) \right] \delta(\xi - m/L). \quad (3.341)$$

³The shorthand notation for convolution in (3.338) should not be misinterpreted. The shift variable is x , not x/L . See Sec. 3.3.6 and the discussion below (3.142).

Not surprisingly, $F_{sup}(\xi)$ is sampled and periodic, and the samples are given by the DFT of the sequence $\{f(n\Delta x)\}$. Thus, performing a DFT of the samples of $f(x)$ produces the samples of the Fourier transform of a sampled, windowed and periodically replicated version of $f(x)$.

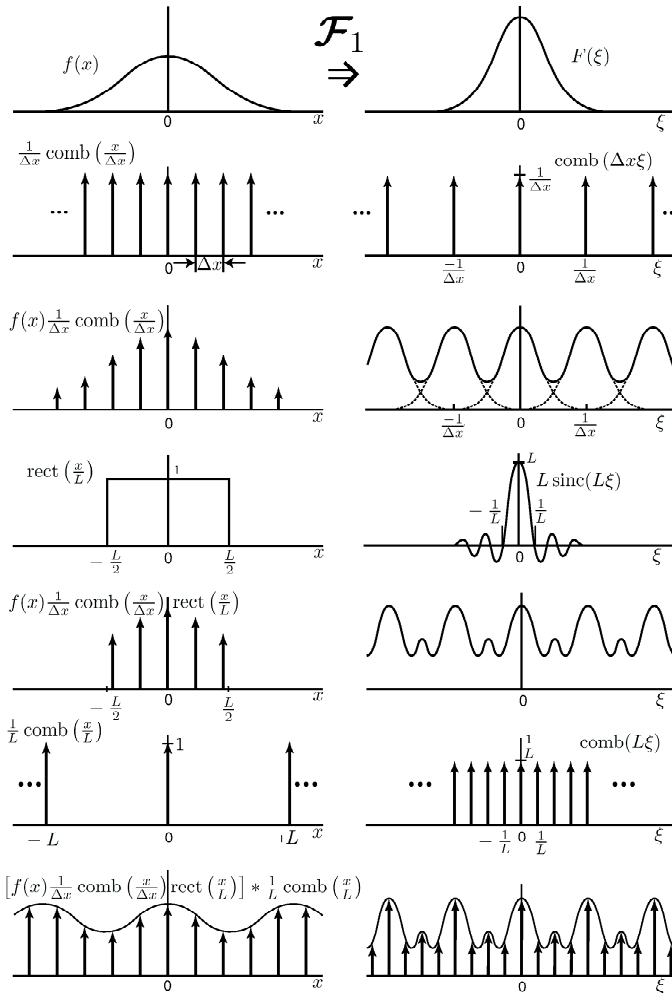

Fig. 3.10 Steps in going from the FT to the DFT.

Errors in the DFT: Their causes and cures Each of the steps leading up to (3.341) constitutes a potential source of error in computation of the continuous Fourier transform by means of the DFT. In this section we briefly discuss the nature of these errors and some ways to minimize them.

As we have seen, sampling the original function produces error if $f(x)$ is not bandlimited or the Nyquist condition is not satisfied. One solution to this problem is to use finer sampling. If we have an analytic expression for $f(x)$, the only price paid for this remedy is increased computer time. In many practical situations, however, the number of samples is limited by a finite sensor array or other technological

considerations. In those cases some sort of anti-aliasing filter as discussed in Sec. 3.5.3 is desirable. In an imaging context, the bandwidth of the signal being sampled can be limited by the characteristics of the imaging lens or by finite detector size.

The windowing step produces an error if the function being sampled does not fit into the window. The nature of the error is seen from (3.337); the convolution of $F_s(\xi)$ with the transform of the window function has the effect of smoothing out sharp features in $F_s(\xi)$ as shown in Fig. 3.10. Since adjacent frequency components are blurred together in this way, the effect is sometimes referred to as *spectral leakage*. The effect can be minimized by using a larger window so that $W(\xi)$ more closely approximates a delta function. Another useful measure is to use a smooth function for $w(x)$ rather than a rect so that $W(\xi)$ falls off more rapidly with increasing ξ .

The final source of error is the sampling of $F(\xi)$ itself. The spacing of samples in the frequency domain is $1/L$, which satisfies the dual Nyquist condition (3.296) if the support of $f(x)$ is L , but nevertheless we may want finer samples in order to fully appreciate the structure of $F(\xi)$. It is often desirable to use a window function that is substantially larger than the support of $f(x)$ simply to decrease the spacing of the points in the frequency domain. In practice, this is done by appending a string of zeros to the sample values $f(n\Delta x)$, creating an artificially longer sequence as the input to the DFT. This procedure is known as *zero padding*.

For further tips on practical applications of the DFT, see Lathi (1992), Hayes (1992), or Walker (1991).

3.6.4 Discrete-Space Fourier Transform

The mathematics of the DFT are based on the assumption that the input is a finite set of N numbers. In this section we investigate the *discrete-space Fourier transform*, or DSFT, which maps an infinite number of discrete values to the spatial-frequency domain. The assumption of an infinite number of samples is often plausible in the analysis of temporal data sets such as those encountered in many communications applications. For such problems the *discrete-time Fourier transform* (Oppenheim and Schaffer, 1989) is a common method of analysis. In imaging applications involving large detector arrays, where boundary effects are less important, the assumption of an infinite set of samples may also be reasonable. We present here a description of the properties of the DSFT for completeness.

Suppose we are given an infinite number of samples f_k . The discrete-space Fourier transform of this set is defined by

$$F_{DS}(\xi) \equiv \sum_{k=-\infty}^{\infty} f_k \exp(-2\pi i k \xi \Delta x), \quad (3.342)$$

where the subscript *DS* is short for *discrete-space* and Δx is the distance between sample values. The sample values f_k can be recovered from $F_{DS}(\xi)$ by the following inverse transformation:

$$f_k \equiv \Delta x \int_{-1/(2\Delta x)}^{1/(2\Delta x)} d\xi F_{DS}(\xi) \exp(2\pi i k \xi \Delta x). \quad (3.343)$$

As we shall see, the DSFT can be thought of as the limit of the DFT in the case of an infinite number of samples, but it has several unique properties of its own.

Relationship with DFT The DFT (3.312) transforms the set of discrete samples $\{f_k\}$ to the samples $\{F_n\}$. If we were to consider a slightly different definition, in which the summation is symmetric, we could write

$$F_n = \sum_{k=-\frac{N}{2}}^{\frac{N}{2}-1} f_k \exp(-2\pi i k n / N). \quad (3.344)$$

When we make the changes of variables, $\Delta\xi = 1/L$, $\xi = n\Delta\xi$ and $\Delta x = L/N$, we find that

$$F_n \Big|_{n=\frac{\xi}{\Delta\xi}} = \sum_{k=-\frac{N}{2}}^{\frac{N}{2}-1} f_k \exp(-2\pi i k \xi \Delta x). \quad (3.345)$$

We know from our discussion of the DFT that as the number of samples N increases, the output of (3.345) becomes increasingly finely sampled. In the limit where N becomes infinite, (3.345) is equivalent to (3.342), and the output is continuous. Thus the transformation of (3.342) is a discrete-to-continuous transformation.

From Sec. 3.6.2 we also know that F_n in (3.345) is periodic with period $1/\Delta x$. Thus $F_{DS}(\xi)$ is also periodic with period $1/\Delta x$. For this reason the integral in (3.343) need only be evaluated over the central zone of the periodic function $F_{DS}(\xi)$; values of the function outside this zone are redundant.

Relationship with Fourier series By comparison with (3.17) we see that (3.342) is a Fourier-series expansion of the continuous function $F_{DS}(\xi)$. The samples of the discrete function f_k in (3.342) play the role of the series coefficients. The inverse discrete-space transform of (3.343) is directly analogous to the formula given for determination of the Fourier series expansion coefficients [cf. (3.19)]. Perhaps the odd thing here is that (3.342) is a Fourier series expansion of a function we think of as being in the Fourier domain!

Another way to see the relationship between the DSFT and the Fourier series is to use operator theory. We noted in Sec. 3.2.3 that the mapping from a function on a finite interval to the infinite set of Fourier coefficients is a linear operator; the DSFT, which is a mapping from an infinite set of coefficients to a function on a finite interval, is the adjoint of the Fourier-series operator. Since we also know from Sec. 3.2.3 that the Fourier-series operator is unitary (up to normalization factors), the DSFT is the inverse of the Fourier series, slightly disguised by the notation.

Relationship with sampling Suppose, as we did in Sec. 3.5.2, that the samples $\{f_k\}$ have been acquired from an underlying continuous function $f(x)$ via the sampling operator \mathcal{S} . The samples can be used to form the auxiliary function $f_s(x)$, related to $f(x)$ by

$$f_s(x) = \mathcal{S}^\dagger \mathcal{S} f(x) = \sum_{k=-\infty}^{\infty} f(x) \delta(x - k\Delta x) = f(x) \frac{1}{\Delta x} \text{comb} \left(\frac{x}{\Delta x} \right). \quad (3.346)$$

The Fourier transform of this function is

$$F_s(\xi) = \sum_{k=-\infty}^{\infty} \int_{-\infty}^{\infty} dx f(x) \delta(x - k\Delta x) \exp(-2\pi i \xi x) = \sum_{k=-\infty}^{\infty} f_k \exp(-2\pi i k \xi \Delta x), \quad (3.347)$$

where $f_k = f(k\Delta x)$. By comparison with (3.342) we see that $F_s(\xi)$ is equivalent to $F_{DS}(\xi)$, the DSFT of the samples of $f(x)$.

Consider again the transform pairs represented by the various rows of Fig. 3.10. We have just found that the DSFT plays a role in row 3 of the figure. The function on the left in row 3 is $f_s(x)$, the continuous auxiliary function obtained by weighting delta functions with the sample values of $f(x)$. The Fourier transform on the right of row 3 is $F_s(\xi)$, the continuous FT of $f_s(x)$. We now know this to be also the DSFT of the sample values f_k , $F_{DS}(\xi)$. The figure shows that $F_{DS}(\xi)$ is the sum of an infinite number of shifted replications of the Fourier transform $F(\xi)$. The amount of overlap of the replications is zero if the bandwidth B of $f(x)$ is such that the sampling distance $\Delta x \leq 1/B$.

In summary, the striking difference between the discrete Fourier transform (DFT) and the discrete-space Fourier transform (DSFT) is that the DFT is a transformation from a finite set of samples to another finite set of samples. In the case of the DSFT, where the number of input samples is infinite, the output is a continuous function. Another way to consider this is that the input to the DSFT is not assumed to be periodic, or equivalently, the period is infinite. The continuous-to-continuous Fourier transform can be recovered from the DSFT in the limit where the sampling distance becomes infinitesimally small.

Relationship with Poisson summation We have seen that $F_{DS}(\xi)$ is a periodic function with periodicity $1/\Delta x$. It is the function we obtain when we add an infinite number of shifted replications of the general (nonperiodic) function $F(\xi)$. That is,

$$F_{DS}(\xi) = \frac{1}{\Delta x} \sum_{n=-\infty}^{\infty} F\left(\xi - \frac{n}{\Delta x}\right), \quad (3.348)$$

which can be verified by taking the Fourier transform of (3.346). By (3.342) we can equate this periodic function with a Fourier series with coefficients f_k , which are the samples of $f(x)$, giving

$$\frac{1}{\Delta x} \sum_{n=-\infty}^{\infty} F\left(\xi - \frac{n}{\Delta x}\right) = \sum_{k=-\infty}^{\infty} f_k \exp(-2\pi i k \xi \Delta x), \quad (3.349)$$

which is equivalent to the Poisson summation formula of (3.197). For the special case $\xi = 0$ we obtain

$$\frac{1}{\Delta x} \sum_{n=-\infty}^{\infty} F\left(\frac{n}{\Delta x}\right) = \sum_{k=-\infty}^{\infty} f_k. \quad (3.350)$$

As expected, the sum of the samples of $f(x)$ is equal to the sum of the samples of its Fourier transform.

3.6.5 Fast Fourier Transform

It can be seen from (3.315) that the DFT can be regarded as a matrix-vector multiplication. We can rewrite that equation in matrix-vector form as

$$\mathbf{F} = \mathbf{Df}, \quad (3.351a)$$

or, in detail,

$$F_n = \sum_{k=0}^{N-1} D_{nk} f_k, \quad (3.351b)$$

where $D_{nk} = W_N^{nk} = \exp(-2\pi ink/N)$. In order to obtain the value of a particular F_n , we must multiply each f_k by the appropriate matrix element, D_{nk} and sum the results. Doing this for all N components appears to require a total of N^2 multiplications and additions, but in fact it is possible to perform a DFT with only about $N \log_2 N$ operations if N is a power of 2. Algorithms for computing a DFT in this manner are known as *fast Fourier transforms* or *FFTs*. The classic text on the FFT is Brigham (1974), and the more recent books by Ramirez (1985) and Walker (1991) are also useful. Excellent short discussions are given by Hayes (1992), Hakimmashhadi (1988), and Kraniuskas (1994).

Though often attributed to Cooley and Tukey (1965), the basic idea of the FFT is actually much older. A fascinating historical survey is given by Heidemann *et al.* (1985) who trace the algorithm back to work by Gauss, first published only posthumously in 1866. Heidemann estimates that Gauss developed the FFT in 1805, which, if accurate, puts it two years before Fourier's own work on the Fourier series. The method was also used by the German numerical analyst Karl Runge in 1905, and there were numerous other independent discoveries of the same basic algorithm. What all of these works have in common is the recognition that the N^2 elements of \mathbf{D} are not independent. Rather, the elements are all powers of W_N , the N^{th} root of unity, so there are only N independent elements.

We now show how to take advantage of this redundancy in the matrix elements. Our treatment closely follows the lucid account given by Hayes (1992), but similar treatments can be found in all of the references given in this section. Assume that N is even,

$$N = 2M, \quad (3.352)$$

and divide the sum in (3.315) into even and odd parts:

$$F_n = \sum_{k=0}^{N-1} f_k (W_N)^{nk} = \sum_{m=0}^{M-1} f_{2m} (W_{2M})^{2mn} + \sum_{m=0}^{M-1} f_{2m+1} (W_{2M})^{(2m+1)n}. \quad (3.353)$$

Since $(W_{2M})^2 = W_M$, we can also write

$$F_n = \sum_{m=0}^{M-1} f_{2m} (W_M)^{mn} + (W_{2M})^n \sum_{m=0}^{M-1} f_{2m+1} (W_M)^{mn}. \quad (3.354)$$

Each of these sums will be recognized as an M -element DFT. It is useful to define separate DFTs of the even and odd terms as

$$F_n^{(e)} = \sum_{m=0}^{M-1} f_{2m} (W_M)^{mn} \quad (3.355a)$$

$$F_n^{(o)} = \sum_{m=0}^{M-1} f_{2m+1} (W_M)^{mn}, \quad (3.355b)$$

where the superscripts denote even and odd, respectively. Thus

$$F_n = F_n^{(e)} + (W_{2M})^n F_n^{(o)}. \quad (3.356)$$

Since each of the M -element DFTs returns M numbers, this formula gives only the first M values of F_n , but the remaining ones are found by adding M to each index:

$$F_{n+M} = F_{n+M}^{(e)} + (W_{2M})^{n+M} F_{n+M}^{(o)} = F_n^{(e)} - (W_{2M})^n F_n^{(o)}, \quad (3.357)$$

where the last step follows since $(W_{2M})^M = \exp(-i\pi) = -1$.

Equations (3.356) and (3.357) show that the desired N -element DFT can be computed as two M -element ones, where $M = N/2$. This result was first derived by Danielson and Lanczos (1942). If N is a power of 2, say 2^K , we can repeat this halving process K times and eventually perform a set of single-point transforms.⁴ The total number of operations is then of order NK or $N \log_2 N$ instead of N^2 . Some additions are also required by (3.356) and (3.357), but if N is large, the number of additions is small compared to $N \log_2 N$. We say that the required number of operations is $\mathcal{O}(N \log_2 N)$, where \mathcal{O} is to be read "on the order of."

Practical algorithms for efficient computation of the DFT are found in many places. Hayes gives programs in BASIC, and Press *et al.* (1992) give ones in FORTRAN and C. Many commercial software packages provide FFT routines integrated with excellent graphics.

3.6.6 Multidimensional DFTs

The 2D DFT The 2D DFT is defined by

$$F_{mn} = \sum_{j=0}^{N-1} \sum_{k=0}^{N-1} f_{jk} \exp[-2\pi i(mj + nk)/N] = \sum_{j=0}^{N-1} \sum_{k=0}^{N-1} f_{jk} (W_N)^{mj+nk}. \quad (3.358)$$

The indices j , k , m and n all run from 0 to $N - 1$.

An alternative form of (3.358) is obtained by regarding F_{nm} and f_{jk} as elements of the $N \times N$ matrices \mathbf{F} and \mathbf{f} , respectively. In both matrices, the first index denotes the row and the second the column. Now we can write

$$\mathbf{F} = \mathbf{D}\mathbf{f}\mathbf{D}, \quad (3.359)$$

where \mathbf{D} is the $N \times N$ matrix defined in (3.351). Note that this is not a similarity transformation since \mathbf{D} itself, rather than \mathbf{D}^\dagger or \mathbf{D}^{-1} , appears in both places. Thus the 2D DFT with N elements in each direction can be conceptualized as resulting from a matrix product of three $N \times N$ matrices.

To see how the 2D DFT can be computed in practice, rewrite (3.358) as:

$$F_{mn} = \sum_{j=0}^{N-1} \left\{ \sum_{k=0}^{N-1} f_{jk} \exp(-2\pi ink/N) \right\} \exp(-2\pi imj/N). \quad (3.360)$$

The quantity in brackets is a 1D N -element DFT on each column, with the column replaced *in situ* by its DFT. The outer sum corresponds to similar 1D DFTs on

⁴The halving process is frequently referred to as decimation or radix-2 decimation, but the word decimation has an evident root in Latin *decem* for ten, not two. Though used more broadly, the word decimate refers to the practice of selecting by lot and killing one-tenth of a population. It does not mean to reduce by a factor of ten, and certainly not to reduce by a factor of two.

the resulting rows. Thus the 2D DFT of an $N \times N$ image can be computed in $\mathcal{O}(N^2 \log_2 N^2)$ operations.

The extension to n dimensions is straightforward: An n D DFT can be performed as a sequence of n 1D DFTs in $\mathcal{O}(N^n \log_2 N^n)$ operations.

General lattices If we regard the n D DFT as a sampled approximation to the Fourier integral, it is of interest to study the case of sampling on an arbitrary lattice as in Sec. 3.4.6. The starting point for this discussion is the n D Fourier series (3.276).

Consider a function $f_0(\mathbf{r})$ defined at all points within a unit cell of an arbitrary lattice. The lattice points are $\mathbf{r} = \mathbf{P}\mathbf{k}$, where \mathbf{k} is a multi-index, *i.e.* an n D vector with integer components. If we extend $f_0(\mathbf{r})$ to a periodic function $f(\mathbf{r})$ as in (3.273) and sample $f(\mathbf{r})$ at the points $\mathbf{r} = \mathbf{P}\mathbf{k}/N$, so that N points fit along each axis in the unit cell, then (3.276) becomes

$$\begin{aligned} f(\mathbf{P}\mathbf{k}/N) &= \frac{1}{|\det(\mathbf{P})|} \sum_{\mathbf{m}} F_0(\mathbf{Q}\mathbf{m}) \exp(2\pi i \mathbf{Q}\mathbf{m} \cdot \mathbf{P}\mathbf{k}/N) = \\ &= \frac{1}{|\det(\mathbf{P})|} \sum_{\mathbf{m}} F_0(\mathbf{Q}\mathbf{m}) \exp(2\pi i \mathbf{m} \cdot \mathbf{k}/N), \end{aligned} \quad (3.361)$$

where $\mathbf{Q}\mathbf{m}$ are the points on the reciprocal lattice and the second form of (3.361) follows from $\mathbf{Q}^t = \mathbf{P}^{-1}$.

With this motivation we define the n D inverse DFT as

$$f_{\mathbf{k}} = \frac{1}{N^n} \sum_{\mathbf{m}=0}^{N-1} F_{\mathbf{m}} \exp(2\pi i \mathbf{m} \cdot \mathbf{k}/N), \quad (3.362)$$

where $f_{\mathbf{k}}$ corresponds to $f(\mathbf{P}\mathbf{k}/N)$ and $F_{\mathbf{m}}$ to $F_0(\mathbf{Q}\mathbf{m})$. We emphasize however, that these are correspondences and not equalities; the DFT is only an approximation to the sampled Fourier series, so (3.362) is a definition, not something derived from (3.361).

Note that the specific geometry of the lattices has disappeared in (3.362); the exponent involves only the scalar product $\mathbf{m} \cdot \mathbf{k}$ of the multi-indices, not the matrices \mathbf{P} and \mathbf{Q} . It is only when we want to interpret $f_{\mathbf{k}}$ and $F_{\mathbf{m}}$ as samples of a function and its Fourier transform that the geometry matters.

The inverse of (3.362), the DFT itself, is given by

$$F_{\mathbf{k}} = \sum_{\mathbf{m}=0}^{N-1} f_{\mathbf{m}} \exp(-2\pi i \mathbf{m} \cdot \mathbf{k}/N). \quad (3.363)$$

Lexicographic ordering Another way to formulate a 2D DFT is to reorder the N^2 elements of \mathbf{f} into an $N^2 \times 1$ column vector by use of *lexicographic ordering*. In this approach we define a new index ℓ as

$$\ell \equiv k + jN, \quad j = 0, \dots, N-1, \quad k = 0, \dots, N-1, \quad \ell = 0, \dots, N^2-1. \quad (3.364)$$

This indexing amounts to starting with 0 at the upper left of the 2D matrix and counting in a raster fashion from left to right and top to bottom.

The inverse of (3.364) is

$$j = \text{int}(\ell/N), \quad k = \ell - jN = \ell \pmod{N}, \quad (3.365)$$

where $\text{int}(x)$ denotes the integer part of x .

A similar ordering of \mathbf{F} is obtained by defining

$$p = n + mN, \quad m = 0, \dots, N-1, \quad n = 0, \dots, N-1, \quad p = 0, \dots, N^2-1, \quad (3.366)$$

with a similar inversion rule. With these definitions, (3.358) becomes

$$F_p^{(lex)} = \sum_{\ell=0}^{N^2-1} D_{p\ell}^{(lex)} f_\ell^{(lex)}, \quad (3.367)$$

or, in matrix-vector form,

$$\mathbf{F}^{(lex)} = \mathbf{D}^{(lex)} \mathbf{f}^{(lex)}, \quad (3.368)$$

where $\mathbf{f}^{(lex)}$ and $\mathbf{F}^{(lex)}$ are the lexicographically ordered $N^2 \times 1$ vectors corresponding to f_{jk} and F_{mn} , respectively, and $\mathbf{D}^{(lex)}$ is an $N^2 \times N^2$ matrix. The elements of $\mathbf{D}^{(lex)}$ are $\exp[-2\pi i(jm + kn)/N]$ with application of (3.365) and the analogous rule for p .

4

Series Expansions and Integral Transforms

This chapter comprises a collection of miscellaneous mathematical concepts and techniques that we shall need later in the book. Section 4.1 develops the theory of orthogonal expansions and provides us with several sets of orthonormal functions that can be used to represent objects and images. Section 4.2 surveys several classical integral transforms that are of use in describing imaging systems. The treatment in this section is brief, amounting to little more than a compendium of properties, since the transforms in question are well known and treated fully in many texts.

Section 4.3 deals with an integral transform that is not so widely known, yet which plays a fundamental role in image science. The *Fresnel transform* arises in signal processing, diffraction theory, coherent imaging and radar, so we present a relatively detailed account of its properties.

Finally, in Sec. 4.4, we introduce the *Radon transform*, an important tool in the mathematical description of tomographic imaging systems.

4.1 EXPANSIONS IN ORTHOGONAL FUNCTIONS

Fourier analysis is an expansion in complex exponentials, but there are many other sets of orthogonal functions that can be used in an exactly parallel manner. Since virtually all of the theorems that apply to conventional Fourier analysis have counterparts with these functions, the broader field of expansion in orthonormal functions is often called *generalized Fourier analysis*. We survey this field here, concentrating on families of orthonormal functions with particular usefulness in image science.

4.1.1 Basic concepts

The main thing that distinguishes one family of orthogonal functions from another is the definition of orthogonality used. The simplest definition is in terms of a scalar product on $\mathbb{L}_2(a, b)$, but we can also use the scalar product appropriate to the weighted Hilbert space $\mathbb{L}_2(a, b; w(x))$ (see Sec. 1.1.4). Norms in $\mathbb{L}_2(a, b; w(x))$ are denoted $\|\cdot\|_w$. In this space, two functions $u_n(x)$ and $u_m(x)$ are said to be orthonormal if

$$(u_n, u_m)_w = \int_a^b dx w(x) u_n^*(x) u_m(x) = \delta_{nm}, \quad (4.1)$$

where $w(x) \geq 0$ for $a < x < b$.

Suppose we are given a set of functions $\{u_n(x), n = 1, \dots, \infty\}$, satisfying (4.1) and wish to use them to represent a function $f(x)$ in $\mathbb{L}_2(a, b; w(x))$. As in Sec. 3.2.1, we begin by simply assuming that $f(x)$ can be represented by a series of the form [cf. (3.17)]

$$f(x) = \sum_{n=1}^{\infty} \alpha_n u_n(x). \quad (4.2)$$

If this expansion is valid, then the coefficients must be given by [cf. (3.19)]

$$\alpha_n = \int_a^b dx' w(x') u_n^*(x') f(x'). \quad (4.3)$$

This set of coefficients is optimal in the sense that

$$\|f(x) - \sum_{n=1}^N \beta_n u_n(x)\|_w \geq \|f(x) - \sum_{n=1}^N \alpha_n u_n(x)\|_w, \quad (4.4)$$

where $\{\alpha_n\}$ is given by (4.3) and $\{\beta_n\}$ is any other set of coefficients (Rade and Westergren, 1990).

The function set $\{u_n(x)\}$ is complete in $\mathbb{L}_2(a, b; w(x))$ if

$$\lim_{N \rightarrow \infty} \|f(x) - \sum_{n=1}^N \alpha_n u_n(x)\|_w = 0 \quad (4.5)$$

for all $f(x)$ in the space. If this condition is satisfied, the assumed expansion (4.2) indeed exists.

Expansions in orthogonal functions obey Parseval's relations analogous to those found in Fourier analysis (Rade and Westergren, 1990). The analog of the Parseval relation for a Fourier series, (3.50), is

$$\sum_{n=1}^{\infty} |\alpha_n|^2 = \int_a^b dx' w(x') |f(x')|^2, \quad (4.6)$$

where $\{u_n(x)\}$ is any complete set of orthonormal functions in $\mathbb{L}_2(a, b; w(x))$, and α_n is given by (4.3). The analog of the generalized Parseval relation (3.51) also holds.

4.1.2 Orthogonal polynomials

Some of the most important sets of orthogonal functions are real polynomials $\{\phi_n(x), n = 0, 1, 2, \dots\}$, where $\phi_n(x)$ is a polynomial of degree n . For historical reasons the polynomials are usually not normalized but instead constructed to satisfy

$$\int_a^b dx w(x) \phi_n(x) \phi_m(x) = h_n \delta_{nm}, \quad (4.7)$$

where h_n is a normalization factor to be discussed below. The orthonormal functions required in Sec. 4.1.1 can be obtained simply by

$$u_n(x) = \frac{\phi_n(x)}{\sqrt{h_n}}. \quad (4.8)$$

The Gram-Schmidt procedure outlined in App. A can be used to construct a set of orthogonal polynomials satisfying (4.7). Starting by convention with $\phi_0(x) = 1$, we write $\phi_1(x) = c_{10} + c_{11}x$, choosing the coefficients so that ϕ_0 and ϕ_1 are orthogonal according to (4.7). Then we write $\phi_2(x) = c_{20} + c_{21}x + c_{22}x^2$, choosing the coefficients via the algorithm in App. A to make ϕ_2 orthogonal to both ϕ_1 and ϕ_0 . Continuing in this way, we can in principle construct the infinite set; a detailed example of this procedure can be found in Arfken and Weber (1995).

The Gram-Schmidt procedure tends to be numerically unstable because it requires subtracting numbers of similar magnitude. A more practical way to compute the polynomials is by means of *recurrence relations*. It can be shown (Walter, 1994) that it is always possible to write

$$xu_n(x) = A_n u_{n+1}(x) + B_n u_n(x) + C_n u_{n-1}(x), \quad n = 1, 2, \dots, \quad (4.9)$$

where the coefficients depend on the interval (a, b) and the weighting function $w(x)$.

One use of the recurrence relation is to prove the completeness of the set of polynomials. Given a function $f(x)$ in $\mathbb{L}_2(a, b; w(x))$ and assuming that the polynomials are orthonormal, we can form the partial sum $S_N(x)$ given by

$$S_N(x) = \sum_{n=0}^N \alpha_n u_n(x), \quad \alpha_n = \int_a^b dx' w(x') u_n(x') f(x'), \quad (4.10)$$

where $u_n(x)$ is $\phi_n(x)$ normalized as in (4.8), and we have omitted the complex conjugate on the assumption that the polynomials are real. In the limit $N \rightarrow \infty$, $S_N(x)$ converges to $f(x)$ in the sense that

$$\lim_{N \rightarrow \infty} \|S_N(x) - f(x)\|_w = 0, \quad (4.11)$$

so the functions $\{u_n(x)\}$ (and hence also $\{\phi_n(x)\}$) are complete in $\mathbb{L}_2(a, b; w(x))$.

We can also write $S_N(x)$ as an integral transform:

$$S_N(x) = \int_a^b dx' w(x') f(x') \sum_{n=0}^N u_n(x) u_n(x') \equiv \int_a^b dx' w(x') f(x') K_N(x, x'). \quad (4.12)$$

Walter (1994) shows that the kernel K_N is given by the *Christoffel-Darboux formula*:

$$K_N(x, x') = \frac{A_N[u_{N+1}(x)u_N(x') - u_N(x)u_{N+1}(x')]}{x - x'}. \quad (4.13)$$

This kernel is the analog of the Dirichlet kernel in Fourier theory [see Secs. 2.2.2 and 3.2.2].

The convergence of $S_N(x)$ can now be restated as

$$\lim_{N \rightarrow \infty} w(x') K_N(x, x') = \delta(x - x'). \quad (4.14)$$

The Dirac delta function allows the integral in (4.12) to be performed readily in the limit, showing that $S_N(x) \rightarrow f(x)$. Thus each distinct set of orthogonal polynomials has associated with it a representation of the delta function.

4.1.3 Sturm-Liouville theory

A rich source of orthonormal function sets is the literature on Hermitian operators. As discussed in detail in Chap. 1, the eigenfunctions of any Hermitian operator can be chosen to form a complete, orthonormal basis in the relevant Hilbert space. In this section we discuss orthonormal functions that arise as eigenfunctions of certain Hermitian differential operators.

Many of the classical second-order partial differential equations encountered in mathematical physics can be solved by the method of separation of variables (Morse and Feshbach, 1953, p. 719). The resulting ordinary differential equations involve differential operators called *Sturm-Liouville operators*. The general form of a Sturm-Liouville operator \mathcal{L} is (Arfken and Weber, 1995)

$$\mathcal{L}f(x) = \frac{d}{dx} \left[p(x) \frac{df(x)}{dx} \right] + q(x)f(x), \quad (4.15)$$

where $p(x)$ and $q(x)$ are real, bounded functions that are characteristic of the original partial differential equation and of the coordinates used for separation. If $p(x) \neq 0$ on an interval $[a, b]$, the operator is said to be *regular* on that interval. If $p(x) = 0$ or $q(x)$ is singular on $[a, b]$, or if the interval is infinite, the operator is said to be *singular*. The points at which $p(x) = 0$ are called the *singular points* of the operator, and the range $[a, b]$ is often taken to extend from one singular point to another.

It is a straightforward exercise in integration by parts to show that any operator in the form (4.15) is Hermitian in $\mathbb{L}_2(a, b)$ subject to certain boundary conditions. That is,

$$\begin{aligned} (f_1(x), \mathcal{L}f_2(x)) &= \int_a^b dx [f_1(x)]^* \mathcal{L}f_2(x) \\ &= (\mathcal{L}f_1(x), f_2(x)) = \int_a^b dx [\mathcal{L}f_1(x)]^* f_2(x). \end{aligned} \quad (4.16)$$

The boundary conditions are that the boundary terms produced by the integration by parts must vanish, which will happen if f_1 and f_2 satisfy

$$\left[f_1^* p \frac{df_2}{dx} \right]_{x=a} = \left[f_1^* p \frac{df_2}{dx} \right]_{x=b} \quad (4.17a)$$

and

$$\left[f_2^* p \frac{df_1}{dx} \right]_{x=a} = \left[f_2^* p \frac{df_1}{dx} \right]_{x=b}. \quad (4.17b)$$

These conditions are satisfied if either the functions or their derivatives vanish at the end points.

The eigenvalue problem for a Sturm-Liouville operator is usually stated as

$$\mathcal{L}\psi_n(x) + \lambda_n w(x) \psi_n(x) = 0, \quad (4.18)$$

where $w(x)$ is real, continuous and positive for $a < x < b$. Though this equation arises naturally in many physical problems (Morse and Feshbach, 1953, p. 719), it has a rather different structure from our usual eigenvalue equation $\mathcal{O}u_n(x) = \lambda_n u_n(x)$. To get the standard form, we can define a new operator \mathcal{L}_w by

$$\mathcal{L}_w f(x) = -\frac{1}{w(x)} \mathcal{L}f(x), \quad (4.19)$$

so that

$$\mathcal{L}_w \psi_n(x) = \lambda_n \psi_n(x). \quad (4.20)$$

This new operator \mathcal{L}_w is Hermitian in the space $\mathbb{L}_2(a, b; w(x))$ (see Sec. 1.1.4) if the original operator \mathcal{L} is Hermitian in $\mathbb{L}_2(a, b)$ since

$$\begin{aligned} \int_a^b dx w(x) f_1^*(x) \mathcal{L}_w f_2(x) &= - \int_a^b dx f_1^*(x) \mathcal{L}f_2(x) \\ &= - \int_a^b dx [\mathcal{L}f_1(x)]^* f_2(x) = \int_a^b dx w(x) [\mathcal{L}_w f_1(x)]^* f_2(x). \end{aligned} \quad (4.21)$$

Thus we can work with either the original \mathcal{L} , considered as an operator in $\mathbb{L}_2(a, b)$, or with the modified operator \mathcal{L}_w in $\mathbb{L}_2(a, b; w(x))$.

With either viewpoint, the eigenfunctions form an orthogonal set with respect to $w(x)$:

$$\int_a^b dx w(x) \psi_n^*(x) \psi_m(x) = h_n \delta_{nm}. \quad (4.22)$$

The eigenfunctions are often but not always polynomials. They form a complete set in the sense that any function in $\mathbb{L}_2(a, b; w(x))$ which satisfies the boundary conditions of the eigenvalue problem can be expanded as

$$f(x) = \sum_n c_n \psi_n(x), \quad c_n = \frac{1}{h_n} \int_a^b dx w(x) \psi_n^*(x) f(x). \quad (4.23)$$

The particular choice of indexing is arbitrary, but $n = 0$ to ∞ is common.

Sturm-Liouville and Fourier Fourier analysis emerges as a special case of Sturm-Liouville theory if we take $p(x) = 1$ and $q(x) = 0$, so that $\mathcal{L} = d^2/dx^2$. For $(a, b) = (-\frac{1}{2}L, \frac{1}{2}L)$ and $w(x) = 1$, the eigenfunctions (for various boundary conditions) are

$$\psi_n(x) = \sin(2\pi nx/L), \quad \psi_n(\pm \frac{1}{2}L) = 0; \quad (4.24a)$$

$$\psi_n(x) = \cos(2\pi nx/L), \quad \psi'_n(\pm \frac{1}{2}L) = 0; \quad (4.24b)$$

$$\psi_n(x) = \exp(2\pi inx/L), \quad \psi_n(\frac{1}{2}L) = \psi_n(-\frac{1}{2}L). \quad (4.24c)$$

Green's functions If zero is not an eigenvalue, a regular Sturm-Liouville operator can be inverted by use of a *Green's function* (Walter, 1994). This function, denoted $G(x, x')$, is the kernel of the integral operator that is the inverse of the differential operator \mathcal{L} . It satisfies

$$\mathcal{L}G(x, x') = \delta(x - x'). \quad (4.25)$$

The Green's function must also satisfy the relevant boundary conditions.

One use of a Green's function is to solve the inhomogeneous differential equation,

$$\mathcal{L}f(x) = s(x), \quad (4.26)$$

subject to boundary conditions on $f(x)$. For example, if $f(x)$ is required to vanish at $x = \pm\frac{1}{2}L$, then the solution to (4.26) is given by

$$f(x) = \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx' s(x') G(x, x'), \quad (4.27)$$

provided $G(\pm\frac{1}{2}L, x') = 0$. That (4.27) indeed solves (4.26) can be verified by operating on both sides with \mathcal{L} and differentiating under the integral sign.

An important practical application of Green's functions is diffraction theory, introduced in Chap. 9. Extension of the concept to higher dimensions and more complicated boundary conditions will be discussed there.

4.1.4 Classical orthogonal polynomials and related functions

This section is a brief summary of some useful orthogonal polynomials and orthogonal functions derived from them. Most of these functions arise from Sturm-Liouville operators. For a tutorial discussion of these functions in the context of mathematical physics, the reader can consult Morse and Feshbach (1953) or Arfken and Weber (1995). A detailed compendium of their properties can be found in Abramowitz and Stegun (1965) or Magnus and Oberhettinger (1949).

Legendre polynomials The Legendre polynomials $P_n(x)$ are perhaps the simplest and best-known of the classical orthogonal polynomials. They are not normalized but satisfy the orthogonality relation (4.7) with $(a, b) = (-1, 1)$, $w(x) = 1$ and $h_n = 2/(2n+1)$. For n even (odd), $P_n(x)$ is a polynomial of order n with only even (odd) terms. The first few Legendre polynomials are

$$P_0(x) = 1, \quad P_1(x) = x, \quad P_2(x) = \frac{1}{2}(3x^2 - 1), \quad P_3(x) = \frac{1}{2}(5x^3 - 3x). \quad (4.28)$$

On the boundaries of the orthogonality interval, the Legendre polynomials satisfy

$$P_n(1) = 1, \quad P_n(-1) = (-1)^n. \quad (4.29)$$

Legendre polynomials are particularly useful for expanding functions of the cosine of an angle. Such functions arise frequently in physical applications when scalar products between 3D vectors occur. If we let $x = \cos\theta$, then the interval $(-1, 1)$ for x corresponds to the interval $(0, \pi)$ for θ . For any function $f(\theta)$ that depends only on $\cos\theta$, $f(2\pi - \theta) = f(\theta)$, so the full angular range $(0, 2\pi)$ is not needed, and the functions $\{P_n(\cos\theta), n = 0, \dots, \infty\}$ form a complete set on $(0, \pi)$. The boundary conditions in (4.29) are also appropriate for functions of $\cos\theta$. All

powers of $\cos \theta$ are 1 at $\theta = 0$ (or $\cos \theta = 1$), and the n^{th} power of $\cos \theta$ is $(-1)^n$ at $\theta = \pi$ (or $\cos \theta = -1$).

One important function that can be expanded in Legendre polynomials is $1/R$, where $R = |\mathbf{r} - \mathbf{r}'|$ is the distance between two 3D vectors \mathbf{r} and \mathbf{r}' . This function fits the scheme of the paragraph above since

$$R = |\mathbf{r} - \mathbf{r}'| = \sqrt{r^2 + r'^2 - 2rr' \cos \theta}, \quad (4.30)$$

where θ is the angle between \mathbf{r} and \mathbf{r}' . The reciprocal of this distance, $1/R$, plays an important role in both electrostatics and optics. It is the potential of a point source, and hence the Green's function for the Poisson equation in electrostatics, and it is one factor in the Green's function for the Helmholtz equation or the time-dependent wave equation in optics (see Chap. 9).

An expansion of $1/R$ can be obtained from the *generating function* for the Legendre polynomials (Arfken and Weber, 1995), which is given by

$$g(u, x) = (1 - 2xu + u^2)^{-\frac{1}{2}} = \sum_{n=0}^{\infty} P_n(x) u^n. \quad (4.31)$$

This function is called a generating function since $P_n(x)$ can, in principle, be generated from

$$P_n(x) = \frac{1}{n!} \left[\frac{\partial^n g(u, x)}{\partial u^n} \right]_{u=0}. \quad (4.32)$$

To get the expansion for $1/R$, we let $x = \cos \theta$ and $u = r'/r$ in (4.31).

Associated Legendre functions Closely related to the Legendre polynomials are the *associated Legendre functions*, defined by¹

$$P_n^m(x) = (1 - x^2)^{m/2} \frac{d^m}{dx^m} P_n(x). \quad (4.33)$$

Since $P_n(x)$ is a polynomial of degree n , we must have $m \leq n$. While it might be expected that only nonnegative values of m are allowed, a series representation of the Legendre polynomials permits $-n \leq m \leq n$ (see Arfken and Weber, 1995, p. 724). The Legendre polynomials themselves are a special case of P_n^m with $m = 0$.

The orthogonality relation for the associated Legendre functions is (Arfken and Weber, 1995, p. 727)

$$\int_{-1}^1 dx P_k^m(x) P_n^m(x) = \int_0^\pi P_k^m(\cos \theta) P_n^m(\cos \theta) \sin \theta d\theta = \frac{2}{2k+1} \cdot \frac{(k+m)!}{(k-m)!} \delta_{kn}. \quad (4.34)$$

The first few associated Legendre functions are

$$\begin{aligned} P_1^1(x) &= (1 - x^2)^{\frac{1}{2}} = \sin \theta, & P_2^1(x) &= 3x(1 - x^2)^{\frac{1}{2}} = 3 \cos \theta \sin \theta, \\ P_2^2(x) &= 3(1 - x^2) = 3 \sin^2 \theta, & P_3^1(x) &= \frac{3}{2}(5x^2 - 1)(1 - x^2)^{\frac{1}{2}} = \frac{3}{2}(5 \cos^2 \theta - 1) \sin \theta, \\ P_3^2(x) &= 15x(1 - x^2) = 15 \cos \theta \sin^2 \theta. \end{aligned} \quad (4.35)$$

¹The reader is cautioned that other normalizations for these functions can be found in the literature. Our convention follows that of Arfken and Weber (1995).

Spherical harmonics The associated Legendre functions are used to construct the *spherical harmonics*, familiar in virtually all branches of mathematical physics (Morse and Feshbach, 1953; Arfken and Weber, 1995). The spherical harmonic $Y_{\ell m}(\theta, \phi)$ is defined by

$$Y_{\ell m}(\theta, \phi) = (-1)^m \sqrt{\frac{2\ell + 1}{4\pi} \frac{(\ell - m)!}{(\ell + m)!}} P_{\ell}^m(\cos \theta) \exp(im\phi). \quad (4.36)$$

These functions satisfy the orthogonality relation,

$$\int_0^{2\pi} d\phi \int_0^{\pi} \sin \theta d\theta Y_{\ell m}^*(\theta, \phi) Y_{\ell' m'}(\theta, \phi) = \delta_{mm'} \delta_{\ell\ell'}, \quad (4.37)$$

and they form a complete set for expansions of square-integrable functions $f(\theta, \phi)$ in spherical polar coordinates.

An important property of spherical harmonics is the *addition theorem* (Arfken and Weber, 1995). If we consider two unit vectors \hat{s} and \hat{s}' , with polar coordinates (θ, ϕ) and (θ', ϕ') , respectively, and denote the angle between \hat{s} and \hat{s}' as θ_0 , then

$$P_{\ell}(\cos \theta_0) = \frac{4\pi}{2\ell + 1} \sum_{m=-\ell}^{\ell} Y_{\ell m}(\theta, \phi) Y_{\ell m}^*(\theta', \phi'). \quad (4.38)$$

This result will prove beneficial in Chap. 10, where we discuss scattering processes.

Zernike polynomials and circular harmonics The circle polynomials, now known as Zernike polynomials, were introduced by Frits Zernike in a classic 1934 paper for which he was to win the Nobel Prize in physics two decades later. The Zernike polynomials $R_k^j(r)$ are orthogonal on $[0, 1]$ with respect to weight r and are therefore well suited to expressing the radial dependence of a 2D function $f(\mathbf{r})$ in polar coordinates.

When $f(\mathbf{r})$ is expressed in Cartesian coordinates, we shall denote it as $f^{(c)}(x, y)$, and in polar coordinates we shall call it $f^{(p)}(r, \theta)$. Since $f^{(p)}(r, \theta)$ is periodic in θ with period 2π , it can be expanded in an angular Fourier series of the form

$$f^{(p)}(r, \theta) = \sum_{j=-\infty}^{\infty} f_j(r) \exp(ij\theta), \quad (4.39)$$

where the coefficients, which are still functions of r , are given by

$$f_j(r) = \frac{1}{2\pi} \int_0^{2\pi} d\theta f^{(p)}(r, \theta) \exp(-ij\theta). \quad (4.40)$$

To obtain a complete expansion of $f^{(p)}(r, \theta)$ in orthogonal functions, we must find an appropriate expansion of $f_j(r)$. In order to do so, the range of the variable r must be specified. We can assume, without loss of generality, that the maximum value of r is unity; if it is any other finite value R , we merely introduce the normalized radius r/R .

Of course, any set of orthogonal polynomials on $[0, 1]$ could be used as a basis for $f_j(r)$, but such an expansion might contain terms that cannot arise physically

and must therefore have zero coefficients. To discover what terms are allowed, we consider an expansion of $f^{(c)}(x, y)$ in a power series:

$$f^{(c)}(x, y) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} A_{nm} x^n y^m. \quad (4.41)$$

Since $x = r \cos \theta$ and $y = r \sin \theta$, we can also write $f(\mathbf{r})$ in polar coordinates as

$$\begin{aligned} f^{(p)}(r, \theta) &= f^{(c)}(r \cos \theta, r \sin \theta) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} A_{nm} r^{n+m} [\cos \theta]^n [\sin \theta]^m \\ &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} A_{nm} r^{n+m} \left[\frac{\exp(i\theta) + \exp(-i\theta)}{2} \right]^n \left[\frac{\exp(i\theta) - \exp(-i\theta)}{2i} \right]^m. \end{aligned} \quad (4.42)$$

The radial Fourier coefficients are thus given by

$$\begin{aligned} f_j(r) &= \frac{1}{2\pi} \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} A_{nm} r^{n+m} \int_0^{2\pi} d\theta \left[\frac{\exp(i\theta) + \exp(-i\theta)}{2} \right]^n \\ &\quad \times \left[\frac{\exp(i\theta) - \exp(-i\theta)}{2i} \right]^m \exp(-ij\theta). \end{aligned} \quad (4.43)$$

With the binomial theorem and a little algebra, we find that

$$\begin{aligned} &\frac{1}{2\pi} \int_0^{2\pi} d\theta \left[\frac{\exp(i\theta) + \exp(-i\theta)}{2} \right]^n \left[\frac{\exp(i\theta) - \exp(-i\theta)}{2i} \right]^m \exp(-ij\theta) \\ &= \frac{1}{2^n} \frac{1}{(2i)^m} \sum_{p=0}^n \sum_{q=0}^m \binom{n}{p} \binom{m}{q} (-1)^q \frac{1}{2\pi} \int_0^{2\pi} d\theta \exp[-2i(p+q)\theta + i(n+m)\theta - ij\theta]. \end{aligned} \quad (4.44)$$

Because of the orthogonality of the complex exponentials [see (3.7)], the last integral is unity if

$$j = 2(p+q) - (n+m), \quad 0 \leq p+q \leq n+m, \quad (4.45)$$

and zero otherwise. This condition restricts the values of j that can be associated with any particular power of r . If $k = n+m$, we must have

$$j = -k, -k+2, \dots, k. \quad (4.46)$$

Thus we must have $|j| \leq k$ (where k is the power of r), and j must vary in steps of 2. Stated differently, a polynomial of degree k in r can only have terms $r^j, r^{|j|+2}, \dots, r^k$ if it is to be used in expanding $f_j(r)$.

If we look for polynomials of this form and require them to be orthogonal on $[0, 1]$ with respect to weight r , we are led to the Zernike polynomials, given by (Born and Wolf, 1965)

$$R_k^j(r) = \sum_{s=0}^{\frac{1}{2}(k-|j|)} \frac{(-1)^s (k-s)!}{s! \left[\frac{k-|j|}{2} - s \right]! \left[\frac{k+|j|}{2} - s \right]!} r^{k-2s}, \quad (4.47)$$

where j and k must satisfy (4.46). The orthogonality condition for the Zernike polynomials is

$$\int_0^1 r dr R_k^j(r) R_{k'}^j(r) = \frac{1}{2(k+1)} \delta_{kk'}. \quad (4.48)$$

The functions $\sqrt{2(k+1)}R_k^j(r)\exp(ij\theta)$ thus form a convenient orthonormal set on the unit disk.

For a detailed treatment of Zernike polynomials, see Born and Wolf (1965), and for a practical discussion of their use in aberration theory, see Mahajan (1981).

Hermite polynomials Hermite polynomials, denoted $H_n(x)$, can be defined as

$$H_n(x) = (-1)^n \exp(x^2) \left(\frac{d}{dx} \right)^n \exp(-x^2). \quad (4.49)$$

The first few Hermite polynomials are:

$$H_0(x) = 1, \quad H_1(x) = 2x, \quad H_2(x) = 4x^2 - 2, \quad H_3(x) = 8x^3 - 12x. \quad (4.50)$$

The Hermite polynomials are orthogonal on $(-\infty, \infty)$ with respect to a Gaussian weighting function (Arfken and Weber, 1995, p. 768):

$$\int_{-\infty}^{\infty} dx H_n(x) H_m(x) \exp(-x^2) = 2^n n! \sqrt{\pi} \delta_{mn}. \quad (4.51)$$

The generating function for the Hermite polynomials is (Poularikas, 1996)

$$\exp(2tx - t^2) = \sum_{n=0}^{\infty} \frac{H_n(x)}{n!} t^n. \quad (4.52)$$

The Hermite polynomial $H_k(x)$ can be obtained from this expression by differentiating k times with respect to t and then setting $t = 0$.

Hermite-Gauss functions Instead of considering the Gaussian in (4.51) as a weight in the scalar product, we can lump it into the definition of the orthogonal functions. Thus we can consider a set of functions $\{HG_n(x)\}$ orthonormal on $(-\infty, \infty)$ with respect to *unit* weight and defined by

$$HG_n(x) = [2^n n! \sqrt{\pi}]^{-\frac{1}{2}} H_n(x) \exp\left(-\frac{1}{2}x^2\right). \quad (4.53)$$

These functions, known as *Hermite-Gauss functions*, arise in a variety of physical applications. In quantum mechanics, they are the wavefunctions for the simple harmonic oscillator. In optics they occur in beam-like solutions of the Helmholtz equation and as eigenmodes of laser resonators.

An important property of the Hermite-Gauss functions is that they form a complete orthonormal basis for $\mathbb{L}_2(\mathbb{R}; w(x) = 1)$ (or simply $\mathbb{L}_2(\mathbb{R})$ for short). A formal proof of this statement is given by Titchmarsh (1948), but it also follows from the observation that the functions are eigenfunctions of a Hermitian operator, namely the Schrödinger operator for the simple harmonic oscillator.

Because of the completeness of the Hermite-Gauss functions in $\mathbb{L}_2(\mathbb{R})$, any function in that space can be expressed with vanishing \mathbb{L}_2 error as

$$f(x) = \sum_{n=0}^{\infty} \alpha_n [2^n n! \sqrt{\pi}]^{-\frac{1}{2}} H_n(x) \exp\left(-\frac{1}{2}x^2\right), \quad (4.54)$$

and the coefficients $\{\alpha_n\}$ can be found by using (4.51).

The discrete expansion in (4.54) may be somewhat surprising. We are more used to expanding functions on $(-\infty, \infty)$ in Fourier basis functions $\{\exp(2\pi i\xi x)\}$, which can be regarded as a basis set with a *continuous* index ξ , but (4.54) shows we can also use a set with a *discrete* index n . The possibility of using a discrete (denumerably infinite) basis follows from the fact that $\mathbb{L}_2(-\infty, \infty)$ is a separable Hilbert space (see Sec. 1.1.5).

The Hermite-Gauss functions are also naturally associated with tempered distributions and Schwartz space (Walter, 1994). A polynomial times a Gaussian is, virtually by definition, a *good function* or *open-support test function* (see Sec. 2.1.2). Schwartz space is the space of good functions, and tempered distributions are linear functionals on this space.

One interesting property of Hermite-Gauss functions, occasionally exploited in imaging applications, is that they are their own Fourier transforms. Explicitly,

$$\int_{-\infty}^{\infty} dx \exp(-\frac{1}{2}x^2) H_n(x) \exp(ixy) = i^n \sqrt{2\pi} \exp(-\frac{1}{2}y^2) H_n(y), \quad (4.55)$$

from which a change of variables shows that

$$\mathcal{F}_1 \{HG_n(\sqrt{2\pi}x)\} = (-i)^n HG_n(\sqrt{2\pi}\xi). \quad (4.56)$$

Thus the Hermite-Gauss functions are eigenfunctions of the Fourier operator.

Laguerre polynomials The Laguerre polynomials, orthogonal on $(0, \infty)$ with respect to the weight $\exp(-x)$, are familiar in the quantum mechanics of the hydrogen atom. They are defined by (Arfken and Weber, 1995)

$$L_n(x) = \sum_{m=0}^n (-1)^m \binom{n}{m} \frac{x^m}{m!}, \quad (4.57)$$

and the orthogonality relation is

$$\int_0^{\infty} dx e^{-x} L_n(x) L_m(x) = \delta_{nm}. \quad (4.58)$$

Imaging uses of Laguerre polynomials are rare, but a few authors (*e.g.*, Seger, 1993) have exploited the fact that Laguerre polynomials can be used to construct eigenfunctions of the zeroth-order Hankel transform. From Sec. 3.4.4 we know that this Hankel transform is the same as the 2D Fourier transform for rotationally symmetric functions. A tabulated integral (Gradshteyn and Ryzhik, 1980, formula 7.421.1) shows that

$$\int_0^{\infty} r dr \exp(-\pi r^2) L_n(2\pi r^2) J_0(2\pi r\rho) = \frac{(-1)^n}{2\pi} \exp(-\rho^2/4\pi) L_n(\rho^2/2\pi). \quad (4.59)$$

The similarity to (4.55) and (4.56) should be noted. Just as Hermite-Gauss functions are eigenfunctions of the 1D Fourier operator, so too are Laguerre-Gauss functions eigenfunctions of the 2D rotationally symmetric Fourier operator.

Chebyshev polynomials There are two kinds of Chebyshev polynomials, both orthogonal on $(-1, 1)$ but with different weights. Chebyshev polynomials of the first kind, denoted $T_n(x)$, satisfy the orthogonality relation

$$\int_{-1}^1 dx (1-x^2)^{-\frac{1}{2}} T_n(x) T_m(x) = \frac{\pi}{2} \delta_{mn} (1 + \delta_{m0}). \quad (4.60)$$

The right-hand side is $\pi/2$ if $m = n \neq 0$ and π if $m = n = 0$.

Chebyshev polynomials of the second kind, denoted $U_n(x)$, satisfy

$$\int_{-1}^1 dx (1-x^2)^{\frac{1}{2}} U_n(x) U_m(x) = \frac{\pi}{2} \delta_{mn}. \quad (4.61)$$

These functions occur most commonly when x is the cosine of some angle, say $x = \cos \theta$. Then we have

$$T_n(\cos \theta) = \cos n\theta = \cos(n \cos^{-1} x), \quad |x| \leq 1, \quad (4.62)$$

$$U_n(\cos \theta) = \frac{\sin(n+1)\theta}{\sin \theta}. \quad (4.63)$$

As we shall see in Chap. 17, Chebyshev polynomials play a prominent role in the analysis of tomographic imaging systems; for a review, see Barrett (1984).

4.1.5 Prolate spheroidal wavefunctions

Walter (1994) refers to prolate spheroidal wavefunctions $\psi_n(x)$ as a lucky accident since they are eigenfunctions of both an integral operator and a Sturm-Liouville differential operator. The Sturm-Liouville operator arises when the wave equation is separated in prolate spheroidal coordinates, hence the name of the functions. In imaging applications, however, the integral operator is more important.

The integral operator in question corresponds to first truncating a function, so that it is spatially limited, and then passing it through an ideal low-pass filter. The prolate spheroidal wavefunction is the eigenfunction of this operator (Marks, 1991; Percival and Walden, 1993):

$$B \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx' \psi(x') \operatorname{sinc}[B(x-x')] = \lambda_n \psi_n(x). \quad (4.64)$$

In abstract operator form, we can rewrite (4.64) as

$$\mathcal{B}_B \mathcal{S}_L \psi_n(x) = \lambda_n \psi_n(x), \quad (4.65)$$

where \mathcal{S}_L is the space-limiting operator [multiplication by $\operatorname{rect}(x/L)$] and \mathcal{B}_B is the band-limiting operator (convolution with $B \operatorname{sinc}(Bx)$ or equivalently, multiplication by $\operatorname{rect}(\xi/B)$ in the frequency domain).

The eigenfunctions depend on the parameters L and B and the eigenvalues depend only on the product LB , but we shall not indicate these dependences explicitly. The first few eigenfunctions are plotted in Fig. 4.1, and the eigenvalue spectrum is shown in Fig. 4.2. The key point to note from Fig. 4.2 is the precipitous rolloff near $n = LB$ of the plot of λ_n vs. n .

Fig. 4.1 The first few prolate spheroidal wavefunctions.

Because of the lucky accident, prolate spheroidal wavefunctions satisfy two separate orthogonality conditions. They are orthonormal on $(-\infty, \infty)$,

$$\int_{-\infty}^{\infty} dx \psi_n(x) \psi_m(x) = \delta_{nm}, \tag{4.66}$$

and they are orthogonal but not normalized on the finite interval $(-\frac{1}{2}L, \frac{1}{2}L)$,

$$\int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \psi_n(x) \psi_m(x) = \lambda_n \delta_{nm}. \tag{4.67}$$

Since the prolates are eigenfunctions of a Hermitian operator on $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$, they are complete on that space. On the infinite interval, however, they are orthonormal but not complete; by (4.65) they are bandlimited so they cannot be used to represent an arbitrary function in $\mathbb{L}_2(-\infty, \infty)$. The best we can say is that they are complete in the space of bandlimited, square-integrable functions on the real line (Paley-Wiener space).

Fig. 4.2 The eigenvalue spectrum λ_n for the integral operator with eigenfunctions given by prolate spheroidal wavefunctions. Figure adapted from Marks (1991).

These properties give the prolates great utility in a variety of bandwidth-extrapolation and superresolution problems [see, *e.g.*, Mammone, (1987)].

Finite Fourier transform Another way of understanding prolate spheroidal wavefunctions is through the finite Fourier transform, performed by multiplying a function by a rect function before doing an ordinary Fourier transform. Under this operation, prolates satisfy (Slepian and Pollak, 1961; Marks, 1991):

$$\mathcal{F}\{\psi_n(x) \text{rect}(x/L)\} = \sqrt{\frac{L\lambda_n}{B}} \psi_n\left(\frac{\xi L}{B}\right), \quad (4.68)$$

where both λ_n and ψ_n depend on the parameter LB . Note that this is not exactly an eigenvalue equation because of the scale factor in the argument on the right. If we use dimensionless variables and set $L/B = 1$, we can say that prolates are eigenfunctions of the finite Fourier transform.

The dual relation to (4.68) is

$$\mathcal{F}\{\psi_n(x)\} = \sqrt{\frac{L}{B\lambda_n}} \psi_n\left(\frac{\xi L}{B}\right) \text{rect}(\xi/B). \quad (4.69)$$

From (4.68) and (4.69), it is straightforward to derive (4.64), so (4.68) can be regarded as the defining property of prolates.

Degrees of freedom One use of prolate spheroidal wavefunctions is in enumerating the degrees of freedom of a bandlimited and approximately spacelimited function. Consider a function $f_0(x)$ that is obtained by starting with an arbitrary square-integrable function $f(x)$ and applying the operator $\mathcal{B}_B\mathcal{S}_L$:

$$f_0(x) \equiv \mathcal{B}_B\mathcal{S}_L f(x) = B \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx' f(x') \text{sinc}[B(x-x')]. \quad (4.70)$$

Since \mathcal{B}_B is applied last, $f_0(x)$ is exactly bandlimited, but if LB is large the function is also approximately spacelimited.

Since $f(x)$ is in $\mathbb{L}_2(-\infty, \infty)$, $\mathcal{S}_L f(x)$ is in $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$ and can be expressed as

$$\mathcal{S}_L f(x) = \sum_{n=0}^{\infty} \alpha_n \psi_n(x) \text{rect}(x/L). \quad (4.71)$$

The operator \mathcal{S}_L is idempotent, so we can write

$$f_0(x) = \mathcal{B}_B\mathcal{S}_L f(x) = \mathcal{B}_B\mathcal{S}_L \sum_{n=0}^{\infty} \alpha_n \psi_n(x) = \sum_{n=0}^{\infty} \alpha_n \mathcal{B}_B\mathcal{S}_L \psi_n(x) = \sum_{n=0}^{\infty} \alpha_n \lambda_n \psi_n(x). \quad (4.72)$$

From Fig. 4.2, however, we see that $\lambda_n \simeq 0$ for $n > LB$ (provided $LB > 1$), so only about LB terms are required to represent $f_0(x)$ in the expansion (4.72).²

We recognize LB as the space-bandwidth product, introduced in Sec. 3.5.2 as a way of estimating the number of degrees of freedom of a signal. Here the same quantity appears as the number of parameters needed to represent a function $f_0(x)$ resulting from the operator in (4.67), placing the concept of space-bandwidth product on a firm theoretical footing. For an excellent review of this topic, see Slepian (1976).

²It is possible to construct pathological functions for which α_n grows rapidly in the vicinity of $n = LB$, and then this argument does not hold.

4.2 CLASSICAL INTEGRAL TRANSFORMS

The Fourier transform is treated in detail in Chap. 3. Here we survey a few other integral transforms with applications in imaging. For simplicity, only 1D versions of the transforms are discussed, but all are readily extended to two or more dimensions in Cartesian coordinates.

Good general treatments of these transforms are given by Bracewell (1965), Jerri (1992) and Poularikas (1996). Extensive tables of transforms are given by Erdélyi (1954), Abramowitz and Stegun (1965), and Oberhettinger (1972, 1973, 1974).

4.2.1 Laplace transform

The Laplace transform is defined as

$$F_L(s) = \int_0^{\infty} dt f(t) \exp(-st). \quad (4.73)$$

We have written the variable of integration as t and taken the range of integration as $(0, \infty)$ since the Laplace transform is most commonly used for functions of time, and we are often interested only in $t > 0$. For example, if we are dealing with a transient signal that is excited at $t = 0$, then we know that there is no signal before the excitation. Similarly, a linear shift-invariant temporal filter is described by its *impulse response* $h(t)$, which must vanish if $t < 0$. This mathematical condition simply says that there can be no output from the filter before an input is applied, or that cause must precede effect. Temporal functions that vanish for $t < 0$ are called *causal* or *one-sided*.

We shall denote the Laplace operator by $\mathcal{L}\mathbf{a}$. Thus we write

$$F_L(s) = \mathcal{L}\mathbf{a}\{f(t)\}. \quad (4.74)$$

If we restrict attention to causal functions, so that $f(t) = 0$ for $t < 0$, then the Laplace transform is formally the same thing as the Fourier transform with the temporal frequency being $s/2\pi i$. That is,

$$F_L(s) = \left[\int_0^{\infty} dt f(t) \exp(-2\pi i \nu t) \right]_{\nu=s/2\pi i} = F(s/2\pi i), \quad (4.75)$$

where $F(\nu)$ is the 1D Fourier transform of $f(t)$. If we do not restrict the function to be causal, then the Laplace transform of $f(t)$ is the same as the Fourier transform of $f(t) \text{step}(t)$ with $\nu = s/2\pi i$, or

$$F_L(s) = [\mathcal{F}_1\{f(t) \text{step}(t)\}]_{\nu=s/2\pi i}. \quad (4.76)$$

Alternatively, for noncausal functions we can also define a *two-sided Laplace transform* $F_{L2}(s)$ and the associated operator $\mathcal{L}\mathbf{a}_2$ via

$$F_{L2}(s) = \mathcal{L}\mathbf{a}_2\{f(t)\} = \int_{-\infty}^{\infty} dt f(t) \exp(-st), \quad (4.77)$$

which is identically $F(s/2\pi i)$ without any further restrictions. Unless the specifi-

cation *two-sided* is given explicitly, the term Laplace transform will refer to the one-sided expression given in (4.73).

One practical difference between Fourier and Laplace transforms is that the Fourier variable ν is usually taken to be real (though we saw in Sec. 3.3.9 that complex frequencies can be useful). The Laplace variable s , on the other hand, is usually regarded as complex. The transform $F_L(s)$ is defined for any complex s for which the integral in (4.73) converges. The one-sided nature of the integral is helpful in this respect since the factor e^{-st} decays rapidly for all positive t if s has a positive real part. Even if $f(t)$ diverges exponentially, say as $\exp(\alpha t)$ with α real, then the Laplace transform will still exist whenever $\text{Re}(s) > \alpha$. The point $s = \alpha$ in the complex s -plane is a singularity of $F_L(s)$ in this case.

Inverse Laplace transform By analogy to the Fourier transform, the inverse Laplace transform involves an integral over s . Since s is complex, we must specify a contour for this integral. The usual choice is the *Bromwich contour* shown in Fig. 4.3. With this contour, the inverse Laplace transform is (Titchmarsh, 1948)

$$\frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} ds F_L(s) e^{st} = \begin{cases} f(t) & \text{if } t > 0 \\ 0 & \text{if } t < 0 \end{cases}, \quad (4.78)$$

where c is a real constant chosen so that the contour is to the right of all singularities of $F_L(s)$ in the complex s -plane. The integral vanishes for $t < 0$ since the integrand in (4.78) is analytic within and on the closed contour shown in Fig. 4.3. For $t > 0$, the validity of (4.78) can be shown by use of (4.73), (2.46) and (2.25).

Fig. 4.3 The Bromwich contour used in the inverse Laplace transform. This contour in the complex s -plane lies to the right of all singularities of $F_L(s)$ and extends vertically from $c - iR$ to $c + iR$, with $R \rightarrow \infty$.

The inversion formula (4.78) is still valid if $F_L(s)$ is replaced by the two-sided transform of (4.75), without the causality restriction, but in that case the integral on the left agrees with $f(t)$ only for $t > 0$. Thus the inverse Laplace transform can be regarded as a representation of a one-sided function for all t or of an arbitrary

function for $t > 0$. In this sense it is analogous to the Fourier series or Fourier cosine transform. We saw in Chap. 3 that a Fourier series is a representation of an arbitrary function on a finite interval or of a periodic function for all space. Similarly, a Fourier cosine transform is a representation of an arbitrary function for positive x or of an even function for all x . No matter what function was used to find the original transform, the inverse transform is a representation of a function with a certain symmetry property: one-sidedness for the Laplace transform, periodicity for the Fourier series, and evenness for the Fourier cosine transform.

Filters and Laplace convolution The Laplace transform is very important for solving equations of motion—differential equations for the time evolution of a linear system subject to boundary conditions. Electrical filters and other causal linear systems fit this description. For spatial functions, the one-sided integral of (4.73) does not usually arise naturally, and we may as well use Fourier transforms. One exception to this statement occurs with exponentially attenuated beams of radiation, for which the Laplace transform is frequently useful.

An important tool in many of these applications is the *Laplace convolution theorem*. The Laplace convolution of two functions $f(t)$ and $p(t)$ is defined by

$$[p *_L f](t) = \int_0^t dt' p(t') f(t - t'), \quad (4.79)$$

which is the same as the ordinary convolution if $p(t)$ and $f(t)$ are both causal.

Just as Fourier transformation converts convolution to multiplication, so too does Laplace transformation convert Laplace convolution to multiplication (Carrier *et al.*, 1966). That is,

$$\begin{aligned} \mathcal{L}\mathbf{a}\{p *_L f\} &= \int_0^\infty dt \exp(-st) \int_0^t dt' p(t') f(t - t') = \int_0^\infty dt' \int_{t'}^\infty dt \exp(-st) p(t') f(t - t') \\ &= \int_0^\infty dt' \exp(-st') p(t') \int_{t'}^\infty dt \exp[-s(t - t')] f(t - t') = P_L(s) F_L(s). \end{aligned} \quad (4.80)$$

Conversely, the inverse Laplace transform of the product $P_L(s)F_L(s)$ is the Laplace convolution (4.79).

4.2.2 Mellin transform

The Mellin transform can be derived from the two-sided Laplace transform by making a change of variables (Bracewell, 1965). If we let $x = \exp(-t)$ in (4.77), we obtain

$$F_{L2}(s) = \int_0^\infty dx f(-\ln x) x^{s-1}. \quad (4.81)$$

The integral on the right is the Mellin transform of the logarithmically distorted function $f(-\ln x)$. Letting $k(x) = f(-\ln x)$, we can write

$$K_M(s) = \int_0^\infty dx k(x) x^{s-1} = \mathcal{M}\{k(x)\} = \mathcal{L}\mathbf{a}_2\{f(t)\}, \quad (4.82)$$

where $K_M(s)$ denotes the Mellin transform of $k(x)$ and \mathcal{M} is the Mellin operator.

Expressions like (4.82) were used by Riemann in the context of number theory, but the first rigorous treatment was due to Mellin (Titchmarsh, 1948).

A similar change of variables in the inverse Laplace transform shows that the inverse Mellin transform is given by (Bracewell, 1965; Carrier *et al.*, 1966)

$$k(x) = \mathcal{M}^{-1}\{K_M(s)\} = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} ds K_M(s) x^{-s}. \quad (4.83)$$

One interpretation of the Mellin transform is in terms of moments of the function being transformed. If s is real and $k(x) = 0$ for $x < 0$, then $K_M(s)$ is the $(s-1)^{th}$ moment of $k(x)$.

Mellin and magnification The Mellin transform finds its main imaging application in dealing with magnification. If $k(x)$ represents an image, then $k(\alpha x)$ represents an image magnified by $1/\alpha$. It follows readily from (4.82) that

$$\mathcal{M}\{k(\alpha x)\} = \int_0^\infty dx k(\alpha x) x^{s-1} = \alpha^{-s} K_M(s) = \exp(-s \ln \alpha) K_M(s). \quad (4.84)$$

Hence the magnification has the effect of multiplying the Mellin transform by $\exp(-s \ln \alpha)$, which has unit modulus if s is pure imaginary. Thus $|\mathcal{M}\{k(\alpha x)\}|$ is invariant to magnification. This property is analogous to the shifting property of Fourier transforms: If a function $f(x)$ is shifted by α , its Fourier transform $F(\xi)$ is multiplied by $\exp(2\pi i \alpha \xi)$, which has unit modulus if ξ is real, and $|F(\xi)|$ is invariant to shift. For this reason, Fourier transforms are important in the analysis of shift-invariant systems, while Mellin transforms are used for magnification-invariant or scale-invariant systems. Applications include modeling of the visual cortex of primates (Kaas, 1978; Cavanaugh, 1978), which evidently functions in a scale-invariant manner, and scale-invariant pattern recognition (Casasent and Psaltis, 1976).

Mellin convolution The Mellin convolution is defined by

$$[p *_M f](x) = \int_0^\infty \frac{dx'}{x'} p\left(\frac{x}{x'}\right) f(x'). \quad (4.85)$$

This expression is similar to the usual convolution expression (3.114); one key difference, however, is that x/x' appears rather than $x-x'$. From the discussion above of Mellin and magnification, we might expect that a Mellin transform would be a useful thing to apply to (4.85). In fact, it gives

$$\begin{aligned} \mathcal{M}\{p *_M f\} &= \int_0^\infty dx x^{s-1} \int_0^\infty \frac{dx'}{x'} p\left(\frac{x}{x'}\right) f(x') = \int_0^\infty \frac{dx'}{x'} f(x') \int_0^\infty dx x^{s-1} p\left(\frac{x}{x'}\right) \\ &= \int_0^\infty dx' x'^{s-1} f(x') \int_0^\infty du u^{s-1} p(u) = F_M(s) P_M(s), \end{aligned} \quad (4.86)$$

where $u = x/x'$. Thus Mellin transformation converts Mellin convolution to multiplication. A related result is

$$\mathcal{M}\left\{\int_0^\infty dx f(x) p(\alpha x)\right\} = \int_0^\infty d\alpha \alpha^{s-1} \int_0^\infty dx f(x) p(\alpha x) = F_M(1-s) P_M(s). \quad (4.87)$$

4.2.3 z transform

The z transform is used in discrete problems where a function $f(t)$ is known only at a discrete set of sample points $\{t_n = n\Delta t, n = 0, 1, 2, \dots\}$. Letting $f_n = f(n\Delta t)$, we can define the z transform of the sequence f_0, f_1, \dots , by constructing a polynomial in z^{-1} , where z is a complex number, with f_n as the weight of the n^{th} term. Explicitly,

$$F_z(z) = \mathcal{Z}\{f_n\} = \sum_{n=0}^{\infty} f_n z^{-n}, \quad (4.88)$$

where \mathcal{Z} is the z -transform operator, which maps a sequence of numbers to a function of a complex variable.

Another way to view the z transform is that it is the Laplace transform of a function $\phi(t)$ constructed from the sample values of $f(t)$ and delta functions (Bracewell, 1965), *i.e.*,

$$\phi(t) = \sum_{n=0}^{\infty} f_n \delta(t - t_n). \quad (4.89)$$

The Laplace transform of $\phi(t)$, denoted $\Phi_L(s)$, is given by³

$$\Phi_L(s) = \sum_{n=0}^{\infty} f_n \exp(-sn\Delta t) = \sum_{n=0}^{\infty} f_n [\exp(-s\Delta t)]^n. \quad (4.90)$$

This expression agrees with (4.88) if we let

$$z = \exp(s\Delta t). \quad (4.91)$$

Since both s and z are arbitrary complex numbers, this substitution entails no loss of generality.

The main utility of the z transform is in analyzing problems involving discrete convolutions. Given two sequences $\{f_n\}$ and $\{p_n\}$, $n = 0, 1, 2, \dots$, their discrete convolution is defined by analogy to (4.79) as

$$(p * f)_n = \sum_{m=0}^n p_m f_{n-m}. \quad (4.92)$$

The z transform yields

$$\mathcal{Z}\{p * f\} = \sum_{n=0}^{\infty} z^{-n} \sum_{m=0}^n p_m f_{n-m} = \sum_{m=0}^{\infty} \sum_{n=m}^{\infty} z^{-m} p_m z^{-(n-m)} f_{n-m} = P_z(z) F_z(z). \quad (4.93)$$

Once again, a particular kind of convolution has been converted to a simple product by the appropriate transform.

³Strictly speaking, the Laplace transform used here has to be two-sided. Even though $\phi(t) = 0$ for $t < 0$, the impulse exactly at $t = 0$ has to be included.

4.2.4 Hilbert transform

The Hilbert transform of a function $f(x)$ is defined by

$$F_{Hi}(x) = [\mathcal{H}\mathbf{i}\{f\}](x) = -\frac{1}{\pi}\mathcal{P}\int_{-\infty}^{\infty} dx' \frac{f(x')}{x-x'}, \quad (4.94)$$

where \mathcal{P} denotes the Cauchy principal value, discussed in App. B. The Hilbert transform of $f(x)$ can be regarded as the convolution of $f(x)$ with the generalized function $-\pi^{-1}\mathcal{P}\{1/x\}$, which was discussed in Secs. 2.1.1 and 3.3.7.

The inverse of the Hilbert transform can be found by use of the convolution theorem (3.132) and the expression (3.167) for $\mathcal{F}\{\mathcal{P}[1/x]\}$. These results allow us to write

$$\mathcal{F}\{F_{Hi}(x)\} = iF(\xi)\operatorname{sgn}(\xi), \quad (4.95)$$

where the sgn function is defined in (2.75) and $F(\xi)$ is the usual Fourier transform of $f(x)$. Thus Hilbert transformation corresponds to multiplication by $i\operatorname{sgn}\xi$ in the frequency domain, and inverse Hilbert transformation is simply multiplication by $-i\operatorname{sgn}\xi$. Use of the convolution theorem in reverse then shows that

$$f(x) = [\mathcal{H}\mathbf{i}^{-1}\{F_{Hi}\}](x) = \frac{1}{\pi}\mathcal{P}\int_{-\infty}^{\infty} dx' \frac{F_{Hi}(x')}{x-x'}. \quad (4.96)$$

Causality and the Kramers-Kronig relations The Hilbert transform plays an important role in the analysis of temporal filters and other causal linear systems. As noted above in Sec. 4.2.1, the temporal impulse response $h(t)$ of a linear, shift-invariant filter must vanish if $t < 0$. As we shall now show, this condition imposes a strong requirement on the Fourier transform of $h(t)$, which is the transfer function of the filter.

We can write the causality condition as

$$h(t) = 0 \quad \text{if } t < 0, \quad (4.97)$$

but an equivalent statement is

$$h(t) = h(t)\operatorname{sgn}(t). \quad (4.98)$$

For $t > 0$, $\operatorname{sgn}(t) = 1$ and (4.98) reads $h(t) = h(t)$. For $t < 0$, (4.98) requires that $h(t) = -h(t)$, which can be satisfied only if $h(t) = 0$.

Taking the Fourier transform of both sides of (4.98), we obtain

$$H(\nu) * \left(-\frac{i}{\pi}\right)\mathcal{P}\left(\frac{1}{\nu}\right) = H(\nu). \quad (4.99)$$

Since $H(\nu)$ is a complex function, this equation, like any equation involving complex variables, is really two equations: one for the real part and one for the imaginary part. If we split $H(\nu)$ into real and imaginary parts as

$$H(\nu) = H_r(\nu) + iH_i(\nu), \quad (4.100)$$

then (4.99) is equivalent to

$$H_r(\nu) = \frac{1}{\pi}\int_{-\infty}^{\infty} d\nu' \frac{H_i(\nu')}{\nu-\nu'} = -\mathcal{H}\mathbf{i}\{H_i(\nu)\}; \quad (4.101a)$$

$$H_i(\nu) = -\frac{1}{\pi} \int_{-\infty}^{\infty} d\nu' \frac{H_r(\nu')}{\nu - \nu'} = \mathcal{H}\mathbf{i}\{H_r(\nu)\}. \quad (4.101b)$$

These equations, known as the *Kramers-Kronig relations*, show that the real and imaginary parts of the transfer function of a causal linear system are a Hilbert-transform pair. Imaging systems, however, do not usually have this nice mathematical property.

Analytic signals In practical applications we often deal with real-valued functions of time that oscillate at a single frequency ω . It is convenient to represent such functions as the real part of a complex exponential:

$$f(t) = A \cos(\omega t + \phi) = \operatorname{Re}\{A \exp(i\omega t + i\phi)\}. \quad (4.102)$$

But we may also be interested in amplitude-modulated waves where A is a function of time or phase-modulated waves where ϕ is a function of time. We consider, therefore, the more general real-valued function,

$$f(t) = A(t) \cos[\omega t + \phi(t)]. \quad (4.103)$$

We may still want to express $f(t)$ as the real part of some complex function $f_c(t)$. Trivially, we can write

$$f_c(t) = f(t) - ig(t), \quad (4.104)$$

where $g(t)$ is an arbitrary real function. No matter what we choose for $g(t)$, we still have $f(t) = \operatorname{Re}\{f_c(t)\}$ since $-ig(t)$ is pure imaginary.

One way to fix $g(t)$ is to require that $f_c(t)$ be an analytic function when t is replaced by a complex variable $z = t + i\tau$. Since the real and imaginary parts of an analytic function must be related by the Cauchy-Riemann equations (see App. B), this condition removes the arbitrariness of the imaginary part $g(z)$. It will be left as an exercise for the reader to show that the Cauchy-Riemann equations are satisfied if we take $g(z)$ to be the Hilbert transform of $f(z)$. Then the *analytic signal* associated with the real function $f(t)$ is defined as

$$f_a(t) = f(t) - i\mathcal{H}\mathbf{i}\{f(t)\}. \quad (4.105)$$

From (4.95), the Fourier transform of the analytic signal, denoted $F_a(\nu)$, is given by

$$F_a(\nu) = F(\nu) [1 + \operatorname{sgn}(\nu)] = \begin{cases} 2F(\nu) & \text{if } \nu > 0 \\ 0 & \text{if } \nu < 0 \end{cases}, \quad (4.106)$$

and therefore $f_a(t)$ itself is given by

$$f_a(t) = 2 \int_0^{\infty} d\nu F(\nu) \exp(2\pi i\nu t). \quad (4.107)$$

An operational way to get the analytic signal is thus to take the Fourier transform of the original real signal, set negative-frequency components to zero, multiply the positive-frequency components by two, and inverse transform.

As an example, consider the single-frequency signal $f(t) = \cos(2\pi\nu_0 t)$. Since $F(\nu) = \frac{1}{2}\delta(\nu - \nu_0) + \frac{1}{2}\delta(\nu + \nu_0)$ for this signal, we find that $F_a(\nu) = \delta(\nu - \nu_0)$. Thus the analytic signal in this case is the expected $\exp(2\pi i\nu_0 t)$. The same result follows from the observation that $\mathcal{H}\mathbf{i}\{\cos(2\pi\nu_0 t)\} = -\sin(2\pi\nu_0 t)$.

4.2.5 Higher-order Hankel transforms

We encountered the zeroth-order Hankel transform in Sec. 3.4.4, where we saw that it was also the 2D Fourier transform for rotationally symmetric functions. Higher-order Hankel transforms are also important in some imaging applications. The n^{th} -order Hankel transform of a 1D function $f(x)$ is defined by

$$F_{Hn}(\rho) = \mathcal{H}_n\{f(x)\} = 2\pi \int_0^\infty x dx J_n(2\pi\rho x) f(x), \quad (4.108)$$

where $J_n(\cdot)$ is the n^{th} -order Bessel function of the first kind. The inverse transform is

$$f(x) = \mathcal{H}_n^{-1}\{F_{Hn}(\rho)\} = 2\pi \int_0^\infty \rho d\rho J_n(2\pi\rho x) F_{Hn}(\rho). \quad (4.109)$$

Thus, for any order, the Hankel transform is its own inverse.

To see how higher-order Hankel transforms can arise in 2D imaging problems, consider the Fourier transform of $f^{(p)}(r, \theta)$ as given by (4.39). The derivation of this transform in polar coordinates parallels the derivation of (3.248). From (3.246) and (4.39), we find

$$\mathcal{F}_2\{f^{(p)}(r, \theta)\} = \sum_{n=-\infty}^{\infty} \int_0^\infty r dr f_n(r) \int_0^{2\pi} d\theta \exp[-2\pi i \rho r \cos(\theta - \theta_\rho)] \exp(in\theta). \quad (4.110)$$

From (3.247) and a bit of algebra, the θ -integral is given by

$$\int_0^{2\pi} d\theta \exp[-2\pi i \rho r \cos(\theta - \theta_\rho)] \exp(in\theta) = 2\pi i^n J_n(2\pi\rho r) \exp(in\theta_\rho). \quad (4.111)$$

Thus

$$\mathcal{F}_2\{f^{(p)}(r, \theta)\} = \sum_{n=-\infty}^{\infty} i^n F_{Hn}(\rho) \exp(in\theta_\rho) = \sum_{n=-\infty}^{\infty} i^n \mathcal{H}_n\{f_n(r)\} \exp(in\theta_\rho). \quad (4.112)$$

This expansion has the form of an angular Fourier series, but with the angular variable θ_ρ itself being a variable in Fourier space. The Fourier coefficient associated with this variable, is i^n times the n^{th} -order Hankel transform of the original radial Fourier coefficient $f_n(r)$. In other words, if we represent both a 2D function and its 2D Fourier transform by angular Fourier series, then the two sets of coefficients are related by Hankel transforms of appropriate order.

4.3 FRESNEL INTEGRALS AND TRANSFORMS

In Sec. 3.3.7 we introduced the quadratic phase factor $\exp(i\pi\beta x^2)$ as a Gaussian function with a complex argument. Another name for a quadratic phase factor is *chirp*; the reason for this designation will be seen in the next chapter. In Chap. 9 we shall encounter the same function in Fresnel diffraction theory, where it is an approximate description of a spherical wave. Here we explore two topics related to chirps: special functions called *Fresnel integrals* and an integral transform called the *Fresnel transform*.

4.3.1 Fresnel integrals

The complex Fresnel integral $Z(x)$ is defined as the integral of a chirp:

$$Z(x) = \int_0^x dt \exp\left(i\frac{\pi}{2}t^2\right). \quad (4.113)$$

Related functions, also called Fresnel integrals, are defined by

$$C(x) = \int_0^x dt \cos\left(\frac{\pi}{2}t^2\right), \quad (4.114a)$$

$$S(x) = \int_0^x dt \sin\left(\frac{\pi}{2}t^2\right). \quad (4.114b)$$

If x is real, $C(x)$ and $S(x)$ are, respectively, the real and imaginary parts of $Z(x)$. These functions are plotted vs. x in Fig. 4.4, and $C(x)$ is plotted vs. $S(x)$ in Fig. 4.5, a plot known as a *Cornu spiral*. Note that $C(0) = S(0) = 0$, and $C(\pm\infty) = S(\pm\infty) = \pm\frac{1}{2}$. Perhaps surprisingly, both $C(x)$ and $S(x)$ are odd functions.

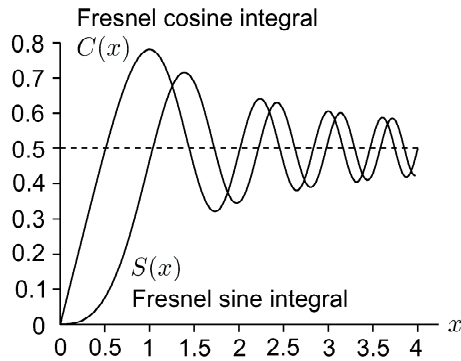

Fig. 4.4 Plots of the Fresnel integrals $C(x)$ and $S(x)$.

Fig. 4.5 The Cornu spiral, a plot of $C(x)$ vs. $S(x)$.

Fourier transform of a chirp segment As an illustration of the use of Fresnel integrals, we now compute the Fourier transform of a finite segment of a chirp:

$$f(x) = \begin{cases} \exp(i\pi\beta x^2) & \text{if } L_1 < x < L_2 \\ 0 & \text{otherwise} \end{cases}. \quad (4.115)$$

The Fourier transform of this function is given by

$$F(\xi) = \int_{L_1}^{L_2} dx \exp(i\pi\beta x^2 - 2\pi i\xi x). \quad (4.116)$$

To evaluate this integral, we complete the square by requiring

$$\pi\beta x^2 - 2\pi\xi x = \frac{\pi}{2}[(t - t_0)^2 - t_0^2], \quad (4.117)$$

which is achieved if

$$t = \sqrt{2\beta}x, \quad t_0 = \sqrt{2/\beta}\xi. \quad (4.118)$$

With these substitutions,

$$F(\xi) = \frac{1}{\sqrt{2\beta}} \exp\left[-i\frac{\pi}{2}t_0^2\right] \int_{\sqrt{2\beta}L_1}^{\sqrt{2\beta}L_2} dt \exp\left[i\frac{\pi}{2}(t - t_0)^2\right]. \quad (4.119)$$

From the definition of the complex Fresnel integral, we find

$$F(\xi) = \frac{1}{\sqrt{2\beta}} \exp(-i\pi\xi^2/\beta) \left[Z\left(\sqrt{2\beta}L_2 - \sqrt{2/\beta}\xi\right) - Z\left(\sqrt{2\beta}L_1 - \sqrt{2/\beta}\xi\right) \right]. \quad (4.120)$$

If we let $L_1 \rightarrow -\infty$ and $L_2 \rightarrow \infty$, then, since $Z(\pm\infty) = \pm\frac{1}{2}(1+i) = \pm\sqrt{i}/2$,

$$F(\xi) \rightarrow \sqrt{i/\beta} \exp(-i\pi\xi^2/\beta), \quad (L_1, L_2) \rightarrow (-\infty, \infty), \quad (4.121)$$

which is exactly the expression (3.185) for the Fourier transform of an infinite chirp.

4.3.2 Fresnel transforms

One use of a chirp is as the kernel in a little-known integral transform, the Fresnel transform (Gori, 1994). As we shall see in Chap. 9, many diffraction problems can be formulated as Fresnel transforms.

The Fresnel transform associated with a chirp of rate β is defined as

$$F_\beta(x) = [\mathcal{F}r_\beta\{f\}](x) = \sqrt{-i\beta} \int_{-\infty}^{\infty} dx' f(x') \exp[i\pi\beta(x - x')^2]. \quad (4.122)$$

Different values of β lead to different functions $F_\beta(x)$, so the operator $\mathcal{F}r_\beta$ actually refers to a whole family of transforms. When we revisit Fresnel transforms in the context of diffraction, we shall see that the parameter β indexes different planes in which the diffraction pattern can be observed.

Since the integral in (4.122) is a convolution, we can find the form for the inverse Fresnel transform by taking *Fourier* transforms of both sides. With (4.121), the result is

$$\mathcal{F}_1\{F_\beta(x)\} = \exp(-i\pi\xi^2/\beta)F(\xi). \quad (4.123)$$

Since the chirp on the right never goes to zero, we can divide through with impunity and obtain

$$F(\xi) = \mathcal{F}_1\{F_\beta(x)\} \exp(+i\pi\xi^2/\beta). \quad (4.124)$$

An inverse Fourier transform yields

$$f(x) = \sqrt{i\beta} \int_{-\infty}^{\infty} dx' F_\beta(x') \exp[-i\pi\beta(x-x')^2] = [\mathcal{F}r_\beta^{-1}\{F_\beta\}](x). \quad (4.125)$$

Thus the inverse Fresnel transform for parameter β is the same as the forward Fresnel transform with parameter $-\beta$. In operator form,

$$\mathcal{F}r_\beta^{-1} = \mathcal{F}r_{-\beta}. \quad (4.126)$$

When we apply this transform to diffraction, reversal of the sign of β will imply propagation of the wave in the opposite direction.

Some useful properties of the Fresnel transform are listed below. For more details, see Gori (1994) or Papoulis (1994).

Convolution Since Fresnel transformation is a convolution, and convolution is associative, it follows that

$$\mathcal{F}r_\beta\{f(x) * p(x)\} = F_\beta(x) * p(x) = f(x) * P_\beta(x). \quad (4.127)$$

Derivatives Differentiation commutes with Fresnel transformation. That is,

$$\mathcal{F}r_\beta\{f'(x)\} = \frac{d}{dx}F_\beta(x), \quad (4.128)$$

which can be proved by differentiating under the integral sign in (4.122), recognizing that

$$\frac{d}{dx} \exp[i\pi\beta(x-x')^2] = -\frac{d}{dx'} \exp[i\pi\beta(x-x')^2], \quad (4.129)$$

and then performing an integration by parts.

Shifting and scaling Shifting and scaling of a function have a very simple effect on its Fourier transform; the situation is not quite so neat with the Fresnel transform. The scaling relation is (Gori, 1994):

$$\mathcal{F}r_\beta\{f(x/k)\} = F_{\beta k^2}(x/k). \quad (4.130)$$

Thus scaling changes only the parameter β in the Fresnel transform, leaving the argument unchanged.

The shift relation is

$$\mathcal{F}r_\beta\{f(x - k/2\pi\beta)\} = \exp(ik^2/4\pi\beta - ikx) \mathcal{F}r_\beta\{f(x) \exp(ikx)\}. \quad (4.131)$$

Correlation invariance The correlation operation is defined in (3.115). Since the Fourier transform of $[f \star p^*](x)$ is just $F(\xi)P^*(\xi)$ [cf. (3.135)], it follows from (4.123) that

$$\mathcal{F}r_\beta\{[f \star p^*](x)\} = [F_\beta \star P_\beta^*](x). \quad (4.132)$$

Thus the Fresnel transform of the complex cross-correlation of two functions is the same as the complex cross-correlation of their Fresnel transforms.

Parseval's relations Since Fresnel transformation is simply multiplication by a pure phase factor in the Fourier domain [see (4.123)], it is a unitary transformation. Since unitary transformations preserve norms and scalar products, we have

$$\int_{-\infty}^{\infty} dx |f(x)|^2 = \int_{-\infty}^{\infty} dx |F_{\beta}(x)|^2, \quad (4.133)$$

$$\int_{-\infty}^{\infty} dx f^*(x)p(x) = \int_{-\infty}^{\infty} dx F_{\beta}^*(x)P_{\beta}(x). \quad (4.134)$$

Fresnel transform of a constant Suppose $f(x) = C$, a constant. Then

$$F_{\beta}(x) = \sqrt{-i\beta} \int_{-\infty}^{\infty} dx' C \exp[i\pi\beta(x-x')^2] = C, \quad (4.135)$$

where the last step follows from (4.121) and the central-ordinate theorem, (3.104). Thus a constant is invariant to Fresnel transformation.

Special functions Gori (1994) gives expressions for Fresnel transforms of sgn, step, rect, cos, delta, comb and Hermite-Gauss functions. The Fresnel transforms of sgn, step and rect functions are all expressible in terms of Fresnel integrals. The cosine turns out to be an eigenfunction of the Fresnel transform:

$$\mathcal{F}r_{\beta}\{\cos(Kx + \phi)\} = \exp(iK^2/4\pi\beta) \cos(Kx + \phi). \quad (4.136)$$

This result follows immediately from (3.153) and (4.123).

The Fresnel transform of a single delta function is easy, but that of a comb is surprisingly subtle; see Gori (1994) for details.

Hermite-Gauss functions transform into different Hermite-Gauss functions with complex arguments, a property that has some use in discussing Gaussian laser beams (Siegman, 1986).

4.3.3 Chirps and Fourier transforms

Though chirps are most naturally associated with *Fresnel* transforms, they can also be used to perform *Fourier* transforms. Given a function $f(x)$, consider the following sequence of operations:

- (a) Multiply $f(x)$ by a chirp, $\exp(-i\pi\beta x^2)$;
- (b) Convolve with the conjugate chirp, $\exp(i\pi\beta x^2)$;
- (c) Multiply again by the original chirp, $\exp(-i\pi\beta x^2)$.

This sequence results in the Fourier transform of $f(x)$, as we now demonstrate. Simply writing out the three steps gives

$$\begin{aligned} & \exp(-i\pi\beta x^2) \{ [f(x) \exp(-i\pi\beta x^2)] * \exp(i\pi\beta x^2) \} \\ &= \exp(-i\pi\beta x^2) \int_{-\infty}^{\infty} dx' f(x') \exp(-i\pi\beta x'^2) \exp[i\pi\beta(x-x')^2] \\ &= \int_{-\infty}^{\infty} dx' f(x') \exp(-2\pi i\beta x x') = F(\beta x). \end{aligned} \quad (4.137)$$

Thus the result of the three steps, though a function of x , is precisely the Fourier transform of $f(x)$, but evaluated at $\xi = \beta x$. As we shall see in Sec. 5.1, frequency ξ and position x are always linearly related for chirps.

The three steps listed above are often referred to as the *chirp-transform algorithm*, but this designation risks confusion with a Fresnel transform. A more precise (though somewhat awkward) term is *chirp-Fourier transform*. Even this term is ambiguous, however, since there is another algorithm that uses chirps to obtain a Fourier transform. We can also perform the following steps:

- (a) Convolve $f(x)$ with a chirp, $\exp(i\pi\beta x^2)$;
- (b) Multiply by the conjugate chirp, $\exp(-i\pi\beta x^2)$;
- (c) Convolve again with the original chirp, $\exp(i\pi\beta x^2)$.

Again the result is $F(\beta x)$, though the proof is somewhat more complicated since two integrals are involved. If it is necessary to distinguish these two chirp-Fourier algorithms, the first can be called the MCM algorithm (for multiply-convolve-multiply) and the second CMC (for convolve-multiply-convolve).

A discrete version of the chirp-Fourier transform leads to the chirp- z transform, an implementation of the z -transform (see Sec. 4.2.3) by means of discrete convolutions with sampled chirps.

Fourier implementation of the Fresnel transform We have just seen that chirps can be used to perform a Fourier transform. It is also possible to go in the other direction and use Fourier transforms to perform a Fresnel transform, or convolution with a chirp.

The defining integral for the Fresnel transform, (4.122), can be rewritten as

$$F_\beta(x) = \sqrt{-i\beta} \exp(i\pi\beta x^2) \int_{-\infty}^{\infty} dx' \{f(x') \exp(i\pi\beta x'^2)\} \exp(-2i\pi\beta x x'). \quad (4.138)$$

The integral can now be recognized as the Fourier transform of the quantity in $\{\}$, with the role of spatial frequency ξ played by βx . The Fresnel transform of $f(x)$ can thus be calculated by the following algorithm:

- (a) Multiply $f(x)$ by a chirp $\exp(i\pi\beta x^2)$;
- (b) Compute the Fourier transform of the product;
- (c) Evaluate the Fourier transform at $\xi = \beta x$;
- (d) Multiply again by $\exp(i\pi\beta x^2)$;
- (e) Multiply by $\sqrt{-i\beta}$.

This approach, though mathematically equivalent to (4.122), has practical implications since the Fourier transform can be performed efficiently with the FFT algorithm.

4.4 RADON TRANSFORM

In 1917, the Austrian mathematician Johann Radon published a classic paper (Radon, 1917) on the reconstruction of a multidimensional function from its integrals over lower-dimensional manifolds. In imaging applications, the concern is usually with a function $f(\mathbf{r})$ defined on a 2D plane, so the manifolds are lines. A continuous set of integrals of $f(\mathbf{r})$ over all parallel lines in a specified direction is called a 1D projection of the 2D function, and the 2D *Radon transform* is the set of 1D projections for all projection directions. This mathematical construct is often used as an idealized description of tomographic imaging systems that collect 1D data from 2D objects. Reconstruction of some representation of the object from a sequence of such measurements is called *reconstruction from projections* or *tomographic reconstruction*. A useful starting point for developing tomographic reconstruction algorithms is the *inverse Radon transform*.

In this section we shall introduce the basic mathematics of the Radon transform and its inverse, postponing until Chaps. 15 and 17 the connection between this theory and real tomographic imaging systems. The notation and approach used here follow Barrett (1984), to which the reader is referred for more details. A more comprehensive discussion at a similar level is given by Deans (1983), and advanced mathematical treatments are given by Helgason (1980) and Natterer (1986).

4.4.1 2D Radon transform and its adjoint

The 2D Radon transform is an integral transform in which the kernel is a line mass as introduced in Sec. 2.4.4. Specifically, if the equation of the line is $\mathbf{r} \cdot \hat{\mathbf{n}} = p$, where $\hat{\mathbf{n}}$ is a unit vector making angle ϕ to the x -axis (see Fig. 2.7), then the line integral is defined by (2.133) as

$$\lambda(p, \phi) = \int_{-\infty}^{\infty} d^2r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}). \quad (4.139)$$

Alternative expressions for $\lambda(p, \phi)$ in rotated coordinate systems are given in (2.133). The set $\lambda(p, \phi)$ for fixed ϕ and all p is the 1D projection of $f(\mathbf{r})$ in direction ϕ , and the set of $\lambda(p, \phi)$ for all p and ϕ is the 2D Radon transform of $f(\mathbf{r})$.

Equation (4.139) can be written in operator form as

$$\lambda(p, \phi) = \mathcal{R}_2\{f(\mathbf{r})\}, \quad (4.140)$$

where \mathcal{R}_2 is the 2D Radon-transform operator as defined in (4.139).

Norms and scalar products in Radon space The Radon operator \mathcal{R}_2 maps the function $f(\mathbf{r})$, or $f(x, y)$, to another function $\lambda(p, \phi)$. If we restrict $f(\mathbf{r})$ to be square-, the domain of \mathcal{R}_2 is $\mathbb{L}_2(\mathbb{R}^2)$. It is necessary, however, to impose certain smoothness or differentiability conditions on $f(\mathbf{r})$ to avoid mathematical difficulties. It suffices to assume that $f(\mathbf{r})$ is a good function as defined in Sec. 2.1.2 (see, *e.g.*, Natterer, 1986). Since any \mathbb{L}_2 function can be approximated arbitrarily closely with a good function, however, there is not much loss of rigor in considering the object space to be $\mathbb{L}_2(\mathbb{R}^2)$.

The range of \mathcal{R}_2 is usually called *Radon space*, but we need to define the characteristics of this space more carefully. All Hilbert spaces are defined in terms

of scalar products. One natural way to define Radon space would be to use p and ϕ as polar coordinates of a vector \mathbf{p} , with area element $d^2p = p dp d\phi$, and to use integrals over area to define norms and scalar products. As we shall see below, however, it is more convenient to treat ϕ as a Cartesian coordinate for this purpose. Thus we define the norm of $\lambda(p, \phi)$ by

$$\|\boldsymbol{\lambda}\|^2 = \int_0^\pi d\phi \int_{-\infty}^\infty dp |\lambda(p, \phi)|^2. \tag{4.141}$$

The function $\lambda(p, \phi)$ constitutes a vector $\boldsymbol{\lambda}$ in Radon space if this norm is finite.

Scalar products are defined similarly:

$$(\boldsymbol{\lambda}_1, \boldsymbol{\lambda}_2) = \int_0^\pi d\phi \int_{-\infty}^\infty dp \lambda_1^*(p, \phi) \lambda_2(p, \phi). \tag{4.142}$$

Having defined the Hilbert spaces, we can now write (4.140) more abstractly as

$$\boldsymbol{\lambda} = \mathcal{R}_2 \mathbf{f}. \tag{4.143}$$

Adjoint From Sec. 1.3.5, we know how to compute the adjoint of an integral operator. Since the kernel of the Radon operator is real, we can write

$$\left[\mathcal{R}_2^\dagger \boldsymbol{\lambda} \right] (\mathbf{r}) = \int_0^\pi d\phi \int_{-\infty}^\infty dp \lambda(p, \phi) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}). \tag{4.144}$$

The integral over p is easily performed, and we have

$$\left[\mathcal{R}_2^\dagger \boldsymbol{\lambda} \right] (\mathbf{r}) = \int_0^\pi d\phi \lambda(\mathbf{r} \cdot \hat{\mathbf{n}}, \phi). \tag{4.145}$$

The substitution $p \rightarrow \mathbf{r} \cdot \hat{\mathbf{n}}$ converts each 1D function of p into a 2D function. As illustrated in Fig. 4.6, this function is defined for all \mathbf{r} , but it varies only along the direction parallel to $\hat{\mathbf{n}}$. Since the original projection direction was perpendicular to $\hat{\mathbf{n}}$, the function is smeared out in the projection direction by the substitution. For this reason, the operation $p \rightarrow \mathbf{r} \cdot \hat{\mathbf{n}}$ is called *backprojection*. The adjoint operation is then equivalent to backprojecting each 1D projection and integrating the result over all projection directions. Geometrically, the 2D Radon transform integrates over all points along a line, and its adjoint integrates over all lines passing through a point (Natterer, 1986).

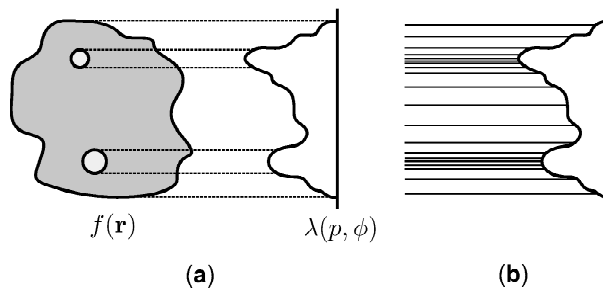

Fig. 4.6 Illustration of the operation of backprojection. (a) A 2D object and one of its 1D projections. (b) Backprojection of the 1D projection into the 2D space. (The density of lines in the backprojection suggests a gray scale).

We can now see why it was more convenient to define the scalar product with $dp d\phi$ rather than $p dp d\phi$; with the latter form, we would have had a factor of $\mathbf{r} \cdot \hat{\mathbf{n}}$ in the definition of backprojection.

Sinogram Since the definition of adjoint treats ϕ as a Cartesian coordinate rather than a polar one, it is useful to plot projection data in this way. A gray-level image of $[\mathcal{R}_2 \mathbf{f}](p, \phi)$ with p and ϕ as the axes is known as a *sinogram* (see Fig. 4.7).

To understand the structure of a sinogram, consider first an object consisting of a single point, $f^\delta(\mathbf{r}) = \delta(\mathbf{r} - \mathbf{r}_0)$. The Radon transform of this object is

$$[\mathcal{R}_2 \mathbf{f}^\delta](p, \phi) = \int_{-\infty}^{\infty} d^2r \delta(\mathbf{r} - \mathbf{r}_0) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) = \delta(p - r_0 \cos(\theta_0 - \phi)). \quad (4.146)$$

Not surprisingly, the 1D projection of a 2D delta function is a 1D delta function. Explicitly, in terms of the p and ϕ coordinates,

$$[\mathcal{R}_2 \mathbf{f}^\delta](p, \phi) = \delta[p - r_0 \cos(\theta_0 - \phi)], \quad (4.147)$$

where r_0 and θ_0 are the polar coordinates of \mathbf{r}_0 .

If we plot this delta function as a function of p for fixed ϕ , we see a spike at $p = r_0 \cos(\theta_0 - \phi)$. If we also vary ϕ , the spike moves along the p axis in a cosinusoidal fashion (see Fig. 4.7b). The amplitude of the cosine is the radial coordinate r_0 , and the phase is the polar angle θ_0 .

Fig. 4.7 The sinogram format, in which $\lambda(p, \phi)$ is plotted against Cartesian coordinates p and ϕ . (a) An object consisting of a single point at $\mathbf{r} = \mathbf{r}_0$. (b) Sinogram depiction of the projection data from the single-point object.

Since the Radon transform is linear, the sinogram of a more general object can be constructed by linear superposition. If we express an object as

$$f(\mathbf{r}) = \int_{\infty} d^2r_0 f(\mathbf{r}_0) \delta(\mathbf{r} - \mathbf{r}_0), \quad (4.148)$$

then its Radon transform is given by

$$[\mathcal{R}_2\mathbf{f}](p, \phi) = \int_{\infty} d^2r_0 f(\mathbf{r}_0) \delta[p - r_0 \cos(\theta_0 - \phi)]. \quad (4.149)$$

The sinogram is thus the superposition of cosinusoidal patterns of the form (4.147) with the gray level of the cosine of amplitude r_0 and phase θ_0 determined by $f(\mathbf{r}_0)$.

4.4.2 Central-slice theorem

To see what information about $f(\mathbf{r})$ is contained in a single 1D projection, we can take the 1D Fourier transform (with respect to p) of $\lambda(p, \phi)$. From (4.139), we find

$$\begin{aligned} \Lambda(\nu, \phi) &= [\mathcal{F}_1\lambda(p, \phi)](\nu) = \int_{-\infty}^{\infty} dp \exp(-2\pi i\nu p) \int_{\infty} d^2r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) \\ &= \int_{\infty} d^2r f(\mathbf{r}) \int_{-\infty}^{\infty} dp \exp(-2\pi i\nu p) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) = \int_{\infty} d^2r f(\mathbf{r}) \exp(-2\pi i\mathbf{r} \cdot \hat{\mathbf{n}}\nu). \end{aligned} \quad (4.150)$$

The remaining integral is recognized as the 2D Fourier transform, but with the vector $\hat{\mathbf{n}}\nu$ appearing in place of the usual spatial frequency $\boldsymbol{\rho}$. Since $\hat{\mathbf{n}}$ is fixed once we have chosen the particular 1D projection $\lambda(p, \phi)$, the points in the frequency plane for which $\boldsymbol{\rho} = \hat{\mathbf{n}}\nu$ describe a line passing through the origin. For this reason, (4.150) is called the *central-slice theorem*. In words, the 1D Fourier transform of the projection $\lambda(p, \phi)$ is equal to the 2D transform of the original function $f(\mathbf{r})$ evaluated along a line through the origin of the Fourier plane. This relation is illustrated in Fig. 4.8.

Fig. 4.8 Illustration of the central-slice theorem. A symmetric 2D function is shown so that its Fourier transform is real.

We can also express the central-slice theorem in operator form as

$$\mathcal{F}_2 = \mathcal{F}_1 \mathcal{R}_2. \quad (4.151)$$

Applied to any 2D function $f(\mathbf{r})$, this relation says that forming a 1D projection and then taking the 1D Fourier transform is equivalent to taking the 2D Fourier transform. In interpreting the operators, however, we must keep in mind the need to evaluate the 2D transform at $\boldsymbol{\rho} = \hat{\mathbf{n}}\nu$.

One consequence of the central-slice theorem is that the Radon transform is invertible if 1D projection data are collected for $0 \leq \phi < \pi$ since all points in the frequency plane are reached by ϕ in this range and $-\infty < \nu < \infty$.

Moreover, projections with $\pi \leq \phi < 2\pi$ are redundant with those with $0 \leq \phi < \pi$ since projections at ϕ and $\phi + \pi$ give information on the same line in the Fourier plane. We can reach this same conclusion by noting that $\phi \rightarrow \phi + \pi$ is equivalent to $\hat{\mathbf{n}} \rightarrow -\hat{\mathbf{n}}$. The delta function in (4.139) is unchanged if $p - \mathbf{r} \cdot \hat{\mathbf{n}} \rightarrow -p + \mathbf{r} \cdot \hat{\mathbf{n}}$, so

$$\lambda(p, \phi) = \lambda(-p, \phi + \pi). \quad (4.152)$$

Thus we can always recover $f(\mathbf{r})$ if we know $\lambda(p, \phi)$ for $-\infty < p < \infty$ and ϕ in any interval of length π .

If $f(\mathbf{r})$ has finite support, we need even less data. If $f(\mathbf{r}) = 0$ for $r > \mathbb{R}_{max}$, then $\lambda(p, \phi) = 0$ for $|p| > \mathbb{R}_{max}$. We do not need to collect projections for which the line of integration does not intersect the object.

4.4.3 Filtered backprojection

One route to the inverse Radon transform starts with the operator relation (4.151). Turning that relation around, we can express the Radon transform as

$$\mathcal{R}_2 = \mathcal{F}_1^{-1} \mathcal{F}_2. \quad (4.153)$$

Thus the inverse is, formally,

$$\mathcal{R}_2^{-1} = \mathcal{F}_2^{-1} \mathcal{F}_1. \quad (4.154)$$

Implicit in this relation is the identification of $\boldsymbol{\rho}$ with $\hat{\mathbf{n}}\nu$, so it is necessary to express the integral over $\boldsymbol{\rho}$ in \mathcal{F}_2^{-1} in terms of ν and ϕ . We could write $d^2\rho = \nu d\nu d\phi$ and integrate over $0 \leq \phi < 2\pi$ and $0 \leq \nu < \infty$, but we will usually know $\lambda(p, \phi)$ only for $0 \leq \phi < \pi$. Fortunately, this suffices to give $\Lambda(\nu, \phi)$ for $-\infty < \nu < \infty$, so it is much more convenient to integrate over $0 \leq \phi < \pi$ and $-\infty \leq \nu < \infty$. When we do so, we must write $d^2\rho = |\nu| d\nu d\phi$ since the area element must be positive. Thus,

$$\begin{aligned} [\mathcal{F}_2^{-1} \mathcal{F}_1 \boldsymbol{\lambda}](\mathbf{r}) &= \int_0^\pi d\phi \int_{-\infty}^\infty |\nu| d\nu \exp(2\pi i \mathbf{r} \cdot \hat{\mathbf{n}}\nu) \int_{-\infty}^\infty dp \lambda(p, \phi) \exp(-2\pi i \nu p) \\ &= \int_0^\pi d\phi \int_{-\infty}^\infty d\nu \exp(2\pi i \mathbf{r} \cdot \hat{\mathbf{n}}\nu) |\nu| \Lambda(\nu, \phi). \end{aligned} \quad (4.155)$$

The integral over ν can be regarded as the inverse Fourier transform of the product $|\nu| \Lambda(\nu, \phi)$. This transform would normally yield a function of p , but we see that $\mathbf{r} \cdot \hat{\mathbf{n}}$ appears where p should be, so we can write

$$\int_{-\infty}^\infty d\nu \exp(2\pi i \mathbf{r} \cdot \hat{\mathbf{n}}\nu) |\nu| \Lambda(\nu, \phi) = \hat{\lambda}(\mathbf{r} \cdot \hat{\mathbf{n}}, \phi), \quad (4.156)$$

where $\hat{\lambda}(p, \phi)$ is a filtered version of $\lambda(p, \phi)$, with the filtering operation expressed in the 1D frequency domain as multiplication by $|\nu|$. For later convenience, we define

$$H(\nu) = |\nu|. \quad (4.157)$$

Putting the pieces together, we now have one form of the inverse Radon transform:

$$f(\mathbf{r}) = [\mathcal{R}_2^{-1}\boldsymbol{\lambda}](\mathbf{r}) = \int_0^\pi d\phi \hat{\lambda}(\mathbf{r} \cdot \hat{\mathbf{n}}, \phi). \quad (4.158)$$

Thus, one recovers $f(\mathbf{r})$ by filtering each projection (multiplying it by $H(\nu)$ in the 1D frequency domain), backprojecting the result and integrating over all projection angles. A discretized version of this inverse, known as *filtered backprojection*, is used in almost all commercial tomographic instruments at this writing.

Alternative form A shift-invariant filtering operation can be specified either as a multiplication in the frequency domain or as a convolution in the space domain. Thus the filtering operation of (4.158) can be written as a convolution of $\lambda(p, \phi)$ with the inverse Fourier transform of $H(\nu)$, which we denote by $h(p)$. The shift variable in the convolution is given by $\mathbf{r} \cdot \hat{\mathbf{n}}$, so we can write

$$\begin{aligned} f(\mathbf{r}) &= \int_0^\pi d\phi \left[\int_{-\infty}^\infty dp' \lambda(p', \phi) h(p - p') \right]_{p=\mathbf{r} \cdot \hat{\mathbf{n}}} \\ &= \int_0^\pi d\phi \int_{-\infty}^\infty dp' \lambda(p', \phi) h(\mathbf{r} \cdot \hat{\mathbf{n}} - p'). \end{aligned} \quad (4.159)$$

We know the functional form of $h(p)$ from Sec. 3.3.7. In particular, from (3.169) with $m = 2$, we see that

$$-\frac{1}{2\pi^2} \mathcal{F}_1 \left\{ \frac{1}{p^2} \right\} = \nu \operatorname{sgn}(\nu) = |\nu|, \quad (4.160)$$

where $1/p^2$ is the rather bizarre generalized function⁴ discussed in Sec. 2.3.3.

Combining (4.159) and (4.160) yields another form for the inverse Radon transform:

$$f(\mathbf{r}) = -\frac{1}{2\pi^2} \int_0^\pi d\phi \int_{-\infty}^\infty dp' \frac{\lambda(p', \phi)}{(\mathbf{r} \cdot \hat{\mathbf{n}} - p')^2}. \quad (4.161)$$

The structure of this result may be surprising; if $f(\mathbf{r})$ is nonnegative, as it is in most tomographic problems, then $\lambda(p, \phi)$ is also nonnegative, so the integrand appears to be nonnegative everywhere. There is an overall minus sign in front of the integral, yet the right-hand side of (4.161) is supposed to equal the nonnegative function $f(\mathbf{r})$. To resolve this paradox, recall from Sec. 2.3.3 that the generalized function $1/p^2$ has a strong negative singularity at the origin (see (2.91) and the discussion in that vicinity, esp. Fig. 2.6b). Because of this singularity, the integral is in fact negative.

⁴Strictly speaking, $\lambda(p', \phi)$ must be a good function (see Sec. 2.1.2) for this generalized function to be defined, so we are dealing with a Schwartz space rather than the more general L_2 space. As we noted in Sec. 2.1.3, however, L_2 functions can be approximated arbitrarily closely by good functions.

4.4.4 Unfiltered backprojection

It is instructive to see what happens if we leave out the filtering operation in the filtered-backprojection algorithm. Since backprojection plus integration over ϕ is the same as \mathcal{R}_2^\dagger , we wish to compute

$$\left[\mathcal{R}_2^\dagger \lambda\right](\mathbf{r}) = \left[\mathcal{R}_2^\dagger \mathcal{R}_2 \mathbf{f}\right](\mathbf{r}). \quad (4.162)$$

If we can find a simple form for $\mathcal{R}_2^\dagger \mathcal{R}_2$, we may be able to construct \mathcal{R}_2^{-1} as

$$\mathcal{R}_2^{-1} = \left[\mathcal{R}_2^\dagger \mathcal{R}_2\right]^{-1} \mathcal{R}_2^\dagger. \quad (4.163)$$

The alert reader will recognize (4.162) as the normal equation developed in Sec. 1.7.4 in the context of least-squares solutions of noisy, inconsistent equations and singular operators. Here, however, we are ignoring noise, and we argued in Sec. 4.4.2 that \mathcal{R}_2 is nonsingular if we know $\lambda(p, \phi)$ for all p and an angular range of π . Therefore (4.163) is just an identity which may provide another form of \mathcal{R}_2^{-1} .

To compute $\mathcal{R}_2^\dagger \mathcal{R}_2 \mathbf{f}$ explicitly, we combine (4.139) and (4.145), yielding

$$\left[\mathcal{R}_2^\dagger \mathcal{R}_2 \mathbf{f}\right](\mathbf{r}) = \int_0^\pi d\phi \int_\infty^\infty d^2 r' f(\mathbf{r}') \delta(\mathbf{r} \cdot \hat{\mathbf{n}} - \mathbf{r}' \cdot \hat{\mathbf{n}}). \quad (4.164)$$

To simplify the integral over ϕ , we define a vector $\mathbf{R} = \mathbf{r} - \mathbf{r}'$ and express it in polar coordinates as (R, θ_R) , where $R = |\mathbf{r} - \mathbf{r}'|$. The angle between $\hat{\mathbf{n}}$ and \mathbf{R} is thus $\phi - \theta_R$, and we have

$$\left[\mathcal{R}_2^\dagger \mathcal{R}_2 \mathbf{f}\right](\mathbf{r}) = \int_\infty^\infty d^2 r' f(\mathbf{r}') \int_0^\pi d\phi \delta[R \cos(\phi - \theta_R)]. \quad (4.165)$$

We can perform the integral over ϕ with the help of (2.33), from which we know

$$\delta(R \cos \phi) = \frac{\delta(\phi - \theta_R - \frac{\pi}{2})}{|R \sin \frac{\pi}{2}|} = \frac{1}{R} \delta\left(\phi - \theta_R - \frac{\pi}{2}\right). \quad (4.166)$$

Since the argument of the delta function vanishes exactly once in $(0, \pi]$, the integral over ϕ yields

$$\left[\mathcal{R}_2^\dagger \mathcal{R}_2 \mathbf{f}\right](\mathbf{r}) = \int_\infty^\infty d^2 r' \frac{f(\mathbf{r}')}{R} = \int_\infty^\infty d^2 r' \frac{f(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}. \quad (4.167)$$

The integral in (4.167) is a convolution; even though neither \mathcal{R}_2 nor \mathcal{R}_2^\dagger describes a shift-invariant system, $\mathcal{R}_2^\dagger \mathcal{R}_2$ does. The point spread function for this operator is $1/r$, and the combined effect of Radon projection and its adjoint (unfiltered backprojection) is to convolve the object with $1/r$.

A graphical way of understanding this result is given in Fig. 4.9. Shown there is an object consisting of the single 2D delta function, $f^\delta(\mathbf{r}) = \delta(\mathbf{r} - \mathbf{r}_0)$. From (4.146) we know that the Radon transform of this object is a 1D delta function. The backprojection operation smears this 1D delta function into a line delta function: $\delta(p - \mathbf{r}_0 \cdot \hat{\mathbf{n}}) \rightarrow \delta(\mathbf{r} \cdot \hat{\mathbf{n}} - \mathbf{r}_0 \cdot \hat{\mathbf{n}})$. Though still 1D, in the sense that it can be used for only one integral, the line delta function is defined in the 2D space. Note that this line delta function passes through the original point \mathbf{r}_0 for all p and ϕ .

Fig. 4.9 Graphical explanation of the point spread function for $\mathcal{R}_2^\dagger \mathcal{R}_2$. (a) A single 2D delta function at $\mathbf{r} = \mathbf{r}_0$ and its projection at angle ϕ . (b) Back-projection of the 1D projection in (a). (c) Sum of many backprojections. This sum limits to a $1/r$ function as the number of projection angles approaches infinity.

We now bring in the integration over angles needed in the definition of \mathcal{R}_2^\dagger . If we had only a finite set of angles (as we necessarily do in any practical situation), then the integral over ϕ would be a sum, and the result would be a spoke pattern as shown in Fig. 4.9c. As the number of angles approaches infinity, the sum of line deltas becomes an integral and the spoke pattern approaches $1/|\mathbf{r} - \mathbf{r}_0|$, a cusp-like function that is singular at the original point location. We shall have more to say about finite angular sampling and the resulting PSF in Chap. 17.

If the object is more complicated than a single point, then there is a spoke pattern, or a $1/r$ pattern in the limit, associated with each object point. Because $\mathcal{R}_2^\dagger \mathcal{R}_2$ is shift invariant (if the object support is infinite), the form of this pattern is the same for each object point. The overlapping of these long-tailed point spread functions results in a considerable blurring of the object.

Deblurring Since the blurring is a simple convolution with a known blur function, it can in principle be corrected by inverse filtering in the Fourier domain. (We are, of course, neglecting practical issues like noise and discrete sampling in this section.)

To find the form of the inverse filter, we must first determine the Fourier transform of the blur function. From (3.248), we know that

$$\mathcal{F}_2 \left\{ \frac{1}{r} \right\} = 2\pi \int_0^\infty r dr J_0(2\pi\rho r) \frac{1}{r}. \quad (4.168)$$

The change of variables $u = 2\pi\rho r$ and a well-known integral yield

$$\mathcal{F}_2 \left\{ \frac{1}{r} \right\} = \frac{1}{\rho} \int_0^\infty du J_0(u) = \frac{1}{\rho}. \quad (4.169)$$

Thus blurring by convolution with $1/r$ is equivalent to multiplication with $1/\rho$ in the Fourier domain.

We can summarize what we have learned to this point by defining a multiplicative operator $\mathcal{M}_{1/\rho}$ which acts on functions in the frequency domain and multiplies their value at each point by $1/\rho$. In terms of this operator, we have

$$\mathcal{R}_2^\dagger \mathcal{R}_2 = \mathcal{F}_2^{-1} \mathcal{M}_{1/\rho} \mathcal{F}_2. \quad (4.170)$$

If we don't worry too much about the isolated point $\rho = 0$, the inverse of multiplication by $1/\rho$ is multiplication by ρ , so $\mathcal{M}_{1/\rho}^{-1} = \mathcal{M}_\rho$, and

$$\left[\mathcal{R}_2^\dagger \mathcal{R}_2 \right]^{-1} = \mathcal{F}_2^{-1} \mathcal{M}_\rho \mathcal{F}_2. \quad (4.171)$$

With (4.163), therefore, we have

$$\mathcal{R}_2^{-1} = \mathcal{F}_2^{-1} \mathcal{M}_\rho \mathcal{F}_2 \mathcal{R}_2^\dagger. \quad (4.172)$$

In words, the inverse Radon transform can be implemented by first performing an unfiltered backprojection, then transforming to the 2D Fourier domain, multiplying by the inverse filter $H(\rho) = \rho$, and inverse-transforming back to the 2D space domain.

4.4.5 Radon transform in higher dimensions

In n dimensions, the Radon transform is an integral of an n D function over a set of $(n-1)$ -dimensional hyperplanes. In particular, the 3D Radon transform is a set of integrals of a 3D function over ordinary 2D planes.

The equation of a 2D plane in a 3D space is $p = \mathbf{r} \cdot \hat{\mathbf{n}}$, which is identical in form to the equation of a line in a 2D space except that now \mathbf{r} and $\hat{\mathbf{n}}$ are 3D vectors. In fact, with appropriate interpretation of the vectors, $p = \mathbf{r} \cdot \hat{\mathbf{n}}$ is the general equation of an $(n-1)$ -dimensional hyperplane in an n D space, and the n D Radon transform is defined as

$$[\mathcal{R}_n \mathbf{f}](p, \hat{\mathbf{n}}) = \int_\infty d^n r f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}). \quad (4.173)$$

Note that the delta function here is 1D, so it can be used to perform only one of the n integrals implicit in $\int d^n r$. Also note that the unit vector $\hat{\mathbf{n}}$ is specified by $n-1$ variables in an n D space. For example, if $n = 3$, we can specify $\hat{\mathbf{n}}$ by two polar angles.

Norms, scalar products and adjoints By analogy to (4.142), we define the norm of the Radon transform of an n D function as

$$\|\boldsymbol{\lambda}\|^2 = \int_S d\Omega \int_0^\infty dp |\lambda(p, \hat{\mathbf{n}})|^2, \quad (4.174)$$

where $d\Omega$ is the element of solid angle in the n D space and the integral is over the unit sphere S . Since $\lambda(p, \hat{\mathbf{n}}) = \lambda(-p, -\hat{\mathbf{n}})$, we could equally well extend the p integral to $(-\infty, \infty)$ and integrate over half the unit sphere:

$$\|\boldsymbol{\lambda}\|^2 = \int_{\frac{1}{2}S} d\Omega \int_{-\infty}^{\infty} dp |\lambda(p, \hat{\mathbf{n}})|^2. \quad (4.175)$$

For example, if $n = 3$, $d\Omega = \sin\theta d\theta d\phi$, where θ and ϕ are the usual spherical coordinates, and the integral is over 4π steradians if $0 \leq p < \infty$ or 2π steradians if $-\infty < p < \infty$. The function $\lambda(p, \hat{\mathbf{n}})$ constitutes a vector $\boldsymbol{\lambda}$ in n D Radon space if the norm defined in (4.174) is finite.

Scalar products are defined by analogy to (4.142) as

$$(\boldsymbol{\lambda}_1, \boldsymbol{\lambda}_2) = \int_S d\Omega \int_0^{\infty} dp \lambda_1^*(p, \hat{\mathbf{n}}) \lambda_2(p, \hat{\mathbf{n}}) = \int_{\frac{1}{2}S} d\Omega \int_{-\infty}^{\infty} dp \lambda_1^*(p, \hat{\mathbf{n}}) \lambda_2(p, \hat{\mathbf{n}}). \quad (4.176)$$

Note that we use $dp d\Omega$ as the volume element here rather than $p^{n-1} dp d\Omega$. With this definition of the scalar product, the adjoint of \mathcal{R}_n is given by

$$[\mathcal{R}_n^\dagger \boldsymbol{\lambda}](\mathbf{r}) = \int_{\frac{1}{2}S} d\Omega \int_{-\infty}^{\infty} dp \lambda(p, \hat{\mathbf{n}}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) = \int_{\frac{1}{2}S} d\Omega \lambda(\mathbf{r} \cdot \hat{\mathbf{n}}, \hat{\mathbf{n}}). \quad (4.177)$$

The interpretation of this equation is analogous to that of (4.145); the substitution $p \rightarrow \mathbf{r} \cdot \hat{\mathbf{n}}$ converts each 1D function of p into an n D function by assigning the value $\lambda(p, \hat{\mathbf{n}})$ uniformly to all \mathbf{r} for which $\mathbf{r} \cdot \hat{\mathbf{n}} = p$. For $n = 3$, this means smearing it uniformly over the original plane of integration.

Central-slice theorem By taking the 1D transform of (4.173) as we did in Sec. 4.4.2, we can derive the n D central-slice theorem. By analogy to (4.150), we have

$$\begin{aligned} \Lambda(\nu, \hat{\mathbf{n}}) &= [\mathcal{F}_1 \lambda(p, \hat{\mathbf{n}})](\nu) = \int_{-\infty}^{\infty} d^n r f(\mathbf{r}) \int_{-\infty}^{\infty} dp \exp(-2\pi i \nu p) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}) \\ &= \int_{-\infty}^{\infty} d^n r f(\mathbf{r}) \exp(-2\pi i \mathbf{r} \cdot \hat{\mathbf{n}} \nu) = F(\hat{\mathbf{n}} \nu), \end{aligned} \quad (4.178)$$

where $F(\boldsymbol{\rho})$ is the n D Fourier transform of $f(\mathbf{r})$. In words, the 1D Fourier transform of the projection is the same as one line through the n D of the original function $f(\mathbf{r})$. Note that the central-slice theorem in any number of dimensions always relates to a line in n D Fourier space, not a hyperplane. In operator form, we can express the central-slice theorem as

$$\mathcal{F}_n = \mathcal{F}_1 \mathcal{R}_n. \quad (4.179)$$

In using this form, the implicit substitution $\boldsymbol{\rho} \rightarrow \hat{\mathbf{n}} \nu$ must always be kept in mind.

Inverse transform From the central-slice theorem, the formal inverse Radon transform is [cf. (4.154)]

$$\mathcal{R}_n^{-1} = \mathcal{F}_n^{-1} \mathcal{F}_1. \quad (4.180)$$

Converting the operators into explicit integrals as in Sec. 4.4.3, we find [cf. (4.155)]

$$\begin{aligned}
[\mathcal{F}_n^{-1} \mathcal{F}_1 \lambda](\mathbf{r}) &= \int_{\frac{1}{2}S} d\Omega \int_{-\infty}^{\infty} |\nu|^{n-1} d\nu \exp(2\pi i \mathbf{r} \cdot \hat{\mathbf{n}} \nu) \int_{-\infty}^{\infty} dp \lambda(p, \hat{\mathbf{n}}) \exp(-2\pi i \nu p) \\
&= \int_{\frac{1}{2}S} d\Omega \int_{-\infty}^{\infty} d\nu \exp(2\pi i \mathbf{r} \cdot \hat{\mathbf{n}} \nu) |\nu|^{n-1} \Lambda(\nu, \hat{\mathbf{n}}). \tag{4.181}
\end{aligned}$$

The integral over ν can be regarded as the inverse Fourier transform of the product $|\nu|^{n-1} \Lambda(\nu, \hat{\mathbf{n}})$, so (4.156) generalizes to

$$\int_{-\infty}^{\infty} d\nu \exp(2\pi i \mathbf{r} \cdot \hat{\mathbf{n}} \nu) |\nu|^{n-1} \Lambda(p, \hat{\mathbf{n}}) = \hat{\lambda}(\mathbf{r} \cdot \hat{\mathbf{n}}, \hat{\mathbf{n}}), \tag{4.182}$$

where again $\hat{\lambda}(p, \hat{\mathbf{n}})$ denotes a filtered version of $\lambda(p, \hat{\mathbf{n}})$. The filter function is now

$$H(\nu) = |\nu|^{n-1}, \tag{4.183}$$

but note that the absolute-value signs are unnecessary if n is odd.

Odd vs. even dimensions The filter function given in (4.183) is fundamentally different for even and odd n . If n is odd, then $H(\nu)$ is just ν^{n-1} , and we know from (3.97) that multiplying a function by $(2\pi i \nu)^k$ in the frequency domain is equivalent to differentiating it k times. Thus the 1D filtering operation before backprojection is equivalent to differentiating the projection data $n-1$ times with respect to p .

The key point is that differentiation is a local operation; to compute any derivative of the projection $\lambda(p, \hat{\mathbf{n}})$ at, say, $p = p_0$, we need to know the function only in an infinitesimal neighborhood of $p = p_0$. That means that we can reconstruct an n D function $f(\mathbf{r})$ at some point \mathbf{r}_0 knowing only its integrals over hyperplanes passing through a neighborhood of \mathbf{r}_0 , provided n is odd.

For n even, we must account for the absolute-value operation in $H(\nu)$, which greatly affects the behavior of its Fourier transform, $h(p)$. One way to think about this difference is in terms of the Hilbert transform, introduced in Sec. 4.2.4. We know from (4.95) that the Hilbert transform is equivalent to multiplying by $i \operatorname{sgn}(\nu)$ in the frequency domain, and for n even we can write

$$H(\nu) = |\nu|^{n-1} = \nu^{n-1} \operatorname{sgn}(\nu). \tag{4.184}$$

Thus, within constant factors, the 1D filtering operation can be expressed as $n-1$ derivatives compounded with a Hilbert transform. (The differentiations and Hilbert transformation can be performed in any order.) From (4.94) we know that Hilbert transformation is essentially convolution with the principal value of $1/p$. Since $1/p$ has long tails, Hilbert transformation is decidedly nonlocal. To reconstruct $f(\mathbf{r})$ at $\mathbf{r} = \mathbf{r}_0$ for n even, we need to know its integrals over all hyperplanes, not just those passing through a neighborhood of \mathbf{r}_0 .

Another way to think about this difference is in terms of the asymptotic behavior of $h(p)$ as $p \rightarrow \infty$. It follows from the Riemann-Lebesgue lemma [see (3.107)] that $p^k h(p) \rightarrow 0$ as $p \rightarrow \infty$ if $H(\nu)$ has bounded derivatives at least up to order k . For n odd, all derivatives of $H(\nu)$ are bounded, so $h(p) \rightarrow 0$ faster than p^{-k} for all k . In fact, we know that $h(p)$ is the $(n-1)^{\text{th}}$ derivative of a delta function in this case, so it is identically zero away from the neighborhood of the origin. For n even, however, the absolute-value signs spoil the differentiability. For $n=2$, for example, the first derivative of $|\nu|$ is bounded but the second is not, and we know from Sec. 4.4.3 that $h(p)$ is the generalized function $1/p^2$. This function coincides with the ordinary function $1/p^2$ for $p \neq 0$, so $p h(p) \rightarrow 0$ as $p \rightarrow \infty$, but $p^2 h(p)$ does not.

3D case If $n = 3$, then $H(\nu) = \nu^2$, and we know that multiplication by ν^2 in a 1D frequency domain is essentially the same thing as taking a second derivative [see (3.99)], which in turn is equivalent to convolving with the second derivative of a 1D delta function. Specifically, the space-domain filter function for the 3D Radon transform is

$$h(p) = \mathcal{F}_n^{-1} \{ \nu^2 \} = -\frac{1}{4\pi^2} \delta''(p). \quad (4.185)$$

Thus one form of the 3D inverse Radon transform is

$$f(\mathbf{r}) = -\frac{1}{4\pi^2} \int_{\frac{1}{2}S} d\Omega \lambda''(\mathbf{r} \cdot \hat{\mathbf{n}}, \hat{\mathbf{n}}), \quad (4.186)$$

where $\lambda''(p, \hat{\mathbf{n}})$ is the second derivative of the projection with respect to p . Reconstruction in this case is just backprojection of the second derivative of the projection.

As in 2D, it is also possible to backproject first and then filter. The reader may show that [cf. (4.167)]

$$\left[\mathcal{R}_3^\dagger \lambda \right] (\mathbf{r}) = \int_{\frac{1}{2}S} d\Omega \lambda(\mathbf{r} \cdot \hat{\mathbf{n}}, \hat{\mathbf{n}}) = \int_{\infty} d^3 r' \frac{f(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^2}. \quad (4.187)$$

It then follows from (2.143) that

$$f(\mathbf{r}) = -\frac{1}{4\pi^2} \nabla^2 \int_{\frac{1}{2}S} d\Omega \lambda(\mathbf{r} \cdot \hat{\mathbf{n}}, \hat{\mathbf{n}}). \quad (4.188)$$

Thus the 3D filter is also a second derivative, the Laplacian.

Dipole-sheet transform The dipole-sheet transform (Barrett, 1982, 1984) is a symmetrized version of the 3D Radon transform and its inverse. The asymmetry can be seen by defining a 3D vector $\mathbf{p} \equiv p \hat{\mathbf{n}}$, so that $d^3 p = p^2 dp d\Omega_{\mathbf{n}}$. With this definition, we can write the inverse 3D Radon transform, (4.186), as

$$f(\mathbf{r}) = -\frac{1}{4\pi^2} \int_{\infty} \frac{d^3 p}{p^2} [\mathcal{R}_3 \mathbf{f}](\mathbf{p}) \delta''(p - \mathbf{r} \cdot \hat{\mathbf{n}}), \quad (4.189)$$

while the forward Radon transform is

$$[\mathcal{R}_3 \mathbf{f}](\mathbf{p}) = \int_{\infty} d^3 r \mathbf{f}(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}). \quad (4.190)$$

These forms differ by the second derivative and the factor of $-1/(4\pi^2 p^2)$ in (4.189); to symmetrize, we can move one derivative and a factor of $i/(2\pi p)$ to the forward transform. We thus define the dipole-sheet operator \mathcal{D}_3 by

$$[\mathcal{D}_3 \mathbf{f}](\mathbf{p}) = \int_{\infty} d^3 r \mathbf{f}(\mathbf{r}) \psi(\mathbf{p}, \mathbf{r}), \quad (4.191)$$

where $\psi(\mathbf{p}, \mathbf{r})$ is the dipole-sheet basis function, defined by

$$\psi(\mathbf{p}, \mathbf{r}) = \frac{i}{2\pi p} \delta'(p - \mathbf{r} \cdot \hat{\mathbf{n}}). \quad (4.192)$$

The derivative of the delta function here has the same structure as the double layer of charge used to enforce boundary conditions in electrostatics (Jackson, 1998).

Regarded as a function in three dimensions, $\delta'(p - \mathbf{r} \cdot \hat{\mathbf{n}})$ vanishes except in the neighborhood of the plane $p = \mathbf{r} \cdot \hat{\mathbf{n}}$, and it can be regarded, loosely, as being $+\infty$ just to one side of this plane and $-\infty$ on the other side. If we think of $\delta(p - \mathbf{r} \cdot \hat{\mathbf{n}})$ as a distribution of charge confined to a plane, then $\delta'(p - \mathbf{r} \cdot \hat{\mathbf{n}})$ is a double layer of positive and negative charges, or a sheet of dipoles.

It follows from (4.189) and (4.190) that the dipole-sheet transform is unitary; the inverse is given by the adjoint. Many other interesting properties of the dipole-sheet transform are given in Barrett (1982, 1984). For example, the transform of any rotationally symmetric function is just a constant times that same function. In addition, as we shall see in Chap. 17, the dipole-sheet transform arises naturally in cone-beam tomography.

Related transforms in an arbitrary number of dimensions are discussed in Ludwig (1966).

4.4.6 Radon transform in signal processing

One application of the Radon transform is to reduce n D signal-processing operations to a sequence of 1D operations (Gmitro *et al.*, 1983; Barrett, 1984b). Though many different operations can be reduced in this way (Easton and Barrett, 1987), we shall confine our attention here to convolutions.

There are two mathematical theorems that make it possible to reduce n D convolutions to 1D. The first one, which follows directly from the central-slice theorem, states that

$$(\mathcal{R}_n \mathbf{f}_1) * (\mathcal{R}_n \mathbf{f}_2) = \mathcal{R}_n(\mathbf{f}_1 * \mathbf{f}_2), \quad (4.193)$$

where the asterisk on the left denotes a 1D convolution with respect to p , while the asterisk on the right denotes an n D convolution. Thus, to convolve two n D functions, one can take the n D Radon transform of each, perform 1D convolutions for every projection angle, and then perform an n D inverse Radon transform. This approach is particularly attractive for n odd because of the local character of the inverse, as discussed above.

The second theorem (Natterer, 1986) does not directly require an inverse Radon transform; it states that

$$(\mathcal{R}_n^\dagger \mathbf{h}) * \mathbf{f} = \mathcal{R}_n^\dagger[\mathbf{h} * (\mathcal{R}_n \mathbf{f})]. \quad (4.194)$$

Note that \mathbf{h} here denotes a set of 1D functions of p , one function for each projection direction. Therefore, the asterisk on the left denotes n D convolution but the one on the right denotes 1D convolution on the variable p . Proof of (4.194) requires writing the operators in integral form and shuffling the order of integration.

If we want to use (4.194) to compute $\mathbf{f}_1 * \mathbf{f}_2$, we must first solve the problem $\mathcal{R}_n^\dagger \mathbf{h} = \mathbf{f}_1$ to find the set of functions \mathbf{h} , but then no further inverse transforms are required. We merely compute a set of 1D convolutions and backproject.

Quite apart from signal processing, (4.194) can also be used to derive inverses of the Radon transform and related transforms. For example, we shall see in Chap. 17 how it is useful in analyzing attenuation problems in SPECT.

5

Mixed Representations

In this chapter we discuss a class of mathematical descriptions called *mixed representations*, since they mix apparently incompatible variables such as spatial position and spatial frequency. These descriptions can also be called *extended representations*, since they use more variables than are needed for a parsimonious specification of a function.

In Sec. 5.1 we introduce a variety of integral transforms where a function of a spatial variable is augmented, apparently redundantly, with a spatial frequency ξ . These transforms are linear, like all of the other integral transforms treated earlier in the book, but in Sec. 5.2 we consider *bilinear* transforms, where a product of the original function with itself appears in the integrand. Later, in Sec. 5.3, the spatial variable will be augmented with a scale variable.

As we shall see, these new variables, though superfluous from a strict mathematical viewpoint, offer new insights into the behavior of the functions. Moreover, when the functions are sampled in all variables, little or no increase in the number of required sample points is needed with the extended representations.

5.1 LOCAL SPECTRAL ANALYSIS

A spatial description $f(x)$ gives information about the behavior of a function at every point x , while its Fourier transform $F(\xi)$ gives information about the behavior at every spatial frequency ξ . Neither description gives any information about what frequencies are associated with what spatial location. Often it would be useful to have the spatial counterpart of a musical score, associating frequencies with positions.

5.1.1 Local Fourier transforms

One mathematical construct to accomplish this end is the *sliding-window Fourier transform* or *local Fourier transform*, defined by

$$F_b(\xi; x_0) = \int_{-\infty}^{\infty} dx b^*(x - x_0) f(x) \exp(-2\pi i \xi x), \quad (5.1)$$

where $b(x)$ is a window function. The window function is usually chosen to be real-valued, but can, in general, be complex. The shape of $b(x)$ is arbitrary as far as the mathematics is concerned, but it is usually taken to be more or less concentrated around $x = 0$, so that the shifted function $b(x - x_0)$ in (5.1) is concentrated around $x = x_0$. Suppose, for example, that $b(x) = \text{rect}(x/\Delta x)$. Then the window in (5.1) extends from $x_0 - \frac{1}{2}\Delta x < x < x_0 + \frac{1}{2}\Delta x$, and only in this range does the behavior of $f(x)$ contribute to $F_b(\xi; x_0)$.

The window width Δx controls the degree of localization in x , but it also controls the resolution in ξ . To see this, suppose that $f(x)$ can be well approximated by $\exp(2\pi i \xi_0 x)$ over the window width. We would like to find that $F_b(\xi; x_0)$ is sharply peaked at $\xi = \xi_0$, approximating a delta function, but (5.1) shows that

$$F_b(\xi; x_0) = B^*(\xi_0 - \xi) \exp[2\pi i (\xi_0 - \xi)x_0], \quad (5.2)$$

where $B(\xi) = \mathcal{F}\{b(x)\}$. Continuing the previous example where $b(x) = \text{rect}(x/\Delta x)$, we now have $F_b(\xi; x_0) \propto \Delta x \text{sinc}[(\xi - \xi_0)\Delta x]$, which has a width (measured from the peak to the first zero) of $1/\Delta x$. Thus if we make Δx smaller to improve the spatial localization, we pay the price in spectral localization.

5.1.2 Uncertainty

One of the most celebrated scientific discoveries of the twentieth century is the *Heisenberg uncertainty principle*, which says that two physical observables that are represented quantum mechanically by noncommuting operators cannot be measured simultaneously with arbitrary precision. Any reduction in the inherent uncertainty in one observable must be accompanied by an increase in the uncertainty of the other. This is a profound result, intimately related to the nature of matter and the measurement process in quantum-mechanical systems, but in a purely formal sense it is a simple consequence of basic Fourier mathematics.

The connection between Fourier analysis and quantum-mechanical uncertainty was made by the physicist C. G. Darwin, grandson of Charles Darwin (Cohen, 1995). We shall present the concept of Fourier uncertainty here in the context of the local Fourier transform and then return briefly to the quantum-mechanical analogy.

To understand the inverse relation between the width of a function like $b(x)$ and the width of its Fourier transform, we need a more general definition of width. A mathematically convenient approach is to treat $|b(x)|^2$, when properly normalized, as a probability density function (PDF) and use the associated standard deviation σ_x (see App. C) as a measure of width. The width is thus the square-root of the variance σ_x^2 , where

$$\sigma_x^2 = \frac{\int_{-\infty}^{\infty} dx (x - \bar{x})^2 |b(x)|^2}{\int_{-\infty}^{\infty} dx |b(x)|^2}. \quad (5.3)$$

In this expression, \bar{x} is the mean value of x with respect to the density $|b(x)|^2$, *i.e.*,

$$\bar{x} = \frac{\int_{-\infty}^{\infty} dx x |b(x)|^2}{\int_{-\infty}^{\infty} dx |b(x)|^2}. \quad (5.4)$$

Similarly, the width of $B(\xi)$ is taken as σ_ξ , where

$$\sigma_\xi^2 = \frac{\int_{-\infty}^{\infty} d\xi (\xi - \bar{\xi})^2 |B(\xi)|^2}{\int_{-\infty}^{\infty} d\xi |B(\xi)|^2}, \quad (5.5)$$

and $\bar{\xi}$ is defined analogously to (5.4). Since a change of variables can set \bar{x} and $\bar{\xi}$ to zero, we shall henceforth neglect these terms without loss of generality.

Use of the Parseval and derivative theorems, (3.80) and (3.98), respectively, lets us express σ_ξ^2 in the spatial domain as

$$\sigma_\xi^2 = \frac{\frac{1}{4\pi^2} \int_{-\infty}^{\infty} dx |b'(x)|^2}{\int_{-\infty}^{\infty} dx |b(x)|^2}, \quad (5.6)$$

where the prime denotes derivative. The Schwarz inequality (1.14) yields

$$\int_{-\infty}^{\infty} dx x^2 |b(x)|^2 \int_{-\infty}^{\infty} dx |b'(x)|^2 \geq \left| \int_{-\infty}^{\infty} dx b^*(x) x b'(x) \right|^2, \quad (5.7)$$

from which it follows that

$$\sigma_x \sigma_\xi \geq \frac{\left| \int_{-\infty}^{\infty} dx b^*(x) x b'(x) \right|}{2\pi \int_{-\infty}^{\infty} dx |b(x)|^2}. \quad (5.8)$$

A more useful form results if we use the operator relation,

$$\frac{d}{dx} x - x \frac{d}{dx} = 1, \quad (5.9)$$

which can be proved by operating on an arbitrary function and using the chain rule of differentiation. This relation can be used to express the function $x b'(x)$, in (5.8). With an integration by parts and a little algebra,¹ we then find that

$$\sigma_x \sigma_\xi \geq \frac{1}{4\pi}. \quad (5.10)$$

The inequality in (5.8) becomes an equality if $b'(x)$ is proportional to $x b(x)$, which occurs if $b(x)$ is a Gaussian function of the general form $A \exp(-\alpha x^2)$. Gaussians are therefore sometimes referred to as minimum uncertainty signals. They are the most common choice for the window function in a local Fourier transform.

It is interesting to verify the uncertainty relation for a rect function, $b(x) = \text{rect}(x)$. Then an easy integral shows that $\sigma_x = 1/(2\sqrt{3})$, but in fact $\sigma_\xi = \infty$ since the integral of $[\xi \text{sinc}(\xi)]^2$ diverges. The sinc has a finite width (unity, in fact) as measured from its peak to the first zero, but an infinite width by the variance measure.

¹The derivation of (5.10) from (5.8) and (5.9) is straightforward if $b(x)$ is real, but a little tricky if it is complex. See Cohen (1995), p. 47.

Relation to quantum mechanics The connection of this Fourier math to quantum mechanics takes two distinctly different forms, depending on just which variables are involved. The most familiar form of Heisenberg uncertainty involves the position and momentum of a particle such as an electron. We discuss this position-momentum uncertainty relation first and then comment briefly on the so-called energy-time uncertainty principle.

For simplicity we consider one-dimensional motion, denoting the electron position by x and its momentum by p . One way of identifying p with a spatial frequency is to follow Prince Louis DeBroglie, who in 1923 postulated that an electron could behave either as a particle or as a wave. When it behaved as a wave, he showed, its wavelength λ would be related to the momentum by $p = h/\lambda$, where h is Planck's constant. This audacious suggestion, made several years before Schrödinger's quantum theory, was experimentally verified in 1927 by Davisson and Germer in New York and Thomson in Aberdeen.

We rewrite the DeBroglie relation as

$$p = \frac{h}{\lambda} = h\xi, \quad (5.11)$$

where ξ is now interpreted as the spatial frequency (reciprocal wavelength) of the electron wave. From (5.10) and (5.11), we see that

$$\sigma_x \sigma_p \geq \frac{1}{2} \hbar, \quad (5.12)$$

where $\hbar = h/2\pi$. This is the usual form of the Heisenberg position-momentum uncertainty principle.

Another way to derive this relation is to follow modern wave mechanics as pioneered by Schrödinger. This theory postulates that the state of a physical system is specified by a wavefunction and that physical observables are represented by Hermitian operators that can operate on this function. For a single particle in one dimension, the wavefunction is denoted $\psi(x)$, and the effect of the position operator, which we shall denote by \hat{X} , is simply multiplication by x . The momentum in this picture is represented by the Hermitian differential operator $\hat{P} \equiv -i\hbar \frac{d}{dx}$. The operator equation (5.9) can thus be reinterpreted as a commutation relation between position and momentum operators:

$$[\hat{P}, \hat{X}] = \hat{P}\hat{X} - \hat{X}\hat{P} = -i\hbar. \quad (5.13)$$

In quantum mechanics the expectation value of an operator $\hat{\Omega}$ for a system in state $\psi(x)$ is given by the \mathbb{L}_2 scalar product,

$$\langle \hat{\Omega} \rangle = (\psi, \hat{\Omega}\psi) = \int_{-\infty}^{\infty} dx \psi^*(x) \hat{\Omega}\psi(x), \quad (5.14)$$

provided the wavefunction is normalized so that

$$\|\psi\|^2 = \int_{-\infty}^{\infty} dx |\psi(x)|^2 = 1. \quad (5.15)$$

The variance of the position is now defined as $\sigma_x^2 = \langle [\hat{X} - \langle \hat{X} \rangle]^2 \rangle$, and similarly for the variance of the momentum.

To derive the uncertainty relation, we take the expectation value of the operator $\hat{\Omega}^\dagger \hat{\Omega}$, where $\hat{\Omega} = \hat{X} + i\epsilon \hat{P}$ and ϵ is an arbitrary real number (Cohen-Tannoudji *et al.*, 1977). Since \hat{X} and \hat{P} are Hermitian, the adjoint of $\hat{X} + i\epsilon \hat{P}$ is $\hat{X} - i\epsilon \hat{P}$ (see Sec. 1.3.5), and we find

$$\langle \hat{\Omega}^\dagger \hat{\Omega} \rangle = \langle \psi, [\hat{X} - i\epsilon \hat{P}][\hat{X} + i\epsilon \hat{P}] \psi \rangle = \langle \hat{X}^2 \rangle + \epsilon^2 \langle \hat{P}^2 \rangle - i\epsilon \langle \hat{P} \hat{X} - \hat{X} \hat{P} \rangle = \langle \hat{X}^2 \rangle + \epsilon^2 \langle \hat{P}^2 \rangle - \epsilon \hbar. \quad (5.16)$$

Since $\langle \hat{\Omega}^\dagger \hat{\Omega} \rangle = (\hat{\Omega} \psi, \hat{\Omega} \psi) = \|\hat{\Omega} \psi\|^2$, we also have

$$\|\hat{\Omega} \psi\|^2 = \langle \hat{X}^2 \rangle + \epsilon^2 \langle \hat{P}^2 \rangle - \epsilon \hbar \geq 0. \quad (5.17)$$

The discriminant of this quadratic form in ϵ is $\hbar^2 - 4\langle \hat{X}^2 \rangle \langle \hat{P}^2 \rangle$; if this discriminant is positive, then the quadratic form has two real roots, and the form itself goes negative between these two values of ϵ . To satisfy (5.17) for all ϵ , we must therefore have

$$\langle \hat{X}^2 \rangle \langle \hat{P}^2 \rangle \geq \frac{1}{4} \hbar^2. \quad (5.18)$$

A change of variables to remove the mean (Cohen-Tannoudji *et al.*, 1977) completes the derivation of the uncertainty relation, (5.12).

An important manifestation of Heisenberg uncertainty arises when a particle moving in three dimensions is localized in one direction (say x) by passing it through a slit. If the slit width is w , then the particle has an uncertainty in the x component of position of this amount and a corresponding minimum uncertainty in p_x of order \hbar/w . An image scientist conversant with the DeBroglie relation, $p = \hbar/\lambda$, would recognize the uncertainty in p_x as a natural consequence of diffraction.

Energy-time uncertainty Another relation, also frequently referred to as an uncertainty relation in quantum mechanics, involves the energy E and the time t . The energy-time uncertainty relation conveys very different physics from the position-momentum principle, however, since time is simply a classical parameter in quantum mechanics, not an operator. Time can be measured with arbitrary precision.

An electromagnetic wave can induce transitions between two energy states of an atom. If the states have an energy difference of ΔE and the wave has frequency ν , then an energy-conserving transition can be made if $\nu = \Delta E/\hbar$. In a quantum-electrodynamical view (discussed further in Sec. 9.1), the field is quantized and the transition corresponds to absorption or emission of one quantum (photon) of energy $\hbar\nu$. Quantization of the field is, however, not necessary to an accurate quantum-mechanical description of the transition; almost all of the salient features can be derived with a purely classical model for the field, using quantum mechanics only for the atom (see Sec. 9.1.4).

If the atom is initially in the lower-energy state and the field is applied at $t = 0$, then there is some probability of observing it in the upper state at time $t = T$ even if $\hbar\nu \neq \Delta E$. All that is required is that $|\hbar\nu - \Delta E|$ be less than about \hbar/T . From a Fourier viewpoint, this result is not surprising since the windowed temporal Fourier transform of the field has a frequency spread of order $1/T$, and some frequency component in this range resonates with the atomic transition. For large T , the Fourier transform of the field over this interval is sharply peaked, and a transition can be observed only if energy is conserved, in the sense that $\hbar\nu = \Delta E$.

5.1.3 Local frequency

Local spectrogram The local spectrogram is the squared modulus of the local Fourier transform,

$$W_b(\xi; x_0) = |F_b(\xi; x_0)|^2, \quad (5.19)$$

where $F_b(\xi; x_0)$ is defined by (5.1). This nonnegative real quantity has many applications in signal analysis and pattern recognition since it shows how the signal energy is distributed in both spatial position and spatial frequency.

If $W_b(\xi; x_0)$ as a function of ξ (for some choice of window function and some shift x_0) exhibits one or more well-defined peaks, then it is reasonable to say that the position of each peak is a frequency associated with position x_0 . For example, suppose $f(x)$ can be approximated by $\cos(2\pi\xi_0x)$ over the region defined by the window when it is centered at $x = x_0$. Then we can write

$$\begin{aligned} W_b(\xi; x_0) &\simeq \left| \int_{-\infty}^{\infty} dx b(x - x_0) \cos(2\pi\xi_0x) \exp(-2\pi i\xi x) \right|^2 \\ &= \frac{1}{4} |B(\xi - \xi_0)|^2 + \frac{1}{4} |B(\xi + \xi_0)|^2. \end{aligned} \quad (5.20)$$

No cross terms appear in this expression if the window is chosen so that $B(\xi - \xi_0)$ and $B(\xi + \xi_0)$ do not overlap at any frequency.

The two terms in (5.20) show peaks when their arguments vanish, namely at $\xi = \pm\xi_0$, so frequencies ξ_0 and $-\xi_0$ are both local to x_0 . Similarly, if $f(x)$ can be approximated by a square wave of fundamental frequency ξ_0 for a window centered at x_0 , then $W_b(\xi; x_0)$ will exhibit peaks at all odd harmonics of $\pm\xi_0$, and all of these frequencies are local to x_0 .

Pure phase functions There is one circumstance where a unique local frequency can be associated with each position x_0 . That is for a *pure phase function* with slowly varying phase. A pure phase function, illustrated in Fig. 5.1, is a complex-valued function of a real variable x with the form

$$f(x) = \exp[i\phi(x)] = \cos \phi(x) + i \sin \phi(x), \quad (5.21)$$

where $\phi(x)$ is real. Since $|f(x)| = 1$, both the real part and the imaginary part are fully determined by the phase function $\phi(x)$. As we shall see later in the book, functions of this form have many applications in optics and imaging. Plane waves, spherical waves and nonabsorbing optical elements such as lenses and prisms can be described by pure phase functions.

If $\phi(x)$ is differentiable to all orders at $x = x_0$, it can be represented as a Taylor series:

$$\phi(x) = \phi(x_0) + (x - x_0) \phi'(x_0) + \frac{1}{2}(x - x_0)^2 \phi''(x_0) + \dots \quad (5.22)$$

If the phase varies sufficiently slowly for x near x_0 that this expansion can be truncated with the linear term, we can write

$$f(x) \simeq \exp[i\phi(x_0) + i(x - x_0) \phi'(x_0)] = \text{const} \cdot \exp[2\pi i \xi_{loc}(x_0)x], \quad (5.23)$$

where

$$\xi_{loc}(x_0) = \frac{1}{2\pi} \phi'(x_0). \quad (5.24)$$

Fig. 5.1 (a) Plot of a phase $\phi(x)$; (b) Real part of the pure phase function $\exp[i\phi(x)]$.

The approximation in (5.23) thus has the effect of replacing the pure phase function $f(x)$ in the vicinity of x_0 with a simple, exactly periodic, complex exponential. The spatial frequency of this exponential is just $\xi_{loc}(x_0)$.

Local period Another way to look at spatial frequency is that it is the reciprocal of the period (or wavelength) of a periodic function. An approximate period $\Lambda(x_0)$ of $f(x)$ in the vicinity of x_0 can be defined by

$$f[x_0 + \Lambda(x_0)] = f(x_0). \quad (5.25)$$

For a pure phase function, this means that

$$\phi[x_0 + \Lambda(x_0)] - \phi(x_0) = 2\pi. \quad (5.26)$$

If $\phi'(x_0)$ is approximately constant over a distance $\Lambda(x_0)$, a Taylor expansion shows that

$$\frac{1}{\Lambda(x_0)} \simeq \frac{1}{2\pi} \phi'(x_0) = \xi_{loc}(x_0). \quad (5.27)$$

Thus $\xi_{loc}(x_0)$ can be interpreted as the reciprocal of the distance from one crest of $f(x)$ in the vicinity of x_0 to the next (see Fig. 5.2).

Fig. 5.2 Interpretation of local spatial frequency as reciprocal of local period.

Local frequency of a chirp In Secs. 3.3.7 and 4.3 we discussed quadratic phase factors, also known as chirp functions. Now we shall discover the reason for the latter designation.

For a 1D chirp of the form

$$f(x) = \exp(i\pi\beta x^2), \quad (5.28)$$

the local frequency is given from (5.24) by

$$\xi_{loc}(x) = \beta x. \quad (5.29)$$

Thus the local frequency increases linearly with x , reminiscent of a bird's chirp which increases with time. The parameter β is known as the *chirp rate*. Because of the linear variation of local frequency, a chirp is also referred to as *linear FM* (frequency modulation).

Pure phase functions and quantum-mechanical operators We saw in Sec. 5.1.2 that DeBroglie related momentum to spatial frequency via $p = h/\lambda = h\xi$. Later Schrödinger represented p by an operator $\hat{P} = -i\hbar \frac{d}{dx}$. For a pure phase function we also know that ξ_{loc} is given by (5.24). With $f(x) = \exp[i\phi(x)]$, we can write

$$\hat{P}f(x) = -i\hbar \frac{d}{dx} \exp[i\phi(x)] = \hbar f(x) \frac{d\phi(x)}{dx} = h\xi_{loc}(x) f(x) = \frac{h}{\Lambda(x)} f(x). \quad (5.30)$$

The DeBroglie relation thus holds for pure phase functions in the sense that applying the momentum operator to such functions is the same as multiplying by Planck's constant over the local wavelength.

Local frequency and analytic signals Another way to define local frequency is by means of the analytic signal, introduced in Sec. 4.2.4. For a real spatial function $f(x)$, the analytic signal $f_a(x)$ is a complex function given by the spatial counterpart of (4.107). If $f_a(x)$ is written as

$$f_a(x) = |f_a(x)| \exp[i\phi_a(x)], \quad (5.31)$$

then a local frequency can be defined as

$$\xi_a(x_0) = \frac{1}{2\pi} \frac{d\phi_a(x)}{dx}. \quad (5.32)$$

This definition applies to all functions $f(x)$, without any assumptions about the phase being slowly varying, but a number of counterintuitive features arise if the function has a large bandwidth (Cohen, 1977). For example, the local frequency may not even be contained in the Fourier transform of $f(x)$.

Extension to two or more dimensions The concept of local spatial frequency can be extended to pure phase functions of two or more real variables. In 2D Cartesian coordinates, for example, such a function would have the form

$$f(x, y) = \exp[i\phi(x, y)]. \quad (5.33)$$

By arguments similar to those used in the 1D case, we can define local spatial frequencies $\xi_{loc}(x_0, y_0)$ and $\eta_{loc}(x_0, y_0)$ for the x and y directions, respectively, by

$$\xi_{loc}(x_0, y_0) = \frac{1}{2\pi} \left[\frac{\partial}{\partial x} \phi(x, y) \right]_{x=x_0, y=y_0}, \quad \eta_{loc}(x_0, y_0) = \frac{1}{2\pi} \left[\frac{\partial}{\partial y} \phi(x, y) \right]_{x=x_0, y=y_0}. \quad (5.34)$$

A succinct vector notation for these expressions is

$$\boldsymbol{\rho}_{loc}(\mathbf{r}_0) = \frac{1}{2\pi} \nabla \phi(\mathbf{r}_0), \quad (5.35)$$

where $\boldsymbol{\rho}_{loc}$ has Cartesian coordinates $(\xi_{loc}, j1\eta_{loc})$, \mathbf{r}_0 has Cartesian coordinates (x_0, y_0) , and ∇ is the usual 2D gradient operator. Because of the gradient, $\boldsymbol{\rho}_{loc}(\mathbf{r}_0)$ is always normal to contours of constant phase.

The vector form of local frequency, (5.35), holds in any number of dimensions. All that is required is to interpret $\boldsymbol{\rho}_{loc}$, \mathbf{r}_0 and ∇ as vectors with an appropriate number of components.

As an example of a multidimensional local frequency, consider a 2D rotationally symmetric chirp defined by

$$f(\mathbf{r}) = \exp(i\pi\beta r^2), \quad (5.36)$$

where $r = |\mathbf{r}| = \sqrt{x^2 + y^2}$. For this function, illustrated in Fig. 5.3, the contours of constant phase are concentric circles, and the local frequency vector is given from (5.35) by

$$\boldsymbol{\rho}_{loc}(\mathbf{r}) = \beta \mathbf{r}. \quad (5.37)$$

This frequency vector is directed radially away from the center of the circles.

Fig. 5.3 Illustration of a 2D rotationally symmetric chirp. The function is complex, and only its real part is shown here.

5.1.4 Gabor's signal expansion

The local Fourier transform of a function $f(x)$ is a way of expressing the spatial and frequency content of that function. In this section we look at the inverse problem: recovering the function from its spatial and frequency content, as expressed by the local Fourier transform. This discussion will lead to a signal expansion developed by Dennis Gabor (1900–1979), one of the founders of modern communications theory. Gabor also brought communications theory into image science, establishing the viewpoint that pervades this book. He received the Nobel prize for physics in 1971 for the invention of holography.

Inversion of the local Fourier transform As a step toward Gabor's signal expansion, we first discuss a method of inverting the local Fourier transform, (5.1) (de Bruijn, 1973; Bastiaans, 1981). Note that (5.1) is an \mathbb{L}_2 scalar product of $f(x)$ with the function $b(x - x_0) \exp(2\pi i \xi x)$. We define a normalized version of this function by

$$u(x; \xi, x_0) = \frac{b(x - x_0) \exp(2\pi i \xi x)}{\left[\int_{-\infty}^{\infty} dx' |b(x')|^2 \right]^{\frac{1}{2}}} = \frac{b(x - x_0) \exp(2\pi i \xi x)}{\|b\|}. \quad (5.38)$$

Consider the family of functions $\{u(x; \xi, x_0)\}$ indexed by two continuous indices ξ and x_0 . Perhaps surprisingly, this family forms a complete set in $\mathbb{L}_2(\mathbb{R})$; no matter what we choose for the window function $b(x)$, any function in $\mathbb{L}_2(\mathbb{R})$ can be expressed as a linear combination of $\{u(x; \xi, x_0)\}$. The closure relation (decomposition of the unit operator) has the form [cf. (1.64)]

$$\int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} dx_0 u^*(x'; \xi, x_0) u(x; \xi, x_0) = \delta(x - x'), \quad (5.39)$$

which can be demonstrated with the help of (2.46) and (2.25). From (5.39) it follows that

$$f(x) = \frac{\int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} dx_0 F_b(\xi; x_0) b(x - x_0) \exp(2\pi i \xi x)}{\int_{-\infty}^{\infty} dx' |b(x')|^2}, \quad (5.40)$$

which is the desired representation of $f(x)$ in terms of its local Fourier transform.

Sampling Just as the local Fourier transform is redundant, using two variables where one would suffice, so too is the set $\{u(x; \xi, x_0)\}$ redundant; it is an *overcomplete* set for \mathbb{L}_2 , in the sense that some subset would form a basis. One way to select such a subset is to sample $u(x; \xi, x_0)$ in the variables ξ and x_0 . We denote the sample interval in x_0 as δx and the interval in ξ as $\delta \xi$. A basis results if $\delta \xi = 1/\delta x$ (Bastiaans, 1981). Samples chosen in this way are said to be points on the *Gabor lattice*, illustrated in Fig. 5.4. The sampled counterpart of (5.40), known as Gabor's signal expansion, has the form

$$f(x) = \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} a_{mn} b(x - m \delta x) \exp(2\pi i n x \delta \xi), \quad (\delta \xi = 1/\delta x). \quad (5.41)$$

Gabor referred to $b(x)$ as the *elementary signal*; the basis functions in the Gabor expansion are thus the elementary signal shifted in discrete steps of δx and modulated with linear phase factors with a discrete set of frequencies $n \delta \xi$. To force (5.41) to look like the other expansions in Chap. 4, we define

$$b_{mn}(x) = b(x - m \delta x) \exp(2\pi i n x \delta \xi), \quad (5.42)$$

so that the Gabor expansion becomes

$$f(x) = \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} a_{mn} b_{mn}(x). \quad (5.43)$$

With suitable choice of the coefficients $\{a_{mn}\}$, this expansion can represent any function in $\mathbb{L}_2(\mathbb{R})$. Unfortunately, since the expansion functions are not orthogonal in general, it is not trivial to find the coefficients.

Fig. 5.4 The Gabor lattice of sample points in the x - ξ plane.

Degrees of freedom The number of coefficients $\{a_{mn}\}$ required to represent a function adequately via a Gabor expansion is another measure of the number of degrees of freedom of the function. To estimate this number, we consider, as in Sec. 5.1, a function that is spatially limited and approximately bandlimited. If we neglect the width of $b(x)$ compared to the width L of the function, then $L/\delta x$ points are required along the x axis in the Gabor lattice. Note that there is no requirement that δx satisfy the Nyquist condition, so this number is quite arbitrary. However, if the function has bandwidth B , then $B/\delta\xi = B\delta x$ points are required along the ξ axis. The total number of points required is simply the space-bandwidth product LB , just as with Nyquist sampling. Whatever we save by sampling more sparsely along x , we must make up by sampling more finely in ξ . The space-bandwidth product is the number of parameters required to specify the function, and all the Gabor expansion does is give us some flexibility in how we distribute the samples between space and spatial frequency.

An important consequence of this discussion is that we do not need *more* samples when we decide to represent a function of one variable with a function of two variables, in spite of the apparent redundancy of the representation.

Biorthonormality It would be easy to find the coefficients $\{a_{mn}\}$ in the Gabor expansion if we could find an auxiliary function $w(x)$ such that

$$\int_{-\infty}^{\infty} dx w_{m'n'}^*(x) b_{mn}(x) = \delta_{mm'} \delta_{nn'}, \quad (5.44)$$

where $w_{mn}(x)$ is defined by analogy to (5.42) as

$$w_{mn}(x) = w(x - m\delta x) \exp(2\pi i n x \delta\xi). \quad (5.45)$$

Equation (5.44) is called a *biorthonormality relation* (Bastiaans, 1981, 1994). If it is satisfied for some $w(x)$, we can multiply both sides of (5.43) by $w_{m'n'}^*(x)$ and integrate over x , obtaining

$$a_{mn} = \int_{-\infty}^{\infty} dx w_{mn}^*(x) f(x). \quad (5.46)$$

The next section describes one approach to finding a suitable $w(x)$. The concept of biorthonormality will recur in Sec. 5.3 in the context of wavelets.

Zak transform An elegant approach to finding $w(x)$ that satisfies (5.44) uses the *Zak transform*, defined for an arbitrary function $\mu(x)$ by (Bastiaans, 1994)

$$\mu_{zak}(x, \xi) = \sum_{m=-\infty}^{\infty} \mu(x + m \delta x) \exp(-2\pi i \xi m \delta x). \quad (5.47)$$

There is an equivalent form of the Zak transform in the frequency domain. From the Poisson summation formula (3.197) with $g(x) = \mu(x) \exp(-2\pi i \xi x)$, we can show that

$$\mu_{zak}(x, \xi) = (\delta x)^{-1} \exp(2\pi i \xi x) \sum_{m=-\infty}^{\infty} M(\xi + m \delta \xi) \exp(-2\pi i m x \delta \xi), \quad (5.48)$$

where $M(\xi)$ is the Fourier transform of $\mu(x)$.

Since (5.47) can be recognized as a Fourier series in ξ (with coefficients that depend on x), it follows at once that $\mu_{zak}(x, \xi)$ is periodic in ξ with period $\delta \xi$. Moreover, from (5.48) it follows that $\mu_{zak}(x, \xi)$ is quasiperiodic in x (periodic except for a phase factor). Thus, for n and k integers,

$$\mu_{zak}(x + k \delta x, \xi + n \delta \xi) = \exp(2\pi i \xi k \delta x) \mu_{zak}(x, \xi). \quad (5.49)$$

Because of this periodicity, $\mu_{zak}(x, \xi)$ is fully determined by its behavior in a unit cell of the Gabor lattice, *i.e.*, $-\frac{1}{2} \delta x < x \leq \frac{1}{2} \delta x$, $-\frac{1}{2} \delta \xi < \xi \leq \frac{1}{2} \delta \xi$.

The inverse of the Zak transform follows easily from its interpretation as a Fourier series in ξ . From (5.47) and (3.19), we see that (Bastiaans, 1994)

$$\mu(x + m \delta x) = \frac{1}{\delta \xi} \int_{-\frac{1}{2} \delta \xi}^{\frac{1}{2} \delta \xi} d\xi \mu_{zak}(x, \xi) \exp(2\pi i \xi m \delta x). \quad (5.50)$$

We can find $\mu(x')$ for any $x' = x + m \delta x$ from this formula by restricting x to the unit cell and letting m range over all integers.

Application of the Zak transform to the Gabor expansion We shall now apply the Zak transform to the problem of finding the coefficients in a Gabor expansion. With a change of variables and the explicit expressions (5.42) and (5.45) for $b_{mn}(x)$ and $w_{mn}(x)$, respectively, the biorthonormality relation (5.44) can be written,

$$\int_{-\infty}^{\infty} dx w^*[x - (m' - m) \delta x] b(x) \exp[2\pi i (n' - n)x \delta \xi] = \delta_{mm'} \delta_{nn'}. \quad (5.51)$$

Letting $k = m - m'$ and $l = n - n'$ and summing over k and l , we find

$$\sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} \int_{-\infty}^{\infty} dx w^*[x + k \delta x] b(x) \exp(-2\pi i x \delta \xi) = 1. \quad (5.52)$$

After a nontrivial amount of algebra, including the use of (2.50), we find (Bastiaans, 1994)

$$\delta x b_{zak}(x, \xi) w_{zak}^*(x, \xi) = 1. \quad (5.53)$$

Thus, like many of the transforms considered in the last chapter, the Zak transform

converts a certain kind of convolution to a simple product; here the convolution is expressed by the integral in (5.44).

To find the auxiliary function $w(x)$ that corresponds to any given elementary signal $b(x)$, we must take the Zak transform of $b(x)$, compute its reciprocal, and perform an inverse Zak transform. The Gabor coefficients $\{a_{mn}\}$ then follow from (5.46). Even for the simple case of a Gaussian elementary signal, however, this program leads to quite complicated expressions involving theta functions.

5.2 BILINEAR TRANSFORMS

To this point, most of the integral transform we have considered have been linear, but it is also of some interest to study *bilinear forms*, where a product of two versions of the function being transformed appears in the integrand. We have already encountered one example of a bilinear form: the autocorrelation integral defined in Sec. 3.3.6 involves an integral of the product of a function with a shifted version of the same function. Two other bilinear forms, the Wigner distribution function and the Woodward ambiguity function, will be introduced here. Stochastic bilinear forms, including a stochastic version of the Wigner distribution function, will be discussed in Chaps. 8 and 10.

5.2.1 Wigner distribution function

Another candidate for a local spectrum is the Wigner distribution function (WDF), introduced by Wigner in 1932 in quantum mechanics and first applied to signal processing by Ville (1948). For an excellent review of the Wigner representation in quantum mechanics, see Tatarskii (1983), and for a detailed treatment in a signal-processing context, see Claasen and Mecklenbräuker (1980). For a snapshot of the applications of Wigner distributions and phase space in optics at the turn of the millennium, see the December, 2000 special issue of *Journal of the Optical Society of America A*.

The WDF of a 1D function $f(x)$ is defined by

$$W_f(x, \xi) = \int_{-\infty}^{\infty} dx' f(x + \frac{1}{2}x') f^*(x - \frac{1}{2}x') \exp(-2\pi i \xi x'). \quad (5.54)$$

Unlike the local Fourier transform, the WDF is not a linear functional of $f(x)$; it is a bilinear form since $f(x)$ appears twice with two different shifts. One way of thinking about the WDF is that it is a sliding-window Fourier transform, where the function itself serves as the window.

As the reader may demonstrate, $W_f(x, \xi)$ can also be expressed in terms of the Fourier transform $F(\xi)$ rather than $f(x)$ directly:

$$W_f(x, \xi) = \int_{-\infty}^{\infty} d\xi' F(\xi + \frac{1}{2}\xi') F^*(\xi - \frac{1}{2}\xi') \exp(2\pi i \xi' x). \quad (5.55)$$

Even though (5.55) is written in terms of $F(\xi)$, it is the WDF of $f(x)$, which is not the same thing as the WDF of $F(\xi)$ itself. For more on this latter function, which we denote as $W_F(\xi, x)$, see Sec. 5.2.3.

Inversion One way to recover $f(x)$, up to a constant, from the WDF is to perform an inverse Fourier transform on the ξ variable in $W_f(x, \xi)$, yielding

$$\int_{-\infty}^{\infty} d\xi W_f(x, \xi) \exp(4\pi i \xi x) = f(2x) f^*(0). \quad (5.56)$$

The modulus of the constant, $|f(0)|$, can be found since

$$\int_{-\infty}^{\infty} d\xi W_f(x, \xi) = |f(x)|^2. \quad (5.57)$$

Thus $f(x)$ can be uniquely determined from $W_f(x, \xi)$ except for a constant phase factor; multiplying $f(x)$ by $\exp(i\alpha)$ with α constant leaves $W_f(x, \xi)$ unchanged.

Similarly,

$$\int_{-\infty}^{\infty} dx W_f(x, \xi) \exp(-4\pi i \xi x) = F(2\xi) F^*(0) \quad (5.58)$$

and

$$\int_{-\infty}^{\infty} dx W_f(x, \xi) = |F(\xi)|^2. \quad (5.59)$$

Pure phase functions revisited Suppose that $f(x) = \exp[i\phi(x)]$. Then the Wigner distribution function is given by

$$W_f(x, \xi) = \int_{-\infty}^{\infty} dx' \exp[i\phi(x + \frac{1}{2}x')] \exp[-i\phi(x - \frac{1}{2}x')] \exp(-2\pi i \xi x'). \quad (5.60)$$

If $\phi(x \pm \frac{1}{2}x')$ is expanded in powers of x' as in (A.176), the quadratic terms cancel. If cubic and higher terms can be neglected, we find

$$W_f(x, \xi) \simeq \int_{-\infty}^{\infty} dx' \exp\left[-2\pi i x' \left(\xi - \frac{1}{2\pi} \frac{\partial\phi(x)}{\partial x}\right)\right] = \delta\left(\xi - \frac{1}{2\pi} \frac{\partial\phi(x)}{\partial x}\right). \quad (5.61)$$

For slowly varying phase functions, therefore, the WDF is nonzero only if $\xi = \xi_{loc}(x)$. If the Taylor expansion is not strictly valid, the WDF will have some width around the line $\xi = \xi_{loc}(x)$ in the ξ - x plane. Examination of the WDF is thus a way of assessing the validity of the local-frequency approximation.

A curious nonlocality There are some decidedly counterintuitive features of the WDF as a local spectrum. For example, suppose $f(x)$ is given by

$$f(x) = \delta(x - x_1) + \delta(x - x_2). \quad (5.62)$$

One might expect a local spectrum of this function to be localized spatially around the two points x_1 and x_2 , but the WDF says otherwise. Some manipulations using formulas from Chap. 2 show that

$$W_f(x, \xi) = \delta(x - x_1) + \delta(x - x_2) + 2\delta\left(x - \frac{x_1 + x_2}{2}\right) \cos[2\pi\xi(x_1 - x_2)]. \quad (5.63)$$

We see that there is a concentration at the midpoint $\frac{1}{2}(x_1 + x_2)$, even though $f(x)$ is zero at that point. This nonphysical effect, resulting from the cross-term when a sum of two delta functions is multiplied by another such sum, is the price we pay for using a bilinear form rather than the square of a linear form as a spectrum. Note, however, that the cosine term is an oscillatory function of ξ ; if we smooth the spectrum in the ξ direction with a filter of width greater than $1/(x_2 - x_1)$, then the cross-term will be removed.

Positivity Another objection to the use of the WDF as a spectrum is that it can take on negative values. One approach to dealing with this problem is to smooth $W_f(x, \xi)$ by convolving with a 2D Gaussian in x and ξ . It can be shown that if the width of the Gaussian is chosen properly, the smoothed WDF cannot go negative (Cohen, 1995). This smoothing operation has an important interpretation in quantum mechanics; it relates to the choice of ordering of the noncommutative operators in an expectation value (Tatarskii, 1983).

5.2.2 Ambiguity functions

Another useful extended representation of a function $f(x)$ is obtained by taking a double Fourier transform of $W_f(x, \xi)$:

$$A_f(\xi', x') = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} d\xi W_f(x, \xi) \exp[2\pi i(\xi x' - \xi' x)]. \quad (5.64)$$

Use of (5.54), (2.46) and some algebra shows that

$$A_f(\xi', x') = \int_{-\infty}^{\infty} dx f(x + \frac{1}{2}x') f^*(x - \frac{1}{2}x') \exp(-2\pi i\xi'x). \quad (5.65)$$

This function, known as the *Woodward ambiguity function*, arises in radar signal processing, where the variable x is time and ξ is temporal frequency. In this application, the ambiguity function measures the degree of similarity between a signal and a delayed and Doppler-shifted version of the same signal. Note that if $\xi' = 0$, then the ambiguity function is essentially an autocorrelation, analogous to (3.115) but defined with a symmetric shift.

The ambiguity function is very similar in form to the WDF, both involving a Fourier transform of the product function $f(x + \frac{1}{2}x') f^*(x - \frac{1}{2}x')$. The difference is that the transform is over the shift variable x' in the WDF and over the center variable x in the ambiguity function.

5.2.3 Fractional Fourier transforms

An interesting line of research emerges if we examine the WDF associated with the Fourier transform $F(\xi)$ of a signal $f(x)$. This procedure should not be confused with the ambiguity function, which is the double Fourier transform of the WDF of a signal $f(x)$; here we are concerned with the WDF of a Fourier transform, not the Fourier transform of the WDF.

We define the WDF of $F(\xi)$ by analogy to (5.54) as

$$W_F(\xi, x) = \int_{-\infty}^{\infty} d\xi' F(\xi + \frac{1}{2}\xi') F^*(\xi - \frac{1}{2}\xi') \exp(-2\pi i x \xi'). \quad (5.66)$$

Comparing this integral to (5.55), we see that

$$W_F(\xi, x) = W_f(-x, \xi). \quad (5.67)$$

Thus W_F is the same function as W_f but rotated by an angle of $\pi/2$ in the x - ξ plane. To compute a Fourier transform, therefore, one can compute the WDF of $f(x)$, rotate it by $\pi/2$, and then compute the inverse WDF. The result will be $F(\xi)$.

This observation has prompted several authors to consider rotations of the WDF by angles other than $\pi/2$ and to use such rotations to define Fourier transforms of fractional (or even complex) order. Rotation of the WDF by an angle of $p\pi/2$ corresponds to a fractional Fourier transform of order p . The case $p = 1$ corresponds to the usual Fourier transform and $p = 0$ to the identity. Since the Fourier domain allows perfect localization of a signal in frequency and the space domain allows perfect spatial localization, the fractional order p controls the tradeoff between spatial and frequency localization.

Given a function $f(x)$, we denote its fractional Fourier transform of order p by $f_p(x)$. An explicit formula for $f_p(x)$ is (Lohmann, 1993)

$$f_p(x) = \int_{-\infty}^{\infty} dx' f(x') \exp \left[\frac{i\pi}{\tan \phi} (x'^2 + x^2) \right] \exp \left[\frac{-2i\pi}{\sin \phi} xx' \right] \quad (5.68)$$

where ϕ is related to the fractional order p by

$$\phi = p \frac{\pi}{2}. \quad (5.69)$$

If $p = 1$, then $\sin \phi = 1$ and $1/\tan \phi = 0$, so the ordinary Fourier transform is obtained. If p is small, so $\sin \phi \simeq \tan \phi \simeq \phi$, then (5.68) reduces to the Fresnel transform of parameter $\beta = 1/\phi$.

Applications of the fractional Fourier transform to optics and imaging are discussed by Lohmann (1993), Ozaktis *et al.* (1994), Ozaktis and Mendlovic (1994), Alieva *et al.* (1994) and Dorsch (1995).

5.3 WAVELETS

As discussed in Sec. 5.1.4, the local Fourier transform can be computed as a sequence of \mathbb{L}_2 scalar products of a function $f(x)$ with expansion functions $u(x; \xi, x_0) \propto b(x - x_0) \exp(2\pi i \xi x)$. These expansion functions are parameterized by a shift x_0 and a modulation frequency ξ , and there is considerable freedom in choosing the elementary signal $b(x)$ from which the expansion functions are constructed. In this section we introduce expansion functions known as *wavelets*, where the parameters are shift and scale rather than shift and frequency. Again, as we shall see, there is considerable freedom in how these functions are constructed.

Though wavelets have many historical antecedents in mathematics and physics, their emergence as practical tools for signal analysis stems from the work of a cadre of European mathematicians in the 1980s. Notable among this group were Morlet, who coined the word wavelets (*ondelettes*), Meyer, Mallat, Grossmann and Daubechies.

Comprehensive treatments of wavelets are given by Kaiser (1994), Walter (1994), Chui (1992) and Daubechies (1992).

5.3.1 Mother wavelets and scaling functions

Just as local Fourier transforms and Gabor expansions are built on elementary signals, wavelets are built on elementary functions called *mother wavelets*. Given

a mother wavelet $\psi(x)$, a wavelet $\psi_{a,b}(x)$ is defined by

$$\psi_{a,b}(x) = \frac{1}{\sqrt{|a|}} \psi\left(\frac{x-b}{a}\right). \tag{5.70}$$

Thus b is the shift of the wavelet, a specifies the scale, and the factor of $1/\sqrt{|a|}$ ensures that the \mathbb{L}_2 norm of $\psi_{a,b}(x)$ is independent of a . Both a and b range over the real line, with negative a corresponding to reversal of the sense of the wavelet. For even wavelets, positive a would suffice.

The Fourier transform of $\psi_{a,b}(x)$ is given by

$$\Psi_{a,b}(\xi) = \sqrt{|a|} \exp(-2\pi i b \xi) \Psi(a\xi). \tag{5.71}$$

The mother wavelet can be derived from a *scaling function* $\phi(x)$, which will usually be chosen to be smooth and compact in some sense. In addition, we shall require the scaling functions to have unit \mathbb{L}_2 norm, so

$$\int_{-\infty}^{\infty} dx |\phi(x)|^2 = 1. \tag{5.72}$$

Given a scaling function, the mother wavelet can be defined by

$$\psi(x) = \sqrt{2} \sum_{n=0}^{2N-1} c_{N-1-n} \phi(2x-n), \tag{5.73}$$

where the value of N and the coefficients are specific to the family of wavelets chosen. For the Haar wavelet (described below), $N = 2$ and there are only two terms in the sum.

The usefulness of scaling functions will be seen below when we discuss multiresolution analysis. A few wavelets and their scaling functions are illustrated in Fig. 5.5.

Examples: Haar and spline One specific example that has received considerable attention is the *Haar wavelet*, for which the scaling function is $\text{rect}(x - \frac{1}{2})$ and the mother wavelet is given by

$$\psi_H(x) = \text{rect}\left(2x - \frac{1}{2}\right) - \text{rect}\left(2x - \frac{3}{2}\right) = \begin{cases} +1 & \text{if } 0 < x < \frac{1}{2} \\ -1 & \text{if } \frac{1}{2} < x < 1 \\ 0 & \text{otherwise} \end{cases}. \tag{5.74}$$

For reference, the Fourier transform of this mother wavelet is

$$\Psi_H(\xi) = \frac{[1 - \exp(-i\pi\xi)]^2}{2\pi i \xi}. \tag{5.75}$$

Haar wavelets are related to a family of interpolating functions called *B-splines*.² The first-order *B-spline* is simply the scaling function for the Haar

²Different books give conflicting accounts of the origin of the term; B may stand for *basis* or *Bernstein*, the latter because of a connection to polynomials of the same name (Chui, 1992).

wavelet, $\text{rect}(x - \frac{1}{2})$. The B -spline of order m , denoted $N_m(x)$, is the first-order function convolved with itself $m - 1$ times (de Boor, 1978). Thus a B -spline of order m is a piecewise polynomial of degree $m - 1$. From any B -spline, a corresponding wavelet can be constructed by

$$\psi_m(x) = \sum_{n=0}^{3m-2} q_n N_m(2x - n), \tag{5.76}$$

where an explicit expression for the coefficients $\{q_n\}$ is given in Chui (1992, Chap. 6). Wavelets constructed this way are piecewise polynomials with compact support. The higher-order spline wavelets are very similar to Gabor functions, being concentrated both spatially and in spatial frequency. The key difference is that the width and frequency are independent in a Gabor function, while they scale together for a wavelet. High-frequency wavelets are narrow, while low-frequency wavelets are broad.

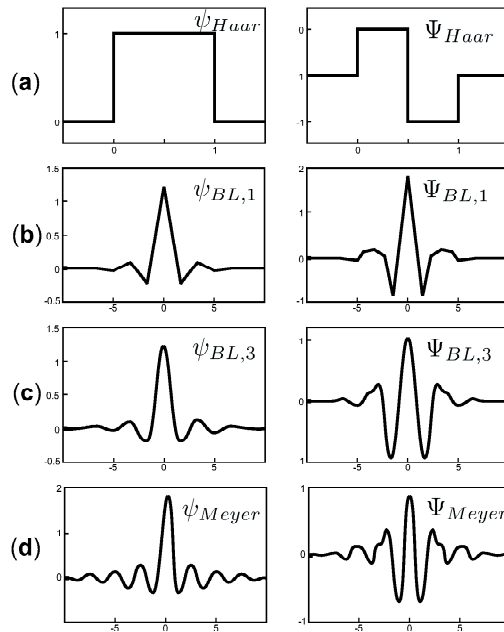

Fig. 5.5 Some wavelets and their scaling functions (adapted from Daubechies, 1992).

5.3.2 Continuous wavelet transform

For a function $f(x)$ in $L_2(\mathbb{R})$, the wavelet transform associated with the mother wavelet $\psi(x)$ is given by

$$[\mathcal{W}f](a, b) = (\psi_{a,b}(x), f(x)) = \frac{1}{\sqrt{|a|}} \int_{-\infty}^{\infty} dx \psi^* \left(\frac{x - b}{a} \right) f(x), \tag{5.77}$$

where $-\infty < a < \infty$ and $-\infty < b < \infty$.

The inverse wavelet transform, to be derived below, is given by

$$f(x) = \frac{1}{C_\psi} \int_{-\infty}^{\infty} \frac{da}{a^2} \int_{-\infty}^{\infty} db [\mathcal{W}f](a, b) \psi_{a,b}(x), \tag{5.78}$$

where the constant C_ψ is most easily defined in the Fourier domain:

$$C_\psi = \int_{-\infty}^{\infty} d\xi \frac{|\Psi(\xi)|^2}{|\xi|}. \tag{5.79}$$

The similarity of (5.78) to the corresponding result for the local Fourier transform, (5.40), should be noted.

For (5.78) to make sense, we must have

$$C_\psi < \infty. \tag{5.80}$$

This condition is known as the *admissibility condition* for the mother wavelet $\psi(x)$. To satisfy it in spite of the apparent singularity at $\xi = 0$, we must have $\Psi(0) = 0$, which implies that

$$\int_{-\infty}^{\infty} dx \psi(x) = 0. \tag{5.81}$$

The admissibility of the Haar wavelets can be verified from (5.75); the integrand in (5.79) is linear for small ξ , so there is no divergence at the origin.

Decomposition of the unit operator The inversion formula (5.78) is equivalent to

$$\frac{1}{C_\psi} \int_{-\infty}^{\infty} \frac{da}{a^2} \int_{-\infty}^{\infty} db \psi_{a,b}^*(x') \psi_{a,b}(x) = \delta(x - x'). \tag{5.82}$$

This equation is the decomposition of the unit operator in $\mathbb{L}_2(\mathbb{R})$ in terms of expansion functions of the wavelet operator \mathcal{W} , hence a statement of the completeness of those functions.

To derive (5.82), we express $\psi_{a,b}(x)$ in terms of its inverse Fourier transform. The integral in (5.82), denoted I , is then given by

$$\begin{aligned} I &= \int_{-\infty}^{\infty} \frac{da}{a^2} \int_{-\infty}^{\infty} db \psi_{a,b}^*(x') \psi_{a,b}(x) \\ &= \int_{-\infty}^{\infty} \frac{da}{|a|} \int_{-\infty}^{\infty} db \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\xi' \Psi^*(a\xi) \Psi(a\xi') \exp[2\pi i b(\xi - \xi')] \exp[2\pi i(\xi x - \xi' x')], \end{aligned} \tag{5.83}$$

where we have used (5.71). The integral over b yields $\delta(\xi - \xi')$ by (2.46), so

$$I = \int_{-\infty}^{\infty} \frac{da}{|a|} \int_{-\infty}^{\infty} d\xi |\Psi(a\xi)|^2 \exp[2\pi i \xi(x - x')]. \tag{5.84}$$

Letting $a' = 1/a$ and $\xi' = a\xi$, we find

$$I = \int_{-\infty}^{\infty} d\xi' |\Psi(\xi')|^2 \int_{-\infty}^{\infty} da' \exp[2\pi i a' \xi'(x - x')] = C_\psi \delta(x - x'), \tag{5.85}$$

where the last step has used (2.46), (2.29) and (5.79). From (5.85), the decomposition of the unit operator in (5.82) follows readily, and from there we get the wavelet inversion formula (5.78).

Reproducing-kernel of the continuous wavelet transform If $f(x)$ is in $\mathbb{L}_2(\mathbb{R})$, then it can be shown that $[\mathcal{W}f](a, b)$ is square-integrable with weight a^{-2} in the 2D a - b plane, so $[\mathcal{W}f](a, b)$ is in $\mathbb{L}_2(\mathbb{R}^2; a^{-2})$. Not every function in this space, however, can be realized by use of the operator \mathcal{W} on a function in $\mathbb{L}_2(\mathbb{R})$, so the space of realizable wavelet transforms is a subspace of $\mathbb{L}_2(\mathbb{R}^2; a^{-2})$. The reader who has perused Sec. 1.8 should expect this subspace to be a reproducing-kernel Hilbert space (Kaiser, 1994).

To find the reproducing kernel, we simply insert the unit operator on $\mathbb{L}_2(\mathbb{R})$, denoted \mathcal{I} , into the wavelet transform. Symbolically, we write

$$\mathcal{W}f = \mathcal{W}\mathcal{I}f. \tag{5.86}$$

The unit operator has kernel $\delta(x - x')$, which of course we express by means of (5.82). With the wavelet transform from (5.77) and some shuffling of integrals, we find that

$$[\mathcal{W}f](a', b') = \int_{-\infty}^{\infty} \frac{da}{a^2} \int_{-\infty}^{\infty} db K(a', b'; a, b) [\mathcal{W}f](a, b), \tag{5.87}$$

where

$$K(a', b'; a, b) = \frac{1}{C_\psi} \int_{-\infty}^{\infty} dx \psi_{a', b'}(x) \psi_{a, b}^*(x). \tag{5.88}$$

Thus the space of all realizable wavelet transforms is a reproducing-kernel Hilbert space with scalar product defined by the measure $a^{-2} da db$ and kernel given by (5.88).

5.3.3 Discrete wavelet transform

Orthonormal wavelets The discussion above shows that the set of all wavelets $\{\psi_{a, b}(x)\}$, $-\infty < a, b < \infty$, is complete for $\mathbb{L}_2(\mathbb{R})$ provided the mother wavelet is admissible. Like the elementary signals in the local Fourier transform, however, this set is overcomplete in the sense that some subset will form a basis. We can sample the wavelet transform and still have an invertible mapping.

A virtually universal sampling of the wavelet transform consists of *binary dilations* ($a = 2^{-j}$) and *dyadic translations* ($b = 2^{-j}k$). The resulting functions are

$$\psi_{jk}(x) = 2^{j/2} \psi(2^j x - k), \quad j, k \text{ integers}. \tag{5.89}$$

With certain conditions on $\psi(x)$, discussed below, every function in $\mathbb{L}_2(\mathbb{R})$ can be written as

$$f(x) = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} c_{jk} \psi_{jk}(x), \tag{5.90}$$

where convergence of this series is in $\mathbb{L}_2(\mathbb{R})$ (see Sec. 3.2.2). If we use the wavelet series in place of the original function $f(x)$, the \mathbb{L}_2 norm of the error converges to zero.

It is straightforward to find the coefficients in (5.90) if we use orthonormal wavelets, *i.e.*, a set $\{\psi_{jk}(x), j, k \text{ integers}\}$ satisfying

$$(\psi_{jk}, \psi_{j'k'}) = \int_{-\infty}^{\infty} dx \psi_{jk}^*(x) \psi_{j'k'}(x) = \delta_{jj'} \delta_{kk'}. \tag{5.91}$$

For orthonormal wavelets, the coefficients are scalar products (ψ_{jk}, \mathbf{f}) , which are samples of the continuous wavelet transform:

$$c_{jk} = [\mathcal{W}f](2^{-j}, 2^{-j}k). \tag{5.92}$$

The decomposition of the unit operator (or closure relation) for orthonormal wavelets is

$$\sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \psi_{jk}(x) \psi_{jk}^*(x') = \delta(x - x'). \tag{5.93}$$

The simplest example of orthonormal wavelets is the set derived from the Haar mother wavelet, but many other complete, orthonormal sets exist as well (Daubechies, 1992; Chui, 1992).

Frames For the continuous wavelet transform, any mother wavelet satisfying the admissibility condition can be used in (5.77) and (5.78). This transform pair is symmetric in the sense that the same function $\psi_{a,b}(x)$ is used in both the forward and the inverse transforms (though of course the variables of integration are different). For the discrete wavelet transform, somewhat stronger conditions must be placed on the choice of mother wavelet, and the forward and inverse transforms may involve different functions.

The theory that determines when an expansion like (5.90) exists, and allows us to find the coefficients, is the theory of *frames*. Frames, like bases, are building blocks of Hilbert space, allowing expansion of any vector in the space (Zayed, 1993). Frames for $\mathbb{L}_2(\mathbb{R})$ are generated from a single function by translations, dilations, modulations or some combination of these operations. Unlike basis functions, the functions that form a frame are not necessarily linearly independent; a frame may be an overcomplete set.

For a set of functions to constitute a frame in $\mathbb{L}_2(\mathbb{R})$, it must satisfy the *stability condition*, which states that there exist constants A and B independent of $f(x)$, with $0 < A \leq B < \infty$, such that

$$A\|\mathbf{f}\|^2 \leq \sum_{j,k} |(\psi_{jk}, \mathbf{f})|^2 \leq B\|\mathbf{f}\|^2, \tag{5.94}$$

for all $f(x)$. Function sets $\{\psi_{jk}(x)\}$ satisfying this condition are called frames, and the constants A and B are the *frame bounds*. If $A = B$, the frame is said to be *tight*. If $\{\psi_{jk}(x)\}$ is a complete orthonormal set, then $A = B = 1$ by Parseval's relation, (4.6).

Whenever (5.94) is satisfied, there exists a *dual frame* of functions $\{\overline{\psi}_{jk}(x)\}$ that are biorthogonal to $\{\psi_{jk}(x)\}$, *i.e.*,

$$(\overline{\psi}_{j'k'}, \psi_{jk}) = \delta_{jj'} \delta_{kk'}. \tag{5.95}$$

The expansion coefficients in (5.90) are then given by (Chui, 1992; Zayed, 1993)

$$c_{jk} = (\overline{\psi}_{jk}, \mathbf{f}). \tag{5.96}$$

We have already encountered two examples of dual frames. The functions $\{w_{mn}(x)\}$ in (5.44) are a dual frame to the Gabor expansion functions, and the reciprocal lattice is a dual frame to an ordinary lattice (see Secs. 4.4.6 and 5.1.5). For orthonormal frames, the dual frame is identical to the original one.

5.3.4 Multiresolution analysis

The completeness relations (5.90) and (5.93) require summation over both translations k and dilations j in order to represent an arbitrary function in $\mathbb{L}_2(\mathbb{R})$ by a discrete wavelet series. There is, however, a subset of functions in $\mathbb{L}_2(\mathbb{R})$ that can be represented by fixing j and summing only over k . This set of functions defines a Hilbert space, which we shall denote as \mathbb{W}_j , with a scalar product defined by

$$(f_{1j}(x), f_{2j}(x))_j = \sum_{k=-\infty}^{\infty} c_{1jk}^* c_{2jk}, \quad (5.97)$$

where c_{1jk} and c_{2jk} are the wavelet coefficients for $f_{1j}(x)$ and $f_{2j}(x)$, respectively, and we are considering only orthonormal wavelets.

Since any function in $\mathbb{L}_2(\mathbb{R})$ can be represented by summing the wavelet series over both j and k , it follows that any such function can be decomposed into a sum of functions, each of which is in one of the subspaces \mathbb{W}_j . Moreover, for orthonormal wavelets, these functions are mutually orthogonal, so the spaces \mathbb{W}_j are orthogonal subspaces of $\mathbb{L}_2(\mathbb{R})$. In formal language, this says that $\mathbb{L}_2(\mathbb{R})$ can be expressed as the *direct sum* of the subspaces \mathbb{W}_j . We thus write

$$\mathbb{L}_2(\mathbb{R}) = \cdots \oplus \mathbb{W}_{j-2} \oplus \mathbb{W}_{j-1} \oplus \mathbb{W}_j \oplus \mathbb{W}_{j+1} \oplus \cdots, \quad (5.98)$$

where \oplus denotes direct sum. A more transparent expression of the same mathematics is

$$f(x) = \sum_{j=-\infty}^{\infty} f_j(x), \quad f(x) \text{ in } \mathbb{L}_2(\mathbb{R}), \quad f_j(x) \text{ in } \mathbb{W}_j. \quad (5.99)$$

The component $f_j(x)$ is said to represent $f(x)$ at the scale 2^{-j} . Often in image analysis, it turns out that the important information about an object or a scene is contained in only a few scales.

Another way of decomposing $\mathbb{L}_2(\mathbb{R})$ is to lump together the subspaces \mathbb{W}_j , creating a cumulative space \mathbb{V}_j defined by

$$\mathbb{V}_j = \cdots \oplus \mathbb{W}_{j-2} \oplus \mathbb{W}_{j-1}. \quad (5.100)$$

Thus \mathbb{V}_j is spanned by wavelets $\{\psi_{ik}(x), i < j, -\infty < k < \infty\}$.

The function in \mathbb{V}_j corresponding to $f(x)$ is

$$f_{\mathbb{V}_j}(x) = \sum_{i=-\infty}^{j-1} f_i(x) = \sum_{i=-\infty}^{j-1} \sum_{k=-\infty}^{\infty} c_{ik} \psi_{ik}(x). \quad (5.101)$$

It follows from this equation that if some function $g(x)$ is in \mathbb{V}_j , then $g(2x)$ is in \mathbb{V}_{j+1} , and conversely.

The spaces \mathbb{V}_j , called *scaling subspaces*, are not orthogonal; \mathbb{V}_j is contained entirely in \mathbb{V}_{j+1} . The full set of scaling subspaces $\{\mathbb{V}_j\}$, with j being an integer ranging from $-\infty$ to ∞ , is said to form a *multiresolution ladder* of nested Hilbert spaces, and the sequence of functions $\{f_{\mathbb{V}_j}(x)\}$ is called the *multiresolution analysis* of

$f(x)$. As j increases, $f_{\mathbb{V}_j}(x)$ contains finer details and more closely approximates $f(x)$, i.e., $f_{\mathbb{V}_j}(x) \rightarrow f(x)$ in the \mathbb{L}_2 sense as $j \rightarrow \infty$.

The definition (5.100) of \mathbb{V}_j can also be written recursively as

$$\mathbb{V}_{j+1} = \mathbb{V}_j \oplus \mathbb{W}_j. \tag{5.102}$$

Since \mathbb{W}_j consists of wavelets with scale index j while \mathbb{V}_j consists of wavelets with scale index less than j , and we are assuming orthogonal wavelets, \mathbb{W}_j is the orthogonal complement of \mathbb{V}_j in \mathbb{V}_{j+1} . Thus any function in \mathbb{V}_{j+1} can be written uniquely as the sum of a function in \mathbb{W}_j and one in \mathbb{V}_j . This recursive characteristic leads to fast algorithms for multiresolution analysis.

Let us suppose that one of the scaling subspaces, say $j = 0$, can be generated by integer translates of a scaling function $\phi(x)$. In other words, \mathbb{V}_0 consists of all functions in $\mathbb{L}_2(\mathbb{R})$ that can be written as linear combinations of $\phi(x - k)$. Then, by (5.102), \mathbb{V}_1 consists of the functions in \mathbb{V}_0 supplemented by linear combinations of wavelets $\psi_{0k}(x)$. By (5.73), however,

$$\psi_{0k}(x) = \psi(x - k) = \sqrt{2} \sum_{n=0}^{2N-1} c_{N-1-n} \phi(2x - 2k - n). \tag{5.103}$$

Thus a function $f_{\mathbb{V}_1}(x)$ in \mathbb{V}_1 can be expressed as a linear combination of $\{\phi(x - k)\}$ and $\{\psi(x - k)\}$ for integer k . However, $\psi(x - k)$ itself can be expressed as a linear combination of $\{\phi(2x - k)\}$ since \mathbb{V}_0 is a subspace of \mathbb{V}_1 . It follows that all functions in \mathbb{V}_1 are linear combinations of $\{\phi(2x - k)\}$. Continuing this process up and down the ladder, we see that every scaling subspace \mathbb{V}_j is spanned by $\phi(2^j x - k)$ for integer k . We are thus led to define basis functions by analogy to (5.89) as

$$\phi_{jk}(x) = 2^{j/2} \phi(2^j x - k). \tag{5.104}$$

The set $\{\phi_{jk}(x), j \text{ fixed}, k \text{ an integer}\}$ is a basis for \mathbb{V}_j , though not necessarily an orthonormal one.

As a trivial example, suppose we wish to approximate a function $f(x)$ with a function in \mathbb{V}_J using Haar functions. The Haar scaling function is a rect function with width 1, so $\phi_{Jk}(x)$ has width 2^{-J} . Approximating $f(x)$ with a function in \mathbb{V}_J thus amounts to representing it with rectangles of this width. Similarly, a Haar wavelet expansion like (5.90) truncated at $j = J - 1$ allows for the finest detail to be a rectangle of width 2^{-J} .

More reproducing-kernel Hilbert spaces Each of the spaces \mathbb{V}_j is a reproducing-kernel Hilbert space (see Sec. 1.8). If we assume that \mathbb{V}_0 is spanned by integer translates of the scaling function $\phi(x)$, then the reproducing kernel for that subspace is (Walter, 1994)

$$h_0(x, x') = \sum_{k=-\infty}^{\infty} \phi(x - k) \phi^*(x' - k). \tag{5.105}$$

The reproducing kernel for \mathbb{V}_j is obtained from $h_0(x, x')$ by (Walter, 1994)

$$h_j(x, x') = 2^j h_0(2^j x, 2^j x'), \tag{5.106}$$

and the reproducing kernel for the wavelet subspace \mathbb{W}_j is given by

$$k_j(x, x') = 2^j \sum_{k=-\infty}^{\infty} \psi(2^j x - k) \psi^*(2^j x' - k). \tag{5.107}$$

The derivation of these kernels parallels the derivation of (5.87) but with sums replacing integrals.

6

Group Theory

Group theory is the mathematics of symmetry, and many imaging systems have symmetry properties. An ordinary circular lens, for example, is symmetric under arbitrary rotations about its optical axis, while a tomographic system with M equally spaced projections is symmetric under rotations of $2\pi/M$. A shift-invariant system, as the name implies, is symmetric with respect to translations. In this section we develop the tools needed to describe and exploit these symmetry properties. Sections 6.1 through 6.6 survey the mathematics, and Sec. 6.7 makes the connection with physics and image science. Section 6.8 then shows how group theory leads to an expanded understanding of familiar concepts such as convolution and Fourier transformation.

An excellent place to begin reading about symmetry and groups is the classic essay by Weyl (1952). Succinct introductions to the mathematics of group theory are given by Kanatani (1990), Margenau and Murphy (1956) and Messiah (1962). More complete treatments are found in Hamermesh (1989), Armstrong (1988), Fässler and Stiefel (1992), Lomont (1959) and numerous other texts.

6.1 BASIC CONCEPTS

6.1.1 Definition of a group

Subject to certain conditions listed below, a *group* is a set of elements and a combination rule referred to as *multiplication*. This rule must allow us to combine any ordered pair of elements and obtain a unique result called the *product* of the two elements, but it need not have any relation to more familiar kinds of multiplication.

We denote the elements of a group by boldface script letters; the group itself will be denoted by boldface block letters. Thus a group \mathbf{G} consists of elements \mathcal{G}_1 ,

$\mathcal{G}_2, \dots, \mathcal{G}_N$. The number of elements N is called the *order* of \mathbf{G} . The combination rule will be denoted by simple juxtaposition of elements, just as with ordinary algebraic multiplication. Thus $\mathcal{G}_m \mathcal{G}_n$ denotes the product of \mathcal{G}_m and \mathcal{G}_n .

In order for the elements $\{\mathcal{G}_n\}$ to form a group, the following conditions must be satisfied:

- (a) The product of any two elements in the group is an element in the group;
- (b) The product of any two elements in the group is unique;
- (c) Multiplication is associative: $(\mathcal{G}_i \mathcal{G}_j) \mathcal{G}_k = \mathcal{G}_i (\mathcal{G}_j \mathcal{G}_k)$;
- (d) There exists a unique identity element \mathcal{E} in the group such that $\mathcal{E} \mathcal{G}_n = \mathcal{G}_n \mathcal{E} = \mathcal{G}_n$ for all elements \mathcal{G}_n in the group;
- (e) Every element in the group has a unique inverse in the group, *i.e.*, for every element \mathcal{G}_n in the group, there is another element \mathcal{G}_n^{-1} in the group such that $\mathcal{G}_n \mathcal{G}_n^{-1} = \mathcal{G}_n^{-1} \mathcal{G}_n = \mathcal{E}$.

Two examples As a simple example of a group, consider the set of all integers (positive, negative and zero) and let the multiplication operation be arithmetic addition. This group satisfies the conditions listed above. The identity element is 0, the inverse of any integer n is $-n$, which is also an element of the group, and all possible products (sums) are members of the group. The order of this group is (countably) infinite.

As an example of a finite group, consider the complex numbers $\{1, i, -1, -i\}$ and let the multiplication rule be ordinary complex multiplication. Again, this set meets the requirements for a group. The identity element is the number 1, every possible product is an element of the group, and every element has an inverse in the group. For example, -1 is the inverse of 1, and $-i$ is the inverse of i . The order of this group is four, and it is frequently denoted as \mathbf{C}_4 .

6.1.2 Group multiplication tables

A convenient way to depict a finite group is by its *group multiplication table* in which an entry in row n and column m is the product $\mathcal{G}_n \mathcal{G}_m$. Since group elements are distinct, all entries in a row (or column) of a multiplication table must be distinct.

	1	i	-1	$-i$
1	1	i	-1	$-i$
i	i	-1	$-i$	1
-1	-1	$-i$	1	i
$-i$	$-i$	1	i	-1

(a)

	\mathcal{E}	\mathcal{R}_1	\mathcal{R}_2	\mathcal{R}_3
\mathcal{E}	\mathcal{E}	\mathcal{R}_1	\mathcal{R}_2	\mathcal{R}_3
\mathcal{R}_1	\mathcal{R}_1	\mathcal{R}_2	\mathcal{R}_3	\mathcal{E}
\mathcal{R}_2	\mathcal{R}_2	\mathcal{R}_3	\mathcal{E}	\mathcal{R}_1
\mathcal{R}_3	\mathcal{R}_3	\mathcal{E}	\mathcal{R}_1	\mathcal{R}_2

(b)

Fig. 6.1 Group multiplication table for the group \mathbf{C}_4 . In (a), the table is depicted for the set $\{1, i, -1, -i\}$, while in (b) it is depicted in abstract form.

The multiplication table for the group C_4 is shown in Fig. 6.1a, where the rows and columns are labelled by the group elements $(1, i, -1, -i)$. We can also denote the elements of C_4 abstractly as, say, $(\mathcal{E}, \mathcal{R}_1, \mathcal{R}_2, \mathcal{R}_3)$ rather than $(1, i, -1, -i)$. The group multiplication table in this notation is reproduced in Fig. 6.1b.

An advantage of the abstract notation is that very different physical entities may have the same group properties. In many applications in physics and image science, for example, group elements refer to geometrical transformations. In C_4 we can think of \mathcal{R}_1 as a 90° rotation, \mathcal{R}_2 as a 180° rotation, and \mathcal{R}_3 as a 270° rotation. Then \mathcal{E} is either no rotation or a 360° one. The product of two such rotations, say $\mathcal{R}_n \mathcal{R}_m$, is interpreted as the rotation \mathcal{R}_m followed by \mathcal{R}_n . For example, $\mathcal{R}_1 \mathcal{R}_3$ is a 270° rotation followed by a 90° one, which is the identity. In this way it is easy to verify that the multiplication table in Fig. 6.1b, originally derived for complex multiplications of the element $\{1, i, -1, -i\}$, holds also for physical rotations of a square. This equivalence is hardly surprising when we recall the Argand representation of a complex number, discussed in App. B, but it does emphasize that the essence of a group is the multiplication table, not the physical interpretation of the elements.

Group multiplication is not necessarily commutative. It may happen that $\mathcal{G}_n \mathcal{G}_m \neq \mathcal{G}_m \mathcal{G}_n$ for one or more pairs of elements in the group. On the other hand, if the group is commutative, then it has some special properties discussed below, and it is given a special name: a commutative group is said to be *Abelian*. The group C_4 is Abelian.

An example of a non-Abelian group is D_3 , defined by the multiplication table of Fig. 6.2. For reasons that will appear in Sec. 6.4, the elements of this group are designated as $\{\mathcal{E}, \mathcal{R}_1, \mathcal{R}_2, \mathcal{M}_1, \mathcal{M}_2, \mathcal{M}_3\}$. The multiplication table shows that $\mathcal{M}_1 \mathcal{M}_2 = \mathcal{R}_2$, for example, but $\mathcal{M}_2 \mathcal{M}_1 = \mathcal{R}_1$, so the elements do not commute.

	\mathcal{E}	\mathcal{R}_1	\mathcal{R}_2	\mathcal{M}_1	\mathcal{M}_2	\mathcal{M}_3
\mathcal{E}	\mathcal{E}	\mathcal{R}_1	\mathcal{R}_2	\mathcal{M}_1	\mathcal{M}_2	\mathcal{M}_3
\mathcal{R}_1	\mathcal{R}_1	\mathcal{R}_2	\mathcal{E}	\mathcal{M}_2	\mathcal{M}_3	\mathcal{M}_1
\mathcal{R}_2	\mathcal{R}_2	\mathcal{E}	\mathcal{R}_1	\mathcal{M}_3	\mathcal{M}_1	\mathcal{M}_2
\mathcal{M}_1	\mathcal{M}_1	\mathcal{M}_3	\mathcal{M}_2	\mathcal{E}	\mathcal{R}_2	\mathcal{R}_1
\mathcal{M}_2	\mathcal{M}_2	\mathcal{M}_1	\mathcal{M}_3	\mathcal{R}_1	\mathcal{E}	\mathcal{R}_2
\mathcal{M}_3	\mathcal{M}_3	\mathcal{M}_2	\mathcal{M}_1	\mathcal{R}_2	\mathcal{R}_1	\mathcal{E}

Fig. 6.2 Group multiplication table for the group D_3 , the symmetry group of an equilateral triangle.

6.1.3 Isomorphism and homomorphism

We saw above that the set of numbers $\{1, i, -1, -i\}$ and the set of rotations of a square have the same multiplication table. We can say that the two sets are two different physical realizations of the same group C_4 , or in more formal language we can say that the two groups are *isomorphic*. Two groups G and G' of order N are isomorphic if there exists a one-to-one correspondence that preserves the multiplication table (Margenau and Murphy, 1956), *i.e.*,

- (a) To each element \mathcal{G}_j of \mathbf{G} , there corresponds one and only one element \mathcal{G}'_j of \mathbf{G}' , and conversely;
- (b) $\mathcal{G}_i\mathcal{G}_j = \mathcal{G}_k$ implies that $\mathcal{G}'_i\mathcal{G}'_j = \mathcal{G}'_k$ for all $i, j, k = 1, \dots, N$, and conversely.

A related concept is *homomorphism*. A group \mathbf{G} is homomorphic to \mathbf{G}' if:

- (a) To each element \mathcal{G}_j of \mathbf{G} , there corresponds one and only one element \mathcal{G}'_j of \mathbf{G}' , and to each element \mathcal{G}'_j of \mathbf{G}' , there corresponds at least one (and perhaps more than one) element of \mathbf{G} .
- (b) $\mathcal{G}_i\mathcal{G}_j = \mathcal{G}_k$ implies that $\mathcal{G}'_i\mathcal{G}'_j = \mathcal{G}'_k$ for all $i, j, k = 1, \dots, N$, but the converse doesn't necessarily hold.

Thus isomorphism is homomorphism that is one-to-one and onto (see Sec. 1.3.4).

6.2 SUBGROUPS AND CLASSES

6.2.1 Definitions

A *subgroup* of a group \mathbf{G} is a subset of the elements of \mathbf{G} that itself constitutes a group under the same multiplication rule as for \mathbf{G} . For example, $(1, -1)$ is a subgroup of $(1, i, -1, -i)$ under complex multiplication. Since every group must contain the identity element, that element is a member of every subgroup, and the identity by itself is a subgroup of order one for any group.

Groups can be uniquely partitioned into *conjugacy classes*, or simply *classes* for short. To define a conjugacy class, we must first define conjugacy (from the Latin *conjugare*, to yoke together). Two elements \mathcal{G}_n and \mathcal{G}_m in a group \mathbf{G} are said to be *conjugate* to each other if there exists an element \mathcal{G}_k in \mathbf{G} such that

$$\mathcal{G}_k^{-1}\mathcal{G}_n\mathcal{G}_k = \mathcal{G}_m. \quad (6.1)$$

In this equation, \mathcal{G}_m is called the *transform* of \mathcal{G}_n by \mathcal{G}_k .

Conjugate elements have the following properties (Margenau and Murphy, 1956):

- (a) Every element in a group is conjugate with itself;
- (b) If \mathcal{G}_n is conjugate to \mathcal{G}_m , then \mathcal{G}_m is conjugate to \mathcal{G}_n ;
- (c) If \mathcal{G}_n is conjugate to both \mathcal{G}_m and \mathcal{G}_p , then \mathcal{G}_m and \mathcal{G}_p are conjugate to each other.

A class is a complete set of elements that are conjugate to each other. The union of all classes is the group itself, and no element can appear in more than one class.

6.2.2 Examples

To see how to decompose a group into its classes, we examine the groups \mathbf{C}_4 and \mathbf{D}_3 , with multiplication tables given by Figs. 6.1 and 6.2, respectively.

In an Abelian group like \mathbf{C}_4 , all elements commute, and it follows at once that

$$\mathcal{G}_k^{-1}\mathcal{G}_n\mathcal{G}_k = \mathcal{G}_n\mathcal{G}_k^{-1}\mathcal{G}_k = \mathcal{G}_n. \quad (6.2)$$

Thus each element is transformed only into itself, so an Abelian group of order N can always be decomposed into N classes of one element each. Hence \mathbf{C}_4 consists of 4 classes.

Since \mathbf{D}_3 is not Abelian, its classes are more interesting. The identity element \mathcal{E} commutes with all other elements, so it forms a class by itself. There is also a class consisting of \mathcal{R}_1 and \mathcal{R}_2 since

$$\begin{aligned} \mathcal{E}^{-1}\mathcal{R}_1\mathcal{E} &= \mathcal{R}_1, & \mathcal{R}_1^{-1}\mathcal{R}_1\mathcal{R}_1 &= \mathcal{R}_1, & \mathcal{R}_2^{-1}\mathcal{R}_1\mathcal{R}_2 &= \mathcal{R}_1, \\ \mathcal{M}_1^{-1}\mathcal{R}_1\mathcal{M}_1 &= \mathcal{R}_2, & \mathcal{M}_2^{-1}\mathcal{R}_1\mathcal{M}_2 &= \mathcal{R}_2, & \mathcal{M}_3^{-1}\mathcal{R}_1\mathcal{M}_3 &= \mathcal{R}_2. \end{aligned} \quad (6.3)$$

A similar argument shows that $\{\mathcal{M}_1, \mathcal{M}_2, \mathcal{M}_3\}$ forms a class. Thus \mathbf{D}_3 can be decomposed into three classes, one each with 1, 2 and 3 elements.

6.3 GROUP REPRESENTATIONS

6.3.1 Matrices that obey the multiplication table

Given a group multiplication table, it is always possible to find a set of square matrices (not necessarily distinct) that behave in the same way under ordinary matrix multiplication. This set of matrices is called a *representation* of the group. Explicitly, a set of nonsingular $K \times K$ matrices $\{\mathbf{M}(\mathcal{G}_n), n = 1, \dots, N\}$ is a representation of the group $\mathbf{G} = \{\mathcal{G}_n, n = 1, \dots, N\}$ if

$$\mathbf{M}(\mathcal{G}_n)\mathbf{M}(\mathcal{G}_m) = \mathbf{M}(\mathcal{G}_n\mathcal{G}_m). \quad (6.4)$$

The order K of the matrices is referred to as the *dimensionality*¹ of the representation.

If the mapping of group elements to matrices is an isomorphism, the representation is *faithful*, which is possible only if all of the matrices are distinct. If a new representation is formed by applying a similarity transformation to each matrix in a representation, the two representations are said to be *equivalent*.

A trivial KD representation of any group of order N is a set of N $K \times K$ unit matrices. This set satisfies the multiplication table for any group, but it is clearly not faithful. Since K is arbitrary, an infinite set of (trivial) group representations can be constructed in this way.

As a more interesting example, \mathbf{C}_4 can be represented by

$$\begin{aligned} \mathbf{M}(\mathcal{E}) &= \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, & \mathbf{M}(\mathcal{R}_1) &= \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}, \\ \mathbf{M}(\mathcal{R}_2) &= \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}, & \mathbf{M}(\mathcal{R}_3) &= \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}. \end{aligned} \quad (6.5)$$

It can be verified that this set of matrices follows the multiplication table of Fig. 6.1. In this example, $K = 2$, so the representation is two-dimensional.

¹This is yet another meaning of the term *dimension*. For some others, see Sec. 2.4.6.

6.3.2 Irreducible representations

A $K \times K$ matrix $\mathbf{M}_{K \times K}$ is said to be in *lower-block-triangular form* if

$$\mathbf{M}_{K \times K} = \begin{bmatrix} \mathbf{M}_{Q \times Q} & \mathbf{0}_{Q \times P} \\ \mathbf{M}_{P \times Q} & \mathbf{M}_{P \times P} \end{bmatrix}, \quad (6.6)$$

where $\mathbf{M}_{Q \times Q}$, $\mathbf{M}_{P \times Q}$ and $\mathbf{M}_{P \times P}$ are matrices with dimensions indicated by the subscripts, $P + Q = K$, and $\mathbf{0}_{Q \times P}$ is a $Q \times P$ matrix of all zeros. Similarly, the matrix is said to be in *upper-block-triangular form* if the block of zeros is in the lower left corner. If $\mathbf{M}_{P \times Q}$ can be made zero, the matrix is *block-diagonal*.

A matrix representation of a group $\{\mathbf{M}(\mathcal{G}_n)\}$ is *reducible* if there exists a similarity transformation \mathbf{S} such that $\mathbf{S}^{-1}\mathbf{M}(\mathcal{G}_n)\mathbf{S}$ is block-triangular (with the same P and Q) for all n . The representation is said to be *fully reducible* if there is a similarity transformation that transforms all of the matrices into block-diagonal form.

A representation that is not reducible is said to be *irreducible*, and irreducible representations will turn out to be crucial in physical applications of group theory. A 1D representation is irreducible, of course.

Example The 2D representation of \mathbf{C}_4 in (6.5) is fully reducible. If we let

$$\mathbf{S} = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & i \\ i & 1 \end{bmatrix}, \quad (6.7)$$

then the four matrices in (6.5) transform to

$$\begin{aligned} \mathbf{S}^{-1}\mathbf{M}(\mathcal{E})\mathbf{S} &= \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, & \mathbf{S}^{-1}\mathbf{M}(\mathcal{R}_1)\mathbf{S} &= \begin{bmatrix} i & 0 \\ 0 & -i \end{bmatrix}, \\ \mathbf{S}^{-1}\mathbf{M}(\mathcal{R}_2)\mathbf{S} &= \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}, & \mathbf{S}^{-1}\mathbf{M}(\mathcal{R}_3)\mathbf{S} &= \begin{bmatrix} -i & 0 \\ 0 & i \end{bmatrix}. \end{aligned} \quad (6.8)$$

Since each of these matrices is block-diagonal (with 1×1 blocks), we can read off two new 1D representations. The upper-left blocks are, in sequence, (1), (i), (-1), ($-i$), and this set of scalars satisfies the multiplication table. (In fact, it is precisely the set we used to define the group in the first place.) Similarly, the lower-right blocks in (6.8) give (1), ($-i$), (-1), (i), and this set also satisfies the multiplication table. Two other 1D representations of \mathbf{C}_4 are: (1), (1), (1), (1); and (1), (-1), (1), (-1).

How many irreducible representations are there? There are some rules that let us deduce the number of irreducible representations of a group and the dimensionality of each without actually finding the representations. Derivations of these rules are given in any standard text on group theory (*e.g.*, Hamermesh, 1989).

The first rule is that the number of nonequivalent irreducible representations is also the number of conjugacy classes in the group. If we have partitioned the group into classes, we know immediately how many irreducible representations there are. For example, we saw above that an Abelian group of order N has N classes, so it also has N irreducible representations. In the case of \mathbf{C}_4 , $N = 4$, and the four irreducible representations are enumerated above just after (6.8).

Another useful rule is an algebraic one: If a group \mathbf{G} of order N has M irreducible representations, and the m^{th} such representation has dimensionality N_m , then it can be shown that (Hamermesh, 1989)

$$\sum_{m=1}^M N_m^2 = N. \quad (6.9)$$

When applied to an Abelian group, for which $M = N$, this constraint shows that all irreducible representations must be 1D since (6.9) can be satisfied only if $N_m = 1$ for all m .

On the other hand, if the number of classes M is less than the order N , then at least one of the irreducible representations must have a dimensionality greater than 1. For example, we know that \mathbf{D}_3 has six elements but only three classes. In this case, (6.9) is sufficient to completely determine the dimensionalities of all three irreducible representations. There is only one combination of three integers such that the sum of their squares is 6, namely $1^2 + 1^2 + 2^2 = 6$, so \mathbf{D}_3 must have one 2D irreducible representation and two 1D ones.

6.3.3 Characters

If the set of $K \times K$ matrices $\{\mathbf{M}(\mathcal{G}_n)\}$ constitutes a representation of a group \mathbf{G} , then the *character* of \mathcal{G}_n in this representation, denoted $\chi(\mathcal{G}_n)$, is the trace of the corresponding matrix:

$$\chi(\mathcal{G}_n) = \text{tr} \{\mathbf{M}(\mathcal{G}_n)\} = \sum_{k=1}^K M_{kk}(\mathcal{G}_n). \quad (6.10)$$

The trace of a square matrix is unchanged by similarity transformations, so equivalent representations have the same sets of characters. For the same reason, elements in the same conjugacy class have the same characters in any given representation.

A matrix representation is irreducible if and only if the sum of the squares of the characters equals the order of the group, *i.e.*,

$$\sum_{n=1}^N |\chi(\mathcal{G}_n)|^2 = N. \quad (6.11)$$

When it is necessary to distinguish characters arising from different representations, we shall use a superscript in parentheses. Thus $\chi^{(m)}(\mathcal{G}_n)$ is the character of element \mathcal{G}_n in the m^{th} representation. Most texts on group theory include *character tables*, listing the character $\chi^{(m)}(\mathcal{G}_n)$ associated with each group element \mathcal{G}_n for each irreducible representation.

6.3.4 Unitary irreducible representations and orthogonality properties

We now state without proof two classical theorems attributed to Schur and Frobenius. For the proofs, see Schensted (1976), Margenau and Murphy (1956) or Hamermesh (1989).

The first theorem says that any irreducible representation of a group can be transformed into a unitary representation by means of a similarity transformation. That is, it is possible to find a matrix \mathbf{S} such that $\mathbf{S}^{-1}\mathbf{M}(\mathcal{G}_n)\mathbf{S}$ is unitary for all n . This theorem allows us to work with unitary irreducible representations at will. Since similarity transformations do not affect traces, all of the results above on characters still apply if we choose to make the irreducible representations unitary.

The second theorem states that unitary irreducible representations have a powerful orthogonality property. Let $\{\mathbf{M}^{(m)}(\mathcal{G}_n)\}$ and $\{\mathbf{M}^{(m')}(\mathcal{G}_n)\}$ be the unitary irreducible representations m and m' , respectively, with dimensionalities N_m and $N_{m'}$. Then it can be shown (Hamermesh, 1989, Chap. 3) that

$$\sum_{n=1}^N \left[M_{ij}^{(m)}(\mathcal{G}_n) \right]^* M_{kl}^{(m')}(\mathcal{G}_n) = \frac{N}{N_m} \delta_{mm'} \delta_{ik} \delta_{jl}. \tag{6.12}$$

Summing a product of matrix *elements* for unitary irreducible representations over the group elements thus yields zero unless they are exactly corresponding elements from the *same* irreducible representation.

For fixed i, j and m , we can think of the set of numbers $\{M_{ij}^{(m)}(\mathcal{G}_n), n = 1, \dots, N\}$ as a vector $\mathbf{m}_{ij}^{(m)}$, so that (6.12) is the scalar product between $\mathbf{m}_{ij}^{(m)}$ and $\mathbf{m}_{kl}^{(m')}$. With this view, it might appear that there are too many orthogonality relations implied by (6.12) since there are at most N orthogonal vectors in an ND space. For each m , there are N_m^2 combinations of i and j and hence that many different vectors $\mathbf{m}_{ij}^{(m)}$, and we must also allow m to vary. From (6.9), however, we see that there are N different vectors $\mathbf{m}_{ij}^{(m)}$, so (6.12) is plausible.

If we let $i = j$ and $k = l$ in (6.12) and sum over i and k , we get an orthogonality relation for the characters:

$$\sum_{n=1}^N \left[\chi^{(m)}(\mathcal{G}_n) \right]^* \chi^{(m')}(\mathcal{G}_n) = N \delta_{mm'}, \tag{6.13}$$

in agreement with (6.11) if $m = m'$.

The orthogonality relations (6.12) and (6.13) pair up matrices or characters associated with the same group element \mathcal{G}_n . It is natural to inquire if there is any orthogonality relation involving different elements. For example, is there an orthogonality relation involving $\chi^{(m)}(\mathcal{G}_n)$ and $\chi^{(m)}(\mathcal{G}_k)$? In general, the answer to this question must be no since elements in the same class have the same characters, but there is an important orthogonality relation if we restrict \mathcal{G}_n and \mathcal{G}_k to be in different classes. For an Abelian group, this is no restriction at all since each class consists of one element.

Let L_j be the number of elements in the j^{th} class, and denote the character of all of these elements in the m^{th} unitary irreducible representation by $\chi_j^{(m)}$. Let M denote the number of (nonequivalent) irreducible representations, which is also the number of classes. Hamermesh (1989) proves the following relations:

$$\sum_{j=1}^M L_j \left[\chi_j^{(m)} \right]^* \chi_j^{(m')} = N \delta_{mm'}. \tag{6.14}$$

$$\sum_{m=1}^M \left[\chi_j^{(m)} \right]^* \chi_k^{(m)} = \frac{N}{L_j} \delta_{jk}. \tag{6.15}$$

These matrix orthogonality relations will lead to corresponding orthogonality relations on certain *functions* when we discuss group transformations on Hilbert spaces in Sec. 6.6.

6.4 SOME FINITE GROUPS

We now expand our repertoire of groups, introducing several new ones that are important in physics and image science.

6.4.1 Cyclic groups

A cyclic group is one in which all elements, including the identity, can be generated from one basic element by raising it to various powers. The cyclic group of order N is denoted \mathbf{C}_N , and we have already studied the special case $N = 4$. If the basic element is denoted \mathcal{R} , then \mathbf{C}_N consists of elements

$$\mathcal{R}_n = \mathcal{R}^n, \quad n = 1, \dots, N, \quad \mathcal{R}^N = \mathcal{E}. \quad (6.16)$$

Since \mathcal{R} can be interpreted as rotation by an angle of $2\pi/N$, \mathbf{C}_N is also called the *N -fold rotation group*.

It follows from (6.16) that \mathbf{C}_N is Abelian for all N , so it has N classes and N irreducible representations, all 1D. We can label these representations by an index $m = 1, \dots, N$. The character of \mathcal{R}_n in the m^{th} irreducible representation is

$$\chi^{(m)}(\mathcal{R}_n) = \exp(-2\pi i m n / N), \quad (6.17)$$

which we recognize immediately as the kernel of the discrete Fourier transform (see Sec. 6.8.4 for more on this connection). The orthogonality relation (6.13) becomes

$$\sum_{n=1}^N \exp\left[-2\pi i \frac{(m - m')n}{N}\right] = N \delta_{mm'}, \quad (6.18)$$

which we have encountered in the discussion of the DFT [*cf.* (3.327) and (3.328)].

The cyclic group of order 2 is called the *inversion group*. The elements are frequently denoted $\{\mathcal{E}, \mathcal{I}\}$ with the multiplication table shown in Fig. 6.3. The two elements in this group are the identity \mathcal{E} and the inversion² \mathcal{I} . The irreducible representations of this group are $\{1, 1\}$ and $\{1, -1\}$.

	\mathcal{E}	\mathcal{I}
\mathcal{E}	\mathcal{E}	\mathcal{I}
\mathcal{I}	\mathcal{I}	\mathcal{E}

Fig. 6.3 Group multiplication table for the group \mathbf{C}_2 , known either as the cyclic group of order 2 or the inversion group.

²Do not confuse the inversion \mathcal{I} with the identity operator, which we also call \mathcal{I} elsewhere in this book. By convention, the identity operator is denoted by the letter E (for German *Einheit*) in group theory, and we use the script \mathcal{E} .

6.4.2 Dihedral groups

Geometrically, the dihedral group \mathbf{D}_N is the set of transformations that leave a regular N -gon (polygon with N sides) unchanged. The example we have used above, \mathbf{D}_3 , is the symmetry group of an equilateral triangle. This figure is unchanged by a rotation of 120° , so the group includes two rotation operators, but it also includes three mirror reflection operators, one passing through each vertex. The mirror operators are the ones designated as \mathcal{M}_n , $n = 1-3$, in Fig. 6.2. The six operators can be divided into three classes, so there are three irreducible representations. Two of the irreducible representations are 1D and one is 2D.

The dihedral group \mathbf{D}_4 is the symmetry group of a square. It includes three rotations (90° , 180° , and 270°) as well as four mirror reflections. With the identity operator, this makes a total of 8 elements. This group has five classes, hence five irreducible representations (four 1D and one 2D).

In general, the dihedral group of order $2N$ (which is denoted \mathbf{D}_N here but \mathbf{D}_{2N} in some books), has $\frac{1}{2}(N+3)$ classes if N is odd and $\frac{1}{2}N+3$ classes if N is even. For odd N there are always two 1D irreducible representations, and for even N there are four 1D ones; in both cases, all of the remaining irreducible representations are 2D (James and Liebeck, 1993). The cyclic group \mathbf{C}_N is always a subgroup of \mathbf{D}_N .

6.5 CONTINUOUS GROUPS

6.5.1 Basic properties

Consider the limit of the cyclic group \mathbf{C}_N as $N \rightarrow \infty$. Since a circle is the limit of a regular polygon as the number of sides tends to ∞ , \mathbf{C}_∞ is the group of rotations that leave a circle unchanged. Instead of labeling the rotation operator with a discrete index n in this case, it is convenient to use a continuous label θ , specifying the rotation angle. Thus the group \mathbf{C}_∞ consists of the set of operators $\{\mathcal{R}(\theta), 0 \leq \theta < 2\pi\}$.

Other kinds of continuous groups are also important in various physical applications. A general affine linear transformation of a real number to another real number, for example, is given by $x' = ax + b$. The group of all such transformations is a *two-parameter continuous group*, where a group element is specified by an ordered pair (a, b) and written $\mathcal{G}(a, b)$. Generalizing, we can write an element of a k -parameter continuous group as $\mathcal{G}(\theta)$, where θ is a k D parameter vector.

The requirements for these elements to form a group are directly analogous to those for discrete groups (Hamermesh, 1989):

- (a) There must be a parameter value θ_0 such that $\mathcal{G}(\theta_0)$ is the identity element \mathcal{E} , *i.e.*, $\mathcal{G}(\theta_0)\mathcal{G}(\theta) = \mathcal{G}(\theta)\mathcal{G}(\theta_0) = \mathcal{G}(\theta)$.
- (b) For each value θ , there must be a corresponding value $\bar{\theta}$ such that $\mathcal{G}(\theta)\mathcal{G}(\bar{\theta}) = \mathcal{G}(\bar{\theta})\mathcal{G}(\theta) = \mathcal{G}(\theta_0) = \mathcal{E}$.
- (c) The product of any two elements must be a member of the group. In other words, for any pair of parameter vectors θ_1 and θ_2 , it must be possible to find another vector $\theta_3 = f(\theta_1, \theta_2)$ such that $\mathcal{G}(\theta_1)\mathcal{G}(\theta_2) = \mathcal{G}(\theta_3)$.

In point (c), if we require $f(\theta_1, \theta_2)$ to be infinitely differentiable with respect to the components of θ_1 and θ_2 , the group is said to be a *Lie group*.

6.5.2 Linear, orthogonal and unitary groups

The *general linear group* or *full linear group* $\mathbf{L}(N)$ on an N D space is the set of all nonsingular $N \times N$ matrices. For $N = 2$, for example, a general linear mapping from $(x, y)^t$ to $(x', y')^t$ is given by

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix}. \quad (6.19)$$

If the matrix elements are real and chosen so that the matrix is invertible, then this transformation is an element of the four-parameter group denoted $\mathbf{L}(2)$. The group operation is 2×2 matrix multiplication, and it is easy to show that $\mathbf{L}(2)$ is a Lie group.

If we add the further condition that the determinant of the transformation matrix be one, $\mathbf{L}(N)$ is known as the *special linear group* of order N , denoted $\mathbf{SL}(N)$. The term *special* in this context indicates simply unit determinant. The group $\mathbf{SL}(2)$ is a 3-parameter continuous group since the condition on the determinant eliminates one of the free parameters.

As discussed in App. A (Sec. A.3.2), an $N \times N$ matrix is called *unitary* if its adjoint equals its inverse. A unitary matrix with real elements is referred to as an *orthogonal* matrix. An orthogonal matrix has determinant ± 1 ; a unitary matrix can have a complex determinant, but its modulus is necessarily one. The group of all unitary $N \times N$ matrices is called $\mathbf{U}(N)$, and the corresponding group of orthogonal matrices is called $\mathbf{O}(N)$. The group of unitary matrices with determinant $+1$ is $\mathbf{SU}(N)$ (for *special unitary* group), and the group of orthogonal matrices with determinant $+1$ is $\mathbf{SO}(N)$. Since an orthogonal $N \times N$ matrix performs a pure rotation on an $N \times 1$ vector, $\mathbf{SO}(N)$ is the rotation group in N dimensions.

6.5.3 Abelian and non-Abelian Lie groups

Like finite groups, continuous groups are termed Abelian if all elements commute. The 2D rotation group \mathbf{C}_∞ is Abelian since $\mathcal{R}(\theta_1)\mathcal{R}(\theta_2) = \mathcal{R}(\theta_2)\mathcal{R}(\theta_1) = \mathcal{R}(\theta_1 + \theta_2)$. The 3D rotation group $\mathbf{SO}(3)$, on the other hand, is not Abelian since a rotation of θ around the x axis followed by a rotation of ϕ around the z axis does not yield the same point as a rotation of ϕ around the z axis followed by a rotation of θ around the x axis.

Even in 2D, the full symmetry group of a disk is not Abelian. This group includes all of the rotations in \mathbf{C}_∞ , but it also includes *improper rotations*, which include inversions. In 2D, a pure rotation can be represented by a 2×2 matrix of real entries with determinant $= 1$. Improper rotations enlarge this group to allow determinant $= -1$. In general, an element of the 2D rotation-inversion group can be represented by (Margenau and Murphy, 1956)

$$\mathbf{M}(\theta, d) = \begin{bmatrix} \cos \theta & \sin \theta \\ -d \sin \theta & d \cos \theta \end{bmatrix}, \quad (6.20)$$

where $d = 1$ for proper rotations and -1 for improper ones. The simplest improper rotation is inversion through the origin, which is described by $\mathbf{M}(\pi, -1)$. It is easy to see that $\mathbf{M}(\theta, 1)$ and $\mathbf{M}(\theta', -1)$ do not commute.

The 1D affine group is another example of a Lie group that is not Abelian (Hamermesh, 1989). An element of this two-parameter group transforms a point x on the real line to another point x' according to

$$x' = \mathcal{S}(a, b)x = ax + b. \quad (6.21)$$

The group multiplication rule is

$$\mathcal{S}(a', b') \mathcal{S}(a, b)x = a'(ax + b) + b' = \mathcal{S}(a'a, a'b + b')x, \quad (6.22)$$

which is not the same thing as $\mathcal{S}(a, b) \mathcal{S}(a', b')x$. The set of pure translation operators $\{\mathcal{S}(1, b)\}$ does, however, form an Abelian subgroup of the 1D affine group. Likewise, the *scale group* $\{\mathcal{S}(a, 0)\}$ (also called the *dilation group*) is an Abelian subgroup of the affine group.

Continuous one-parameter Abelian groups such as \mathbf{C}_∞ have an infinite number of 1D irreducible representations, and no other finite-dimensional³ irreducible representations. As with finite Abelian groups, the characters are identical with the irreducible representations. If we impose the reasonable condition that the representations be single valued, then the set of irreducible representations is denumerably infinite and can be labelled with a single integer m . For \mathbf{C}_∞ , the character associated with $\mathcal{R}(\theta)$ in representation m will be denoted $\chi^{(m)}(\theta)$; by analogy to (6.17), it is given by

$$\chi^{(m)}(\theta) = e^{-im\theta}, \quad m = 0, \pm 1, \pm 2, \dots \quad (6.23)$$

Determination of irreducible representations and characters for non-Abelian Lie groups is much more complicated, leading to discussion of Lie algebras, infinitesimal generators and commutators, all of which are beyond our present needs. An excellent reference on these topics is Hamermesh (1989).

6.6 GROUPS OF OPERATORS ON A HILBERT SPACE

So far we have considered groups of geometrical transformations such as rotations, translations and mirror reflections. These transformations map one point in a Euclidean space to another, say $\mathbf{r} \rightarrow \mathbf{r}'$, where \mathbf{r} and \mathbf{r}' are both vectors in \mathbb{R}^2 . In Sec. 6.6.1 we shall see how to connect these geometrical transformations to transformations of a function $f(\mathbf{r})$ that itself maps \mathbb{R}^2 to \mathbb{R}^1 or \mathbb{C}^1 . If the functions in question live in a Hilbert space, we can relate a group of geometrical operators to a group of operators in the Hilbert space. Subspaces of this Hilbert space are discussed in Secs. 6.6.2 and 6.6.3, and some useful orthogonality relations are derived in Sec. 6.6.4.

Other operators on a Hilbert space, including various integral transforms, have been introduced previously, and the mathematics discussed here is equally applicable to these kinds of operators whenever a useful group can be identified. A connection between geometrical transformations and other Hilbert-space operators will be given in Sec. 6.7, and integral transforms will be explored further in Sec. 6.8.

³Some one-parameter Lie groups also have infinite-dimensional irreducible representations, though \mathbf{C}_∞ does not.

6.6.1 Geometrical transformations of functions

The connection between geometrical transformations and associated transformations of functions is straightforward. A nonsingular geometrical operator \mathcal{G} maps a point \mathbf{r} to a new point $\mathbf{r}' = \mathcal{G}\mathbf{r}$. A transformed function $f'(\mathbf{r}')$ is defined by assigning it the value at point \mathbf{r}' that the original function had at point \mathbf{r} , *i.e.*, $f'(\mathcal{G}\mathbf{r}) = f(\mathbf{r})$. The functional transformation operator \mathcal{T} corresponding to the geometrical operator \mathcal{G} is thus

$$\mathcal{T}f(\mathbf{r}) = f'(\mathbf{r}) = f(\mathcal{G}^{-1}\mathbf{r}). \quad (6.24)$$

If we have a group of geometrical operators $\{\mathcal{G}_n\}$, we can define a corresponding group of functional operators $\{\mathcal{T}_n\}$ simply by adding subscripts in (6.24). There is an isomorphism between $\{\mathcal{T}_n\}$ and $\{\mathcal{G}_n\}$; the multiplication rule for the set $\{\mathcal{T}_n\}$ is the same as the one for $\{\mathcal{G}_n\}$ since

$$\mathcal{T}_m \mathcal{T}_n f(\mathbf{r}) = f(\mathcal{G}_n^{-1} \mathcal{G}_m^{-1} \mathbf{r}) = f[(\mathcal{G}_m \mathcal{G}_n)^{-1} \mathbf{r}]. \quad (6.25)$$

To demonstrate that these functional transformation operators are linear, we note that

$$\mathcal{T}_n[\alpha f_1(\mathbf{r}) + \beta f_2(\mathbf{r})] = \alpha f_1(\mathcal{G}_n^{-1} \mathbf{r}) + \beta f_2(\mathcal{G}_n^{-1} \mathbf{r}) = \alpha \mathcal{T}_n f_1(\mathbf{r}) + \beta \mathcal{T}_n f_2(\mathbf{r}), \quad (6.26)$$

proving the linearity. Moreover, if \mathcal{G}_n is a continuous mapping, then $f(\mathcal{G}_n \mathbf{r})$ is a square-integrable function if $f(\mathbf{r})$ is, so \mathcal{T}_n is a linear operator mapping an \mathbb{L}_2 Hilbert space to itself.

6.6.2 Invariant subspaces

A subspace \mathbb{S} of a Hilbert space \mathbb{U} is said to be invariant under a group \mathbf{T} if, for any vector \mathbf{f} in \mathbb{S} and any operator \mathcal{T}_n in \mathbf{T} , $\mathcal{T}_n \mathbf{f}$ is also a vector in \mathbb{S} . For a concrete mental picture, consider a 2D subspace or plane in Hilbert space. If this plane is an invariant subspace, then application of any group operator to a vector in the plane produces another vector in the plane. In a function space, each vector is a function, and each function in the plane can be written as a linear combination of two basis functions. Saying that this plane is invariant under the group means that a group operator acting on any linear combination of the basis functions can only produce some other linear combination of them.

More generally, K linearly independent (but not necessarily orthogonal) functions $\{u_k(\mathbf{r}), k = 1, \dots, K\}$, form a basis for a KD space. Any function $f(\mathbf{r})$ that can be written as

$$f(\mathbf{r}) = \sum_{k=1}^K \alpha_k u_k(\mathbf{r}) \quad (6.27)$$

is a vector in this space. Once the basis functions are given, an arbitrary function in the space is specified by a KD column vector of coefficients $\boldsymbol{\alpha}$.

Now consider the effect of the group operator \mathcal{T}_n on $f(\mathbf{r})$. If a KD space containing $f(\mathbf{r})$ is invariant to the group, then the transformed function $\mathcal{T}_n f(\mathbf{r})$ can be written as a linear combination of the basis functions, *i.e.*,

$$\mathcal{T}_n f(\mathbf{r}) = \sum_{k=1}^K \alpha_k \mathcal{T}_n u_k(\mathbf{r}) = \sum_{j=1}^K \beta_j^{(n)} u_j(\mathbf{r}), \quad (6.28)$$

where $\{\beta_j^{(n)}\}$ is the set of coefficients for $\mathcal{T}_n f(\mathbf{r})$. Again, we can arrange these coefficients into a column vector $\boldsymbol{\beta}^{(n)}$. Since the basis vectors themselves are in the space, we can also write

$$\mathcal{T}_n u_k(\mathbf{r}) = \sum_{j=1}^K M_{jk}(\mathcal{T}_n) u_j(\mathbf{r}), \quad (6.29)$$

where $\{M_{jk}(\mathcal{T}_n), j = 1, \dots, K\}$ is the appropriate set of expansion coefficients for $\mathcal{T}_n u_k(\mathbf{r})$.

Since the basis functions are linearly independent, (6.28) and (6.29) imply that

$$\beta_j^{(n)} = \sum_{k=1}^K M_{jk}(\mathcal{T}_n) \alpha_k, \quad (6.30)$$

or, in matrix-vector form,

$$\boldsymbol{\beta}^{(n)} = \mathbf{M}(\mathcal{T}_n) \boldsymbol{\alpha}. \quad (6.31)$$

The set of $K \times K$ matrices $\{\mathbf{M}(\mathcal{T}_n)\}$ obeys the group multiplication table of the group of Hilbert-space operators \mathbf{T} and hence forms a *KD* representation of that group. As noted previously, the multiplication rule for the set $\{\mathcal{T}_n\}$ is the same as the one for $\{\mathcal{G}_n\}$, so the matrices $\{\mathbf{M}(\mathcal{T}_n)\}$ are essentially the matrices $\{\mathbf{M}(\mathcal{G}_n)\}$ introduced in Sec. 6.3, but now associated with a specific invariant subspace of a Hilbert space and a particular basis. The subspace \mathbb{S} is said to be reducible if the matrix representation $\{\mathbf{M}(\mathcal{T}_n)\}$ is reducible; otherwise it is irreducible.

In summary, if the operators of a group \mathbf{T} act on some Hilbert space, and the *KD* subspace \mathbb{S} of that Hilbert space is invariant under \mathbf{T} , then any set of basis functions $\{u_n(\mathbf{r})\}$ for \mathbb{S} can be used to form a *KD* matrix representation of the group \mathbf{T} . The same basis functions can be used to represent any function in the subspace as a *KD* vector, and the matrices of the group representation allow transformation of these vectors by the group operators.

Construction of invariant subspaces The paragraph above lists some nice features of invariant subspaces, but how do we find such subspaces? The simplest way is to start with an arbitrary function $u(\mathbf{r})$ in the Hilbert space and apply each of the group operators in turn, obtaining the set $\{u_n(\mathbf{r}), n = 1, \dots, N\}$, where, with (6.24),

$$u_n(\mathbf{r}) = \mathcal{T}_n u(\mathbf{r}) = u(\mathcal{G}_n^{-1} \mathbf{r}). \quad (6.32)$$

If \mathcal{T}_1 is the identity operator \mathcal{E} , then $u_1(\mathbf{r})$ is the original function $u(\mathbf{r})$.

These functions are not necessarily orthogonal, but they can be linearly independent if $u(\mathbf{r})$ is sufficiently general. For example, if the group includes rotation by some angle ϕ , we must make sure that the chosen $u(\mathbf{r})$ is not invariant to this rotation. With this caveat, the set $\{u_n(\mathbf{r})\}$ will be assumed to be linearly independent and hence to constitute a basis for an *ND* subspace of the Hilbert space.

A function in this subspace is one that can be represented in the form

$$f(\mathbf{r}) = \sum_{n=1}^N \alpha_n u_n(\mathbf{r}) = \sum_{n=1}^N \alpha_n \mathcal{T}_n u(\mathbf{r}). \quad (6.33)$$

The original function $u(\mathbf{r})$ is in the subspace since it corresponds to $\alpha_n = \delta_{n1}$.

To see that the subspace is invariant under the group, operate on $f(\mathbf{r})$ with any operator in the group, yielding

$$\mathcal{T}_k f(\mathbf{r}) = \sum_{n=1}^N \alpha_n \mathcal{T}_k \mathcal{T}_n u(\mathbf{r}). \quad (6.34)$$

By the definition of a group, $\mathcal{T}_k \mathcal{T}_n$ is also a unique element of the group, which we can denote as \mathcal{T}_j . As n ranges from 1 to N for any fixed k , \mathcal{T}_j becomes each of the group elements exactly once, so

$$\mathcal{T}_k f(\mathbf{r}) = \sum_{j=1}^N \alpha_{n(j,k)} \mathcal{T}_j u(\mathbf{r}) = \sum_{j=1}^N \alpha_{n(j,k)} u_j(\mathbf{r}), \quad (6.35)$$

where $\alpha_{n(j,k)}$ is the coefficient α_n associated with $\mathcal{T}_n = \mathcal{T}_k^{-1} \mathcal{T}_j$ in (6.33). Since $\mathcal{T}_k f(\mathbf{r})$ has the same form as (6.33), it is also in the subspace for all k , so the subspace is indeed invariant under the group.

6.6.3 Irreducible subspaces

The subspace obtained by the procedure just outlined will necessarily be reducible since the dimensionality of the subspace is the order of the group, and the only finite group for which there is an irreducible representation with dimension equal to the order of the group is the trivial group consisting only of the identity [see (6.9)]. To find irreducible subspaces, we could set about to reduce the one specified by (6.33), but there is a shortcut based on character tables. For simplicity, we consider an Abelian group, so that all irreducible representations are 1D.

Irreducible subspaces for Abelian groups Given an arbitrary function $u(\mathbf{r})$ in a Hilbert space and a finite Abelian group of transformations in that space, we define

$$u^{(m)}(\mathbf{r}) = \frac{1}{N} \sum_{n=1}^N [\chi^{(m)}(\mathcal{T}_n)]^* \mathcal{T}_n u(\mathbf{r}), \quad (6.36)$$

where N is the order of the group and $\chi^{(m)}(\mathcal{T}_n)$ is the character associated with group element \mathcal{T}_n in the m^{th} unitary irreducible representation.

We contend that the function $u^{(m)}(\mathbf{r})$ constructed in this way is the basis for the m^{th} (1D) irreducible representation, so that the only functions in the corresponding 1D subspace of the Hilbert space are scalar multiples of $u^{(m)}(\mathbf{r})$. If this contention is correct, $u^{(m)}(\mathbf{r})$ must transform according to a simple version of (6.29), with $K = 1$ and $M_{jk}(\mathcal{T}_n)$ replaced by the character $\chi^{(m)}(\mathcal{T}_n)$.

To check this contention, we operate on $u^{(m)}(\mathbf{r})$ with any operator in the group, say \mathcal{T}_k . By the same argument that led to (6.35), we find

$$\mathcal{T}_k u^{(m)}(\mathbf{r}) = \frac{1}{N} \sum_{j=1}^N [\chi^{(m)}(\mathcal{T}_k^{-1} \mathcal{T}_j)]^* \mathcal{T}_j u(\mathbf{r}). \quad (6.37)$$

For a 1D irreducible representation, however, the character of a product is the product of the characters, so $\chi^{(m)}(\mathcal{T}_k^{-1} \mathcal{T}_j) = \chi^{(m)}(\mathcal{T}_k^{-1}) \chi^{(m)}(\mathcal{T}_j)$. Moreover, since

we can always work with unitary representations, $[\chi^{(m)}(\mathcal{T}_k^{-1})]^* = \chi^{(m)}(\mathcal{T}_k)$, and we are left with

$$\mathcal{T}_k u^{(m)}(\mathbf{r}) = \chi^{(m)}(\mathcal{T}_k) \frac{1}{N} \sum_{j=1}^N [\chi^{(m)}(\mathcal{T}_j)]^* \mathcal{T}_j u(\mathbf{r}) = \chi^{(m)}(\mathcal{T}_k) \cdot u^{(m)}(\mathbf{r}), \quad (6.38)$$

in accordance with (6.29). Hence, any $u^{(m)}(\mathbf{r})$ constructed according to (6.36), using characters of a 1D irreducible representation, is invariant under the group; the action of the operator \mathcal{T}_k is simply to multiply $u^{(m)}(\mathbf{r})$ by the corresponding character, and we say that $u^{(m)}(\mathbf{r})$ *transforms according to the m^{th} irreducible representation of the group*. Every function in the 1D subspace constructed from $u(\mathbf{r})$ and associated with the m^{th} irreducible representation must be a scalar multiple of $u^{(m)}(\mathbf{r})$.

From the basis functions for all of the irreducible representations, $\{u^{(m)}(\mathbf{r}), m = 1, \dots, M\}$, we can recover the original $u(\mathbf{r})$ merely by summing:

$$u(\mathbf{r}) = \sum_{m=1}^M u^{(m)}(\mathbf{r}) = \frac{1}{N} \sum_{m=1}^M \sum_{n=1}^N [\chi^{(m)}(\mathcal{T}_n)]^* \mathcal{T}_n u(\mathbf{r}). \quad (6.39)$$

This result can be derived from (6.15), but some comment on the notation is needed first. For an Abelian group (the present concern), there is one element per class, so $\chi_j^{(m)} = \chi^{(m)}(\mathcal{T}_j)$ and (6.15) can be rewritten as

$$\frac{1}{N} \sum_{m=1}^M [\chi^{(m)}(\mathcal{T}_j)]^* \chi^{(m)}(\mathcal{T}_{j'}) = \delta_{jj'}. \quad (6.40)$$

Now we simply let $\mathcal{T}_{j'}$ be the identity operator \mathcal{E} and recognize that $\chi^{(m)}(\mathcal{E}) = 1$ for a 1D irreducible representation. Then (6.39) follows readily from (6.36) and (6.40).

Equation (6.39) shows that any function in the Hilbert space can be decomposed into a sum of basis functions of the irreducible representations of a group of operators that act on that Hilbert space, at least if the group is Abelian. For the generalization to the non-Abelian case, the reader is referred to Hamermesh (1989).

Example Consider the cyclic group \mathbf{C}_4 of rotations by multiples of $\pi/2$ in the complex plane and denote the function to be decomposed as $u(z) = u(r^{i\theta})$. The transformation operator \mathcal{T}_n in this case corresponds to letting $\theta \rightarrow \theta + (n-1)\pi/2$ or, equivalently, letting $z \rightarrow i^{n-1}z$. The irreducible representations of \mathbf{C}_4 are listed in Sec. 6.3.2, and the characters are identical to these representations since \mathbf{C}_4 is Abelian. From the characters and (6.36), we find

$$\begin{aligned} u^{(1)}(z) &= \frac{1}{4} [1 \cdot u(z) + 1 \cdot u(iz) + 1 \cdot u(-z) + 1 \cdot u(-iz)]; \\ u^{(2)}(z) &= \frac{1}{4} [1 \cdot u(z) + i \cdot u(iz) - 1 \cdot u(-z) - i \cdot u(-iz)]; \\ u^{(3)}(z) &= \frac{1}{4} [1 \cdot u(z) - 1 \cdot u(iz) + 1 \cdot u(-z) - 1 \cdot u(-iz)]; \\ u^{(4)}(z) &= \frac{1}{4} [1 \cdot u(z) - i \cdot u(iz) - 1 \cdot u(-z) + i \cdot u(-iz)]. \end{aligned} \quad (6.41)$$

Since the sum of these four equations is $u(z)$, (6.39) is satisfied.

Another manifestation of the same mathematics is the group of powers of the Fourier operator. We saw in Sec. 3.3.5 that $\mathcal{F}\mathcal{F}u(x) = u(-x)$, so the square of the Fourier operator is the coordinate-inversion operator which maps $u(x)$ to $u(-x)$. From this observation it is easy to deduce that the group $\{\mathcal{F}^{n-1}, n = 1, \dots, 4\}$ is isomorphic to \mathbf{C}_4 . Application of each operator in turn to an arbitrary function $u(x)$ yields: $u(x), U(x), u(-x), U(-x)$, where $U(x)$ is the Fourier transform of $u(x)$ after the substitution $\xi \rightarrow x$. With this interpretation of the operator, the basis functions (6.41) become

$$\begin{aligned} u^{(1)}(x) &= \frac{1}{4} [u(x) + U(x) + u(-x) + U(-x)] ; \\ u^{(2)}(x) &= \frac{1}{4} [u(x) + iU(x) - u(-x) - iU(-x)] ; \\ u^{(3)}(x) &= \frac{1}{4} [u(x) - U(x) + u(-x) - U(-x)] ; \\ u^{(4)}(x) &= \frac{1}{4} [u(x) - iU(x) - u(-x) + iU(-x)] . \end{aligned} \tag{6.42}$$

No matter what we start with for $u(x)$, each of these functions transforms into a constant times the same function under any group operator. In particular, each is a self-Fourier function (Mendlovic *et al.*, 1994).

6.6.4 Orthogonality of basis functions

We are often required to evaluate scalar products such as

$$(f_1(\mathbf{r}), f_2(\mathbf{r})) = \int_{\infty} d^2r f_1^*(\mathbf{r}) f_2(\mathbf{r}) . \tag{6.43}$$

It can be shown (Hamermesh, 1989) that this integral must be zero if $f_1(\mathbf{r})$ and $f_2(\mathbf{r})$ are basis functions for two different irreducible representations of some group. The only requirement we need to impose on the group is that it consist of transformations on the Hilbert space in which the scalar product is defined. Moreover, even if $f_1(\mathbf{r})$ and $f_2(\mathbf{r})$ are not basis functions for irreducible representations, we know from the discussion above that they can be written as sums of such basis functions, and the only cross-products in $f_1^*(\mathbf{r}) f_2(\mathbf{r})$ that contribute to the scalar product are those involving basis functions from the same irreducible representation.

We can go a step further if we choose to make all of the irreducible representations unitary, which we can always do by use of a suitable similarity transformation. Then the orthogonality relations discussed in Sec. 6.3 come into play and lead to a powerful orthogonality relation on the basis functions.

Suppose that the set of functions $\{u_p^{(m)}(\mathbf{r}), p = 1, \dots, N_m\}$ transforms according to the m^{th} unitary irreducible representation of \mathbf{T} , that is, according to (6.29) with unitary matrices. Then it can be shown that (Schensted, 1976; Hamermesh, 1989)

$$\left(u_p^{(m)}(\mathbf{r}), u_{p'}^{(m')}(\mathbf{r}) \right) = V \delta_{mm'} \delta_{pp'} , \tag{6.44}$$

where the quantity V does not depend on p . In words, (6.44) says that *basis functions of two different unitary irreducible representations ($m \neq m'$) or two different rows of the same representation ($m = m', p \neq p'$) are orthogonal*. If the basis functions are also normalized, then $V = 1$ in (6.44).

Simple example: Even and odd functions The reader is, no doubt, already familiar with one special case of (6.44). Consider the Hilbert space $\mathbb{L}_2(\mathbb{R})$ and the inversion group of Fig. 6.3. This simple two-element group, when recast as a functional transformation, has elements \mathcal{T}_E and \mathcal{T}_I with the interpretations

$$\mathcal{T}_E f(x) = f(x), \quad \mathcal{T}_I f(x) = f(-x). \quad (6.45)$$

To construct a basis for a 2D invariant subspace of $\mathbb{L}_2(\mathbb{R})$, we start with an arbitrary function $f(x)$ in that space and, as in (6.32), apply the two group operators, yielding basis vectors $f(x)$ and $f(-x)$. The corresponding group representation is, of course, reducible since the inversion group is Abelian and has only 1D irreducible representations. Since the irreducible representations are $(1, 1)$ and $(1, -1)$, the basis functions for the irreducible representations are given from (6.36) as

$$f_e(x) = \frac{1}{2} [f(x) + f(-x)], \quad f_o(x) = \frac{1}{2} [f(x) - f(-x)], \quad (6.46)$$

where the subscripts e and o stand for *even* and *odd*, respectively.

The original 2D subspace consisted of all functions that could be written as linear combinations of $f(x)$ and $f(-x)$, and it is clear that all of these functions can also be written as linear combinations of $f_e(x)$ and $f_o(x)$. In other words, any function can be written uniquely as the sum of an even and an odd function. However, the new 1D subspaces spanned (separately) by $f_e(x)$ and $f_o(x)$ are also invariant under the inversion group. Explicitly,

$$\mathcal{T}_E f_e(x) = f_e(x), \quad \mathcal{T}_I f_e(x) = f_e(x); \quad (6.47)$$

$$\mathcal{T}_E f_o(x) = f_o(x), \quad \mathcal{T}_I f_o(x) = -f_o(x) = \text{const} \cdot f_o(x). \quad (6.48)$$

Since $f_e(x)$ and $f_o(x)$ are basis functions for two different unitary irreducible representations of a group of transformations on $\mathbb{L}_2(\mathbb{R})$, it follows from the discussion below (6.43) that their scalar product on $\mathbb{L}_2(\mathbb{R})$ must be zero. Of course, this is nothing more than the familiar statement that the integral of the product of an odd function and an even function over a symmetric interval must vanish, but it serves as a prototype of a much broader class of symmetry relations that can lead to vanishing scalar products.

6.7 QUANTUM MECHANICS AND IMAGE SCIENCE

The main purpose of this section is to convince the reader that a discussion of group theory belongs in a book on image science. Toward this end, we take a brief look at how group theory is useful in quantum mechanics and suggest a formal analogy between quantum mechanics and image science. An excellent general reference for quantum-mechanical applications of group theory is Tinkham (1964).

6.7.1 Smattering of quantum mechanics

A central tenet of quantum mechanics is that all physical observables can be represented by Hermitian operators on a Hilbert space. The only possible outcome of a physical measurement is one of the eigenvalues of the operator. If the system is in an eigenstate of the operator in question, then the result of the measurement will,

with probability one, be the corresponding eigenvalue. Otherwise, the probability of obtaining a particular eigenvalue, say λ_n , is the probability of finding the system in the corresponding eigenstate. Thus quantum mechanics is intimately connected with eigenanalysis of Hermitian operators.

The most important Hermitian operator in quantum mechanics is the Hamiltonian \mathcal{H} , corresponding to the total energy of a system. It operates on the wavefunction of the system, which for simplicity we assume to be a function of a single 3D spatial variable \mathbf{r} . This assumption is valid if we consider only a single electron in a potential field and ignore its spin. With this simplification, the Hilbert space in which \mathcal{H} operates can be taken as $\mathbb{L}_2(\mathbb{R}^3)$. The eigenfunctions of \mathcal{H} , vectors in this Hilbert space, are called *stationary states* of the system, and the eigenvalues specify the allowed energy levels in the system. The eigenvalue equation for \mathcal{H} , called the time-independent Schrödinger equation, is

$$\mathcal{H}\psi_k(\mathbf{r}) = W_k\psi_k(\mathbf{r}). \quad (6.49)$$

Though the notation does not yet show it, several linearly independent eigenfunctions may correspond to the same eigenvalue W_k , in which case the level is said to be *degenerate*. As we shall see, degeneracies can (and usually do) arise as a result of symmetry properties of the Hamiltonian.

6.7.2 Connection with image science

As discussed in Chap. 1 and developed much more fully in Chap. 7, an imaging system can often be described in terms of a linear operator mapping one Hilbert space, called object space, to another Hilbert space called image space. If the two spaces are not identical, then the operator cannot be Hermitian. This is a pity since Hermitian operators have many nice mathematical properties, as detailed in Chap. 1.

Fortunately, we can always construct a relevant Hermitian operator simply by forming $\mathcal{H}^\dagger\mathcal{H}$, where \dagger denotes the adjoint operator. Eigenanalysis of this new operator, which maps object space to itself, then provides a full system characterization, including sets of orthonormal basis vectors for both object and image space (see Sec. 1.5). This method, called *singular-value decomposition*, is a central theme of this book.

Singular-value decomposition begins with solving the key eigenvalue equation (1.111),

$$\mathcal{H}^\dagger\mathcal{H}u_k(\mathbf{r}) = \mu_k u_k(\mathbf{r}). \quad (6.50)$$

The formal analogy between (6.49) and (6.50) is strong; the most important theoretical task in both quantum mechanics and image science is to solve an eigenvalue equation for a Hermitian operator.

As in quantum mechanics, the eigenfunctions $u_k(\mathbf{r})$ may be degenerate, and again degeneracies usually arise from symmetries; in image science it is symmetries of $\mathcal{H}^\dagger\mathcal{H}$ that play a key role.

6.7.3 Symmetry group of the Hamiltonian

When group theory is applied to quantum mechanics, the discussion usually begins with an enumeration of the operators that commute with the Hamiltonian of the

system. That is, we look for a set of operators $\{\mathcal{T}_n\}$ such that

$$\mathcal{T}_j^{-1}\mathcal{H}\mathcal{T}_j = \mathcal{H}. \quad (6.51)$$

An equivalent statement is

$$[\mathcal{T}_j, \mathcal{H}] = 0, \quad (6.52)$$

where $[\mathcal{T}_j, \mathcal{H}]$ is the *commutator* of the two operators, defined by

$$[\mathcal{T}_j, \mathcal{H}] = \mathcal{T}_j\mathcal{H} - \mathcal{H}\mathcal{T}_j. \quad (6.53)$$

The operators $\{\mathcal{T}_j\}$ usually arise from various symmetry properties of \mathcal{H} . A simple example is the inversion operator defined by (6.45). If the Hamiltonian itself is symmetric with respect to inversion, $\mathbf{r} \rightarrow -\mathbf{r}$, then it does not matter if we apply the inversion to a function and then operate with \mathcal{H} or first operate with \mathcal{H} and then apply the inversion. The inversion operator then commutes with the Hamiltonian. The group of all such symmetry operators is called the *symmetry group of the Hamiltonian*, and that group plus the Hamiltonian itself is called a *complete set of commuting observables*. Note, however, that this latter set does not necessarily form a group since the Hamiltonian may not have an inverse.

An analogous *symmetry group of the imaging system* consists of the set of operators that commute with $\mathcal{H}^\dagger\mathcal{H}$. Thus all of the results obtained by applying group theory to quantum mechanics have immediate applicability to image science.

6.7.4 Symmetry and degeneracy

We now expand on the connection between symmetry and degeneracy. The discussion here is specifically for quantum mechanics, but the corresponding results for image science are obtained by substituting $\mathcal{H}^\dagger\mathcal{H}$ for \mathcal{H} everywhere.

Suppose we have a set of linearly independent eigenfunctions $\psi_k^{(p)}(\mathbf{r})$ of \mathcal{H} , satisfying (6.49) with the same eigenvalue W_k , *i.e.*,

$$\mathcal{H}\psi_k^{(p)}(\mathbf{r}) = W_k\psi_k^{(p)}(\mathbf{r}), \quad p = 1, 2, \dots, P_k. \quad (6.54)$$

This set of eigenfunctions is called a *multiplet* in quantum mechanics, and P_k is called its *multiplicity*. As discussed in Chap. 1, the eigenfunctions can be chosen (via Gram-Schmidt orthogonalization) to be orthonormal.

Now consider the group of transformation operators $\{\mathcal{T}_n, n = 1, \dots, N\}$, all of which commute with \mathcal{H} . The action of \mathcal{T}_n on an arbitrary function in the relevant Hilbert space is defined by (6.24). Since \mathcal{H} and \mathcal{T}_n commute, we have

$$\mathcal{H}\mathcal{T}_n\psi_k^{(p)}(\mathbf{r}) = \mathcal{T}_n\mathcal{H}\psi_k^{(p)}(\mathbf{r}) = W_k\mathcal{T}_n\psi_k^{(p)}(\mathbf{r}). \quad (6.55)$$

Thus the transformed function $\mathcal{T}_n\psi_k^{(p)}(\mathbf{r})$ is also an eigenfunction of \mathcal{H} , with the same eigenvalue as for $\psi_k^{(p)}(\mathbf{r})$.

This might be a trivial result since it may happen that $\mathcal{T}_n\psi_k^{(p)}(\mathbf{r})$ is simply a constant times $\psi_k^{(p)}(\mathbf{r})$, which means that the functional form is unchanged by the transformation. In that case, $\psi_k^{(p)}(\mathbf{r})$ is an eigenfunction of both \mathcal{H} and \mathcal{T}_n .

On the other hand, $\mathcal{T}_n\psi_k^{(p)}(\mathbf{r})$ might also be a new, linearly independent, function, but it still has to be an eigenfunction of \mathcal{H} with eigenvalue W_k . That means it

can be written as a linear combination of functions in the multiplet. The coefficients in this linear superposition can depend on k and \mathcal{T}_n , so we write

$$\mathcal{T}_n \psi_k^{(p)}(\mathbf{r}) = \sum_{p'=1}^{P_k} M_{p'p}^{(k)}(\mathcal{T}_n) \psi_k^{(p')}(\mathbf{r}). \quad (6.56)$$

The right-hand side still satisfies the Schrödinger equation with eigenvalue W_k . Moreover, since the transformed function has the general form of (6.29), the set of functions $\{\psi_k^{(p)}(\mathbf{r}), p = 1, \dots, P_k\}$ spans an invariant subspace of the symmetry group of the Hamiltonian.

The set of matrices $\{\mathbf{M}^{(k)}(\mathcal{T}_n)\}$ forms a representation of the symmetry group. Since the eigenfunctions in the multiplet are orthonormal, the elements of this matrix are given by⁴

$$M_{p'p}^{(k)}(\mathcal{T}_n) = \left(\psi_k^{(p')}, \mathcal{T}_n \psi_k^{(p)} \right). \quad (6.57)$$

6.7.5 Reducibility and accidental degeneracy

Is the representation $\{\mathbf{M}^{(k)}(\mathcal{T}_n)\}$ defined by (6.57) reducible? If it is, it means that there is a subset of the functions $\{\psi_k^{(p)}(\mathbf{r})\}$ that transforms among itself under the group transformations $\{\mathcal{T}_n\}$. Functions in this subset are, of course, degenerate with those in its complement since all of the functions $\{\psi_k^{(p)}(\mathbf{r})\}$ are eigenfunctions of the Hamiltonian with the same eigenvalue W_k , but this degeneracy is not mandated by the symmetry of the Hamiltonian. We know that transformed functions $\mathcal{T}_n \psi_k^{(p)}(\mathbf{r})$ are degenerate if \mathcal{T}_n commutes with \mathcal{H} , but the converse does not necessarily hold; two degenerate functions are not necessarily related by a group transformation.

Degeneracy unrelated to the elements of the symmetry group is said to be *accidental*. True accidental degeneracy, however, almost never occurs; if we compute eigenvalues to floating-point precision, it would be surprising if two unrelated eigenvalues were exactly the same. What we call an accidental degeneracy is more often due to hidden symmetries, elements of the symmetry group of the Hamiltonian that have not been taken into account. The accident is a result of our state of knowledge.

If there is no accidental degeneracy, the eigenfunctions $\{\psi_k^{(p)}(\mathbf{r})\}$ are degenerate because of symmetry. That is, the eigenfunctions transform among themselves under the group transformations $\{\mathcal{T}_n\}$, and there is no subset that does so. The degenerate eigenfunctions then span an irreducible subspace of the symmetry group of the Hamiltonian, and the matrices in (6.57) form an irreducible matrix representation of that group.

Thus, barring accidental degeneracies, the degenerate eigenfunctions $\{\psi_k^{(p)}(\mathbf{r})\}$ transform according to some irreducible representation of the symmetry group of the Hamiltonian. The multiplicities of the eigenvalues of \mathcal{H} correspond to the dimensionalities of the irreducible representations of its symmetry group. In particular, 1D irreducible representations must be associated with nondegenerate eigenfunctions (again barring accidents).

⁴In Dirac notation, this matrix element would be written $\langle k, p' | \mathcal{T}_n | k, p \rangle$.

6.7.6 Parity

To illustrate the ideas developed above, consider a system with inversion symmetry. Physically, this means that there is no way to distinguish \mathbf{r} from $-\mathbf{r}$; they are equivalent position vectors. Mathematically, inversion symmetry means that the inversion operator \mathcal{T}_I commutes with the Hamiltonian. The 1D definition of \mathcal{T}_I given in (6.45) generalizes, in multiple dimensions, to

$$\mathcal{T}_I f(\mathbf{r}) = f(-\mathbf{r}). \quad (6.58)$$

If there is no other symmetry operator (other than the identity) that also commutes with the Hamiltonian, the symmetry group is the inversion group, with the multiplication table given in Fig. 6.3. Since this group is Abelian, it has only 1D irreducible representations and hence no degeneracies (or, at least, none mandated by symmetry).

Since \mathcal{H} commutes with \mathcal{T}_I , a nondegenerate eigenfunction of \mathcal{H} must also be an eigenfunction of \mathcal{T}_I . That is, if

$$\mathcal{H}\psi_k(\mathbf{r}) = W_k\psi_k(\mathbf{r}), \quad (6.59)$$

then

$$\mathcal{T}_I\mathcal{H}\psi_k(\mathbf{r}) = \mathcal{H}\mathcal{T}_I\psi_k(\mathbf{r}) = W_k\mathcal{T}_I\psi_k(\mathbf{r}), \quad (6.60)$$

so $\mathcal{T}_I\psi_k(\mathbf{r})$ is also an eigenfunction of \mathcal{H} with eigenvalue W_k .

Since there is no degeneracy, we must have

$$\mathcal{T}_I\psi_k(\mathbf{r}) = C\psi_k(\mathbf{r}), \quad (6.61)$$

where C is a constant.

Another interpretation of (6.61) is that $\psi_k(\mathbf{r})$ is an eigenfunction of \mathcal{T}_I with eigenvalue C . Operating on both sides of (6.61) with \mathcal{T}_I and recognizing that \mathcal{T}_I^2 is the identity shows that $C^2 = 1$ or $C = \pm 1$. Thus (6.61) can be rewritten as

$$\mathcal{T}_I\psi_k(\mathbf{r}) = \pm\psi_k(\mathbf{r}). \quad (6.62)$$

Nondegenerate eigenfunctions of an inversion-symmetric Hamiltonian must therefore be either purely even or purely odd. They are said to be functions of definite *parity*, with *even parity* referring to the plus sign and *odd parity* referring to the minus sign in (6.62).

From a group-theoretical perspective, an even eigenfunction transforms according to the irreducible representation $(1, 1)$, while an odd one transforms according to $(1, -1)$.

6.7.7 Rotational symmetry in three dimensions

In classical mechanics and quantum mechanics we often consider central potentials, where the force acting on a particle is a function of only the distance of the particle from some center of attraction. In a coordinate system with origin at that center point, the potential is independent of the angular coordinates. In the language of group theory, the symmetry group of the Hamiltonian is $\mathbf{SO}(3)$.

As we noted in Sec. 6.5.3, $\mathbf{SO}(3)$ is not Abelian. It has a set of irreducible representations usually denoted by an index ℓ , ($\ell = 0, \dots, \infty$), and the ℓ^{th} irreducible

representation has $2\ell + 1$ dimensions. This set exhausts the list of odd-dimensional irreducible representations of $\mathbf{SO}(3)$, but there are also even-dimensional ones. The basis functions for the even-dimensional irreducible representations have the apparently unphysical property that $\psi(\phi) \neq \psi(\phi + 2\pi)$, but they must nevertheless be considered for particles with spin (Tinkham, 1964).

The basis functions for the ℓ^{th} odd-dimensional irreducible representation are the spherical harmonics $Y_\ell^m(\theta, \phi)$ with m ranging from $-\ell$ to ℓ . (See Sec. 4.1.4 for a definition of the spherical harmonics.) If we ignore spin, the wavefunction for an electron in a central potential is thus specified by three indices, usually taken as n , ℓ and m , and it has the form

$$\psi_{n\ell m}(r, \theta, \phi) = u_{n\ell m}(r) Y_\ell^m(\theta, \phi). \tag{6.63}$$

States with the same n and ℓ but different m are necessarily degenerate.

6.8 FUNCTIONS AND TRANSFORMS ON GROUPS

A function is a mapping from some set, called the domain of the function, to the real or complex numbers. A familiar example of the domain is the real line or some portion of it, but we can be much more general in thinking about functions. In this section we shall allow the domain to be the elements of a group. If we have some rule for assigning a real or complex number to each element, we have defined a function on a group. From there it is straightforward to generalize further to functionals or integral transforms on groups. In particular, the familiar concepts of convolution and Fourier transformation can be extended.

We shall introduce these ideas by way of finite groups. Then we shall introduce the important concept of invariant integration, from which we can discuss convolutions and Fourier transforms on infinite groups. Many of the results obtained in Chaps. 3 and 4 will recur and be reinterpreted from a group-theoretic perspective. Then we shall revisit Chap. 5, and especially wavelets, from this new viewpoint.

6.8.1 Functions on a finite group

Consider a finite group \mathbf{G} of order N and denote the elements of this group by $\mathcal{G}_1, \mathcal{G}_2, \dots, \mathcal{G}_N$. A function on the group is any rule that associates a unique scalar, denoted $f(\mathcal{G}_n)$, with any element \mathcal{G}_n . Since the product of two group elements is also a group element, this same rule gives us a definition of $f(\mathcal{G}_n \mathcal{G}_m)$ for all n and m in $(1, \dots, N)$. Since we have not yet imposed any restrictions on either the function or the group structure, *any* sequence of N numbers f_n can be considered a function on any group of order N .

These functions can be embedded in a Hilbert space by defining a scalar product. The definition of the scalar product of two functions $f_1(\mathcal{G}_n)$ and $f_2(\mathcal{G}_n)$ on \mathbf{G} is

$$(f_1, f_2) = \sum_{n=1}^N f_1^*(\mathcal{G}_n) f_2(\mathcal{G}_n), \tag{6.64}$$

and the norm is defined by

$$\|f\|^2 = \sum_{n=1}^N |f(\mathcal{G}_n)|^2. \quad (6.65)$$

The space $\mathbb{L}_2(\mathbf{G})$ is the set of all functions on \mathbf{G} with finite norm.

As in Sec. 6.6.1, we can define a group of transformations $\{\mathcal{T}_m\}$ by [cf. (6.24)]:

$$\mathcal{T}_m f(\mathcal{G}_n) = f(\mathcal{G}_m^{-1} \mathcal{G}_n). \quad (6.66)$$

The group \mathbf{T} of transformations is isomorphic to the original group \mathbf{G} . That is, if $\mathcal{G}_i \mathcal{G}_j = \mathcal{G}_k$, then $\mathcal{T}_i \mathcal{T}_j = \mathcal{T}_k$.

In ordinary 3D vector analysis, a scalar is a quantity that is independent of coordinate transformations. In the vector space $\mathbb{L}_2(\mathbf{G})$, scalar products are invariant to the transformations defined in (6.66), *i.e.*,

$$(\mathcal{T}_m f_1, \mathcal{T}_m f_2) = \sum_{n=1}^N f_1^*(\mathcal{G}_m^{-1} \mathcal{G}_n) f_2(\mathcal{G}_m^{-1} \mathcal{G}_n) = \sum_{k=1}^N f_1^*(\mathcal{G}_k) f_2(\mathcal{G}_k) = (f_1, f_2), \quad (6.67)$$

where we have used the fact that $\mathcal{G}_m^{-1} \mathcal{G}_n$ is a unique element \mathcal{G}_k of \mathbf{G} (by the definition of a group). Since both k and n run over all group elements, the sum over k is identical to the sum over n .

The invariance demonstrated in (6.67) shows that each operator \mathcal{T}_m is unitary. On a finite-dimensional space, any operator that merely shuffles components is unitary.

Example The considerations above can be illustrated with the rotation group \mathbf{C}_N , where the element \mathcal{G}_n can be interpreted as rotation in a plane by an angle $\theta_n = 2\pi n/N$. To define a function on this group, we associate a number $f(\theta_n)$ with each of N angles uniformly distributed around a circle. A transformation of this function by \mathcal{T}_m corresponds to cyclically rotating the numbers by m steps, so that $f(\theta_n) \rightarrow f(\theta_n - \theta_m)$. Scalar products are unchanged by this rotation, which just cyclically relabels the numbers.

6.8.2 Extension to infinite groups

The equations above can be extended to encompass denumerably infinite groups just by letting $N \rightarrow \infty$. The more interesting case is continuous groups as introduced in Sec. 6.5, where group elements are specified by a continuous parameter θ (possibly a vector). We shall now denote elements of this group by \mathcal{G}_θ (which is the same thing as $\mathcal{G}(\theta)$ in Sec. 6.5) and the group itself as \mathbf{G} .

A function on \mathbf{G} can be defined by devising a rule for associating a scalar $f(\mathcal{G}_\theta)$ with each group element \mathcal{G}_θ , or equivalently with each θ . In the latter view, the function could be denoted as $f(\theta)$.

A group \mathbf{T} of transformations on functions on \mathbf{G} can be defined by analogy to (6.66) as

$$\mathcal{T}_\theta' f(\mathcal{G}_\theta) = f(\mathcal{G}_\theta^{-1} \mathcal{G}_\theta). \quad (6.68)$$

As in the case of discrete groups, \mathbf{T} is isomorphic to \mathbf{G} .

Example: Translation group A translation in the 2D plane is specified by a 2D vector \mathbf{r} , and the set of all possible translations forms an Abelian Lie group. Thus a function on the translation group could be denoted $f(\mathbf{r})$. This function might represent some physical object, for example, the radiant exitance (see Sec. 9.2 for a definition) on a plane at a point defined by translation \mathbf{r} from an origin.

A function on the translation group can itself be translated by the operator $\mathcal{T}_{\mathbf{r}'}$, yielding

$$\mathcal{T}_{\mathbf{r}'} f(\mathbf{r}) = f(\mathbf{r} - \mathbf{r}'). \tag{6.69}$$

With this form, we are not far from being able to discuss convolution; all we need is a definition of integration on a group.

Invariant integration Several of the expressions in Sec. 6.8.1 require summation over group elements. In the continuous case, the sums must be replaced by integrals over θ , but we have many options on how to define this integral. A useful way to resolve the ambiguity is to require an invariance property analogous to the one displayed in (6.67). To achieve this invariance, we define a *left-invariant integration measure* or *left Haar measure* $d\theta_L$ by requiring that

$$\int_{\mathbf{G}} d\theta_L f(\mathcal{G}_{\theta'} \mathcal{G}_{\theta}) = \int_{\mathbf{G}} d\theta_L f(\mathcal{G}_{\theta}), \tag{6.70}$$

for all $\mathcal{G}_{\theta'}$ in \mathbf{G} . We could also define a *right-invariant integration measure* or *right Haar measure* $d\theta_R$ by requiring that

$$\int_{\mathbf{G}} d\theta_R f(\mathcal{G}_{\theta} \mathcal{G}_{\theta'}) = \int_{\mathbf{G}} d\theta_R f(\mathcal{G}_{\theta}), \tag{6.71}$$

but we shall use the left-invariant measure exclusively.

For any particular continuous group, (6.70) and (6.71) are sufficient to determine the invariant measures uniquely. For the translation group, where $\theta = \mathbf{r} = (x, y)$, $d\theta_L = d\theta_R = dx dy$. If the left- and right-invariant measures coincide, as in this example, the group is said to be *unimodular*.

Hilbert space To treat a function $f(\mathcal{G}_{\theta})$ on a continuous group \mathbf{G} as a vector in a Hilbert space, a scalar product is defined by

$$(f_1, f_2) = \int_{\mathbf{G}} d\theta_L f_1^*(\mathcal{G}_{\theta}) f_2(\mathcal{G}_{\theta}). \tag{6.72}$$

This scalar product is invariant to the transformations $\mathcal{T}_{\theta'}$ defined in (6.68).

The norm is given by $\|f\|^2 = (f, f)$, and $L_2(\mathbf{G})$ is the space of all functions on \mathbf{G} with finite norm.

6.8.3 Convolutions on groups

We encountered several different kinds of convolution (continuous, discrete, Mellin, Laplace) in Chap. 4. Now we shall see that all of them are special cases of a more general concept called *group convolution*.

Given two functions $f(\mathcal{G}_n)$ and $p(\mathcal{G}_n)$ on a discrete group \mathbf{G} of order N (possibly infinite), their group convolution is defined by

$$[p *_G f](\mathcal{G}_m) = \sum_{n=1}^N p(\mathcal{G}_n^{-1} \mathcal{G}_m) f(\mathcal{G}_n). \tag{6.73}$$

Similarly, for a continuous group, convolution is defined by

$$[p *_G f](\mathcal{G}_{\theta'}) = \int_{\mathbf{G}} d\theta_L p(\mathcal{G}_{\theta}^{-1} \mathcal{G}_{\theta'}) f(\mathcal{G}_{\theta}). \quad (6.74)$$

The connection of this expression to ordinary, continuous convolution is immediate. If \mathbf{G} is the translation group, $\theta = \mathbf{r}$, $f(\mathcal{G}_{\theta}) = f(\mathbf{r})$, $p(\mathcal{G}_{\theta}^{-1} \mathcal{G}_{\theta'}) = p(\mathbf{r}' - \mathbf{r})$ and

$$[p *_G f](\mathcal{G}_{\theta'}) = [p * f](\mathbf{r}') = \int_{-\infty}^{\infty} 2r p(\mathbf{r}' - \mathbf{r}) f(\mathbf{r}), \quad (6.75)$$

which is the usual expression.

For this example, and for Abelian groups in general,

$$[p *_G f](\mathcal{G}_{\theta}) = [f *_G p](\mathcal{G}_{\theta}), \quad (6.76)$$

but for non-Abelian groups, the order matters.

Mellin convolution The Mellin convolution is defined in (4.85) by

$$[p *_M f](x) = \int_0^{\infty} \frac{da}{a} p\left(\frac{x}{a}\right) f(a). \quad (6.77)$$

We shall now show that this expression is group convolution on the scale group discussed in Sec. 6.5.3; the exercise will also serve to clarify the idea of invariant measures.

A scale transformation is specified by a positive scale factor a , defined so that $p(x/a)$ is a magnified version of $p(x)$; that is, $p(x/a)$ has the same value at $x = ax_0$ as $p(x)$ does at $x = x_0$. Thus the transformation operator \mathcal{T}_a and the scale operator \mathcal{G}_a are defined by

$$\mathcal{T}_a p(x) = p(\mathcal{G}_a^{-1} x) = p(x/a). \quad (6.78)$$

Now, since the group consists of all scale factors in the range $0 < a < \infty$, any function defined on the positive real line can be regarded as a function on the scale group, and we can write $f(\mathcal{G}_a)$ as $f(a)$; conversely, an arbitrary function $f(x)$ can be interpreted as $f(\mathcal{G}_x^{-1})$. With this notation,

$$p(x/a) = p(\mathcal{G}_a^{-1} x) = p(\mathcal{G}_a^{-1} \mathcal{G}_x). \quad (6.79)$$

By these manipulations, we have cast the integrand of the Mellin convolution into the same form as for a general group convolution, but we still need to compute the left-invariant measure. By its definition, (6.70), this measure must satisfy

$$\int_0^{\infty} da_L f(a/x) = \int_0^{\infty} da_L f(a), \quad (6.80)$$

for all positive x . The change of variables $a' = a/x$ on the left-hand side of (6.80), with subsequent dropping of the prime, yields the right-hand side if $da_L = da/a$. Thus, finally,

$$[p *_M f](x) = \int_0^{\infty} \frac{da}{a} p\left(\frac{x}{a}\right) f(a) = \int_{\mathbf{G}} da_L p(\mathcal{G}_a^{-1} \mathcal{G}_x) f(\mathcal{G}_a) = [p *_G f](\mathcal{G}_x). \quad (6.81)$$

It will be left as an exercise to reduce the other forms of convolution from Chap. 4 to appropriate group convolutions.

6.8.4 Fourier transforms on groups

We saw in Chap. 4 that each of the convolutions introduced there could be reduced to a simple product by a related integral transform. In particular, the usual continuous convolution becomes a product under ordinary Fourier transformation. Now we shall see why that result is general.

Let $\mathbf{M}^{(m)}(\mathcal{G}_n)$ be the matrix corresponding to \mathcal{G}_n in the m^{th} unitary irreducible representation of group \mathbf{G} (see Sec. 6.3). If \mathbf{G} is discrete (though possibly infinite), then the *group Fourier transform* of a function $f(\mathcal{G}_n)$ on \mathbf{G} is defined by

$$\mathbf{F}_m \equiv \sum_{n=1}^N f(\mathcal{G}_n) \mathbf{M}^{(m)}(\mathcal{G}_n). \tag{6.82}$$

The corresponding definition for a continuous group is

$$\mathbf{F}_m = \mathcal{F}_{\mathbf{G}}\{f\} \equiv \int_{\mathbf{G}} d\theta_L f(\mathcal{G}_{\theta}) \mathbf{M}^{(m)}(\mathcal{G}_{\theta}), \tag{6.83}$$

where the index m is an integer if the group has a countable set of irreducible representations.

Note that \mathbf{F}_m is a matrix of the same dimensions as $\mathbf{M}^{(m)}(\mathcal{G}_n)$. One way to think about \mathbf{F}_m is that it is a *matrix-valued function on representations*. That is, it assigns a matrix to each unitary irreducible representation of \mathbf{G} . The index m plays the role of Fourier frequency, but the Fourier transform is not one number for each frequency but, in general, a matrix. To complicate matters even further, different m will yield matrices of different dimensionality.

Most of these complications disappear for Abelian groups, where all irreducible representations are one-dimensional (see Sec. 6.3.2). In that case, \mathbf{F}_m is a scalar F_m and the integrand in (6.83) is a rather conventional integral transform.

Example 1: Finite group The structure of a group Fourier transform can be illustrated by considering the cyclic group \mathbf{C}_N , which is a finite-dimensional Abelian group. Since all of the irreducible representations are one-dimensional, the matrices $\mathbf{M}^{(m)}(\mathcal{G}_n)$ reduce to scalars, which are identical to the characters given in (6.17):

$$\mathbf{M}^{(m)}(\mathcal{G}_n) = \exp(-2\pi imn/N). \tag{6.84}$$

It is easy to show that these matrices are unitary and obey the group multiplication rule.

With these representations, (6.82) takes a familiar form,

$$F_m = \sum_{n=1}^N f(\mathcal{G}_n) \exp(-2\pi imn/N), \tag{6.85}$$

which is just the discrete Fourier transform of the sequence $f(\mathcal{G}_n)$.

Example 2: Continuous, Abelian group Next consider the translation group in 1D, where the operators are given by a 1D counterpart of (6.69). This group is Abelian, and its irreducible representations are scalars given by $\exp(-2\pi i\xi x)$, where x labels a group element [like n in (6.85)] and ξ labels the representation (like m). The

left-invariant measure is just dx , so the Fourier transform is, not surprisingly,

$$F(\xi) = \int_{-\infty}^{\infty} dx f(x) \exp(-2\pi i \xi x). \tag{6.86}$$

Example 3: Another continuous, Abelian group We know that the scale group leads to Mellin convolution. What is the corresponding Fourier transform? Once again the group is Abelian, so we seek 1D irreducible representations. We have seen that group elements are specified by nonnegative numbers x , and it can be verified that the following functions form a unitary representation:

$$M^{(\alpha)}(x) = x^{i\alpha}, \tag{6.87}$$

where α is a real number labeling the representation. We determined the left-invariant measure in Sec. 6.8.3. Thus the Fourier transform derived from the scale group has the form

$$F(\alpha) = \int_0^{\infty} \frac{dx}{x} x^{i\alpha} f(x). \tag{6.88}$$

From (4.82) we recognize this integral as the Mellin transform of $f(x)$ with the Mellin variable $s = i\alpha$. (The Mellin transform can be evaluated for arbitrary complex s , but a purely real α is required for $M^{(\alpha)}(x)$ to be a unitary representation.)

Shift theorem One of the most important theorems of ordinary Fourier analysis is the shift theorem, (3.108). We now derive its counterpart for group Fourier analysis.

If $f(\mathcal{G}_\theta)$ is a function on a continuous group \mathbf{G} , then a shifted function, with shift corresponding to $\mathcal{G}_{\theta'}$, can be defined by

$$f_s(\mathcal{G}_\theta) = f(\mathcal{G}_{\theta'}^{-1} \mathcal{G}_\theta). \tag{6.89}$$

From (6.83),

$$\mathcal{F}_{\mathbf{G}}\{f_s\} \equiv \int_{\mathbf{G}} d\theta_L f(\mathcal{G}_{\theta'}^{-1} \mathcal{G}_\theta) \mathbf{M}^{(m)}(\mathcal{G}_\theta). \tag{6.90}$$

The group product of any two group elements is another group element, so we can write

$$\mathcal{G}_{\theta'}^{-1} \mathcal{G}_\theta = \mathcal{G}_{\theta''}, \tag{6.91}$$

from which we find

$$\mathcal{F}_{\mathbf{G}}\{f_s\} = \int_{\mathbf{G}} d\theta_L f(\mathcal{G}_{\theta''}) \mathbf{M}^{(m)}(\mathcal{G}_{\theta'} \mathcal{G}_{\theta''}) = \mathbf{M}^{(m)}(\mathcal{G}_{\theta'}) \int_{\mathbf{G}} d\theta''_L f(\mathcal{G}_{\theta''}) \mathbf{M}^{(m)}(\mathcal{G}_{\theta''}), \tag{6.92}$$

where we have used the invariance of $d\theta_L$ and the fact that the matrices $\mathbf{M}^{(m)}(\mathcal{G}_\theta)$ obey the group multiplication rule. We recognize the integral in (6.92) as the transform of f , so we have

$$\mathcal{F}_{\mathbf{G}}\{f_s\} = \mathbf{M}^{(m)}(\mathcal{G}_{\theta'}) \mathcal{F}_{\mathbf{G}}\{f\}, \tag{6.93}$$

which is the generalized shift theorem. As an exercise, the reader should show that (6.93) leads to the ordinary shift theorem for the translation group.

Fourier transform of a convolution Next we derive the group counterpart of the convolution theorem, (3.132). Combining (6.74) and (6.83), we have

$$[\mathcal{F}_{\mathbf{G}}\{p *_G f\}]_m = \int_{\mathbf{G}} d\theta'_L \int_{\mathbf{G}} d\theta_L p(\mathcal{G}_{\theta}^{-1}\mathcal{G}_{\theta'}) f(\mathcal{G}_{\theta}) \mathbf{M}^{(m)}(\mathcal{G}_{\theta'}). \quad (6.94)$$

The manipulations are now very similar to the ones used in the derivation of the shift theorem. With $\mathcal{G}_{\theta}^{-1}\mathcal{G}_{\theta'} \equiv \mathcal{G}_{\theta''}$, the invariance of the integration measure and the representational nature of $\mathbf{M}^{(m)}(\mathcal{G}_{\theta})$, we have

$$\begin{aligned} [\mathcal{F}_{\mathbf{G}}\{p *_G f\}]_m &= \left[\int_{\mathbf{G}} d\theta''_L p(\mathcal{G}_{\theta''}) \mathbf{M}^{(m)}(\mathcal{G}_{\theta''}) \right] \left[\int_{\mathbf{G}} d\theta_L f(\mathcal{G}_{\theta}) \mathbf{M}^{(m)}(\mathcal{G}_{\theta}) \right] \\ &= [\mathcal{F}_{\mathbf{G}}\{p\} \mathcal{F}_{\mathbf{G}}\{f\}]_m, \end{aligned} \quad (6.95)$$

as anticipated.

Fourier inversion theorem When we derived various inversion theorems in Chaps. 3 and 4, the procedure was always to multiply a transformed quantity by one of the basis functions, sum or integrate, and appeal to the orthogonality of the basis functions. The situation is more complicated with group Fourier transforms which map scalar-valued functions on a group to matrices of various sizes. The inverse thus has to map a set of matrices back to a scalar function, suggesting that a trace operation might be involved. (The trace of a matrix is a scalar.) Perusal of Sec. 6.3.4 suggests further that the orthogonality relation (6.15) might be useful. This is indeed the case for a finite group, to which we restrict attention here.

To move in the direction of applying (6.15), we multiply (6.82) by $[\mathbf{M}^{(m)}(\mathcal{G}_k)]^\dagger$ and take the trace of the resulting matrix. This procedure yields

$$\text{tr} \left\{ [\mathbf{M}^{(m)}(\mathcal{G}_k)]^\dagger \mathbf{F}_m \right\} = \sum_{n=1}^N f(\mathcal{G}_n) \chi^{(m)}\{\mathcal{G}_k^{-1}\mathcal{G}_n\}, \quad (6.96)$$

where we have appealed to the unitary nature of the representation to set

$$\text{tr} \left\{ [\mathbf{M}^{(m)}(\mathcal{G}_k)]^\dagger \mathbf{M}^{(m)}(\mathcal{G}_n) \right\} = \text{tr} \left\{ \mathbf{M}^{(m)}(\mathcal{G}_k^{-1}\mathcal{G}_n) \right\} = \chi^{(m)}(\mathcal{G}_k^{-1}\mathcal{G}_n). \quad (6.97)$$

Guided by (6.15), we now multiply (6.97) by the character for the identity element in the m^{th} irreducible representation, $\chi^{(m)}(\mathcal{E})$, which is just the dimension of the representation, N_m (hence a real number). After summing over representations, we have

$$\sum_m N_m \text{tr} \left\{ [\mathbf{M}^{(m)}(\mathcal{G}_k)]^\dagger \mathbf{F}_m \right\} = \sum_{n=1}^N f(\mathcal{G}_n) \sum_m [\chi^{(m)}(\mathcal{E})]^* \chi^{(m)}(\mathcal{G}_k^{-1}\mathcal{G}_n). \quad (6.98)$$

By (6.15), the sum over m can be nonzero only if \mathcal{E} and $\mathcal{G}_k^{-1}\mathcal{G}_n$ are in the same class. But the identity element \mathcal{E} is always in a class by itself (literally), so we must have $\mathcal{G}_k^{-1}\mathcal{G}_n = \mathcal{E}$ or $\mathcal{G}_k = \mathcal{G}_n$. The sum over m in (6.98) is thus a group representation of a Kronecker delta; from (6.15) with $L_j = 1$ for the identity class,

$$\sum_m [\chi^{(m)}(\mathcal{E})]^* \chi^{(m)}(\mathcal{G}_k^{-1}\mathcal{G}_n) = N \delta_{kn}. \quad (6.99)$$

Kronecker performs the remaining sum in (6.98) for us, and we have, finally,

$$f\{\mathcal{G}_k\} = \frac{1}{N} \sum_m N_m \operatorname{tr} \left\{ \left[\mathbf{M}^{(m)}(\mathcal{G}_k) \right]^\dagger \mathbf{F}_m \right\}. \quad (6.100)$$

This equation is the inversion theorem for Fourier transforms on a finite group. It holds also for certain continuous groups called *nonunimodular locally compact groups* (Duflo and Moore, 1976) if the order of the group, N , is replaced by the *volume of the group* $V(\mathbf{G})$, defined by

$$V(\mathbf{G}) = \int_{\mathbf{G}} d\theta_L. \quad (6.101)$$

Unfortunately, this volume is not always finite.

6.8.5 Wavelets revisited

Wavelets are related to the affine group, introduced in Sec. 6.5.3. This group brings two new complications to the fore. First, unlike the translation and scale groups used for Fourier and Mellin transforms, respectively, the affine group is not Abelian. Second, its irreducible representations have infinite dimensionality.

To accommodate the second problem, we need to broaden our concept of representation. A matrix representation of dimension K is a set of $K \times K$ matrices that obey the group multiplication rule. Equivalently, as noted in Sec. 6.6.2, the matrices can be regarded as operators on a K -dimensional Hilbert space (usually a subspace of \mathbb{L}_2). Thus a representation is a set of *operators* that obey the group multiplication rule. In this sense, the set of operators $\{\mathcal{T}_n\}$ defined in (6.66) is a representation of a finite group, and the set $\{\mathcal{T}_\theta\}$ defined in (6.68) is a representation of an infinite group. Since these operators act on infinite Hilbert spaces, they define representations of infinite dimensionality. Usually such representations are reducible, but in the case of the affine group we are stuck with representations of infinite dimensionality.⁵

There are three infinite-dimensional unitary representations of the affine group, but they are equivalent to one another through a similarity transformation, so there is really only one representation (Sibul, 1995). The representation of the affine group used most commonly, and specifically in wavelet analysis, consists of a set of operators on $\mathbb{L}_2(\mathbb{R})$ defined by

$$\mathcal{T}_{a,b} f(x) = \frac{1}{\sqrt{|a|}} f\left(\frac{x-b}{a}\right) = \frac{1}{\sqrt{|a|}} f\{\mathcal{S}(a,b)^{-1}x\}, \quad (6.102)$$

where $\mathcal{S}(a,b)$ is the operator used to define the group in (6.21). The factor of $1/\sqrt{a}$ is required for unitarity.

Since $\mathcal{T}_{a,b}$ is an operator in $\mathbb{L}_2(\mathbb{R})$, its action can be expressed as an integral transform,

$$[\mathcal{T}_{a,b} \mathbf{f}](x) = \int_{-\infty}^{\infty} dx' t_{a,b}(x,x') f(x'), \quad (6.103)$$

⁵There is a trivial exception to this statement. If we fix the translation at 0, we can find one-dimensional representations of the affine group. These representations, which are also representations of Abelian subgroups of the affine group, are of no use in discussing the full affine group.

where $t_{a,b}(x, x')$ is the kernel of $\mathcal{T}_{a,b}$. Comparison of (6.102) and (6.103) shows that we must have

$$t_{a,b}(x, x') = \frac{1}{\sqrt{|a|}} \delta\left(x' - \frac{x-b}{a}\right), \tag{6.104}$$

where $\delta(\cdot)$ is the usual 1D Dirac delta function.

In terms of the operator, $\mathcal{T}_{a,b}$, the continuous wavelet transform defined in (5.73) can be written as

$$w(a, b) = \int_{-\infty}^{\infty} dx f(x) \mathcal{T}_{a,b} \psi^*(x). \tag{6.105}$$

The wavelet transform is a function of the parameters a and b specifying an element of the affine group, so it is a function on that group.

Fourier transform on the affine group From the discussion in Sec. 6.8.4, it is natural to examine the group Fourier transform of $w(a, b)$. Recall from the discussion below (6.83) that a group Fourier transformation maps a scalar-valued function on the group to a matrix-valued function on representations. For the affine group, there is only one representation, so there is just one Fourier coefficient like \mathbf{F}_m in (6.83) — the index m is irrelevant! It would seem that we have lost an enormous amount of information by transforming a function of two variables down to a single Fourier coefficient, but the thing that saves us is that this coefficient is an operator in an infinite-dimensional Hilbert space.

Specifically, the Fourier transform of $w(a, b)$ on the affine group is defined, by a modest generalization of (6.83), as

$$\mathcal{F}_G\{w\} \equiv \tilde{\mathbf{w}} = \int_{-\infty}^{\infty} \frac{da}{a^2} \int_{-\infty}^{\infty} db w(a, b) \mathcal{T}_{a,b}. \tag{6.106}$$

In comparing (6.106) with (6.83), note that $d\theta_L = da db/a^2$ and that the \mathbb{L}_2 operator $\mathcal{T}_{a,b}$ plays the role of the matrix $\mathbf{M}^{(m)}(\mathcal{G}_\theta)$. If we had chosen to write (6.83) in terms of matrix *elements*, $M_{nn'}^{(m)}(\mathcal{G}_\theta)$ would have appeared, with the indices n and n' running up to the dimensionality of the representation. Correspondingly, for the infinite-dimensional representation used in (6.106), the indices are the arguments of the kernel $t_{a,b}(x, x')$. Finally, the operator $\tilde{\mathbf{w}}$ should not be confused with the wavelet transformation operator $\mathcal{W}(a, b)$ used in Chap. 5; the latter maps from \mathbb{L}_2 to wavelet space, while the former maps \mathbb{L}_2 to itself.

Relation to the inverse wavelet transform The remaining question is how $\tilde{\mathbf{w}}$ is related back to the original function $f(x)$. The inverse wavelet transform (5.78) provides the answer. From that equation and (6.106), we find

$$f(x) = \frac{1}{C_\psi} \tilde{\mathbf{w}} \psi(x). \tag{6.107}$$

Thus the wavelet-transformation operator $\mathcal{W}(a, b)$ maps a function in \mathbb{L}_2 to a function in wavelet space, the group Fourier transform maps that function to an *operator* on \mathbb{L}_2 , and application of that operator to the original mother wavelet recovers the original \mathbb{L}_2 function. In shorthand,

$$\frac{1}{C_\psi} [\mathcal{F}_G \mathcal{W}(a, b) \mathbf{f}] \psi(x) = f(x). \tag{6.108}$$

This result may become a bit more transparent when we realize that the wavelet-transformation operator $\mathcal{W}(a, b)$ corresponds to a scalar product in \mathbb{L}_2 , so that

$$\mathcal{W}(a, b) \mathbf{f} = (\mathcal{T}_{a,b}\psi, \mathbf{f}) = [\mathcal{T}_{a,b}\psi]^\dagger \mathbf{f}. \quad (6.109)$$

Taking the group Fourier transform and applying the resulting operator to ψ yields

$$\begin{aligned} [\mathcal{F}_G \mathcal{W}(a, b) \mathbf{f}] \psi &= \int_G d\theta_L \left\{ [\mathcal{T}_{a,b}\psi]^\dagger \mathbf{f} \right\} [\mathcal{T}_{a,b}\psi] \\ &= \int_G d\theta_L [\mathcal{T}_{a,b}\psi] [\mathcal{T}_{a,b}\psi]^\dagger \mathbf{f}. \end{aligned} \quad (6.110)$$

Equations (6.108) and (6.110) then state that

$$\frac{1}{C_\psi} \int_G d\theta_L [\mathcal{T}_{a,b}\psi] [\mathcal{T}_{a,b}\psi]^\dagger = \mathcal{I}, \quad (6.111)$$

where \mathcal{I} is the identity operator in \mathbb{L}_2 . We know independently from (5.80) that this is the correct resolution of the identity for wavelets.

Deterministic Descriptions of Imaging Systems

With the background gained from Chapters 1-6, we are now ready to undertake the main task of this book, mathematical analysis of imaging systems. As noted in the Prologue, this analysis must consist of two distinct components, which we can call *deterministic* and *stochastic*. Deterministic analysis is the description of objects, images and the mapping between them without regard to noise or other sources of randomness or uncertainty. Such analysis is the topic of this chapter. Stochastic analysis, which addresses these random aspects, is taken up in the next chapter.

We begin in Sec. 7.1 with a survey of possible deterministic descriptions of objects and images. Since an object or an image can always be regarded as a vector in some Hilbert space, the concepts and tools of linear algebra introduced in Chap. 1 will be essential here, and the reader is assumed to have a good grasp of those topics.

Similarly, an imaging system can always be regarded as a transformation from one Hilbert space to another, and many imaging systems are linear, so the discussion of linear operators in Chap. 1 is also key in this chapter. Specifically, as in Chap. 1, we distinguish three important classes of linear operators: (1) continuous-to-continuous (CC) operators, which map a function of a continuous variable to another function of a (possibly different) continuous variable; (2) continuous-to-discrete (CD) operators, which map functions to finite sets of numbers or discrete vectors; and (3) discrete-to-discrete (DD) operators, which map one discrete vector to another. Each type of operator has an important application in image science, and each is discussed in detail in one major section of this chapter.

Linear CC operators are treated in Sec. 7.2. Not surprisingly, Fourier analysis will be a crucial tool in this section, and the reader will frequently be referred to Chap. 3 for mathematical details.

As mentioned in the prologue, CD mappings are the most natural for describing digital imaging systems since real objects are functions and digital images are discrete vectors. Section 7.3 is a detailed treatment of these mappings, one we shall rely on heavily in later chapters.

On the other hand, we cannot deal directly with functions when we want to represent an object in a computer, so discrete object models and DD operators are also essential in image science. Though such discrete models are often taken for granted in the imaging literature, there are some mathematical subtleties which we shall discuss in Sec. 7.4. This treatment will be of considerable use in Chap. 15 when we discuss inverse problems and image reconstruction.

Finally, in Sec. 7.5, we move beyond linear systems and discuss nonlinear imaging operators.

7.1 OBJECTS AND IMAGES

In the prologue we glimpsed some of the enormous diversity of things that can be regarded as objects to be imaged. There is a similar diversity in the mathematical language that can be used to describe those objects and the images they produce. The goal of this section is to survey these mathematical descriptions and lay the groundwork for discussing imaging systems in the later sections.

7.1.1 Objects and images as functions

An object to be imaged can often be described naturally as a function on a three-dimensional (3D) Euclidean space. A point in this space is described by the Cartesian coordinates (x, y, z) or, more succinctly, by a vector \mathbf{r} from the origin to the point. When an object is regarded as a scalar-valued function in this space, it is denoted $f(\mathbf{r})$ or, equivalently, $f(x, y, z)$. The value of this function is often referred to as the *gray level* of the object. Following common, though loose, terminology, we shall often refer to a scalar-valued function of a 3D vector as a 3D function for short.

The physical meaning of $f(\mathbf{r})$ depends, of course, on the nature of the imaging system. For example, in nuclear medicine, $f(\mathbf{r})$ refers to the density of a radioactive tracer, perhaps measured in radioactive disintegrations per second per cubic centimeter. The goal of an imaging system in nuclear medicine is to produce a map of this density. Similarly, in fluorescence microscopy the object of interest is the fluorescent radiation from the sample. Suitable units could be the number of emitted photons per cm^3 or watts per cubic meter (W/m^3). Alternatively, the object can be described by the density of the fluorophor.

Sometimes it is a useful approximation to regard the object as being confined to a plane. For example, an ordinary camera focused on an object a long distance away (at infinity) does not record any depth information, so the object is effectively planar. As another example, a computed-tomography system that uses a thin fan of radiation receives no information about the object outside the slab defined by the fan, so again the object is essentially planar. In these cases we shall still denote the object by $f(\mathbf{r})$, with the understanding that \mathbf{r} is now a two-dimensional (2D) vector so that $f(\mathbf{r})$ stands for $f(x, y)$. Occasionally 2D and 3D vectors will both occur in the same problem, and in those cases we shall use \mathbf{r} for the 3D position vector and \mathbf{r} for the 2D one.

In the camera example with a planar object, $f(\mathbf{r})$ could refer to the reflected optical flux per unit area¹ and be measured in W/m^2 . In x-ray computed tomography, the quantity of interest is the x-ray attenuation coefficient μ , measured in cm^{-1} , for example. The object $f(\mathbf{r})$ in this case is the two-dimensional distribution of μ .

Other variables Interesting objects are almost always functions of time. They move about from place to place or change their orientation with respect to the imaging system at some rate. The strength of the radiation from the object can also be a function of time. Thus we should be writing $f(\mathbf{r}, t)$ consistently instead of simply $f(\mathbf{r})$. Only if the object function is essentially constant over the imaging time is the static description really justified.

Other variables may also be required. For example, the radiation emitted by or reflected from the object can have a range of energies or wavelengths, and this dependence should be accounted for in the functional argument. Thus we might want to describe an object as $f(\mathbf{r}, t, \lambda)$, where λ is the wavelength of the radiation. Specific functions that incorporate this spectral information are introduced in Chap. 10.

Sometimes the angle of the radiation with respect to the object surface or a symmetry axis of the imaging system is important. In these cases the functional dependence must include one or more angles. Again, specifics as to how this is done are postponed to Chap. 10.

For notational simplicity, we shall usually not list all of the possible variables in the argument of f . Instead we shall write $f(\mathbf{r})$ but, when necessary, interpret \mathbf{r} more broadly than as spatial coordinates. If q variables are required to specify the object, \mathbf{r} will be interpreted as a $q\text{D}$ vector. The time variable will be included only when the dynamics of the object play a role in the imaging system.

Restrictions on the value of the function Physical considerations often place restrictions on the values that an object function $f(\mathbf{r})$ can assume. For example, if $f(\mathbf{r})$ represents a concentration of a radiotracer or fluorophor, it cannot be negative, and if it represents a reflectivity it must satisfy $0 \leq f(\mathbf{r}) \leq 1$.

Sometimes it is reasonable to assume that $f(\mathbf{r})$ can have only two values. If we photograph a newspaper, for example, the object is only black and white (even in the half-tone photographs!). Such objects are said to be *binary-valued*, or just binary for short.

Vector-valued functions So far we have considered only scalar-valued functions, but vector-valued functions or *vector fields* arise in some imaging applications. Perhaps the most familiar example is the electric field, which is central to coherent imaging. In this case each of the three Cartesian components of the field is a separate scalar-valued function of space, time and any other relevant variables. While the three components may be interrelated because of the wave equation or other constraints, full specification of the vector field requires all three functions.

Color images can also be regarded as vectors. If a scene is recorded through three separate color filters (say, red, green and blue), then each individual image is

¹The proper radiometric term for this quantity is *radiant exitance*, but we postpone a complete discussion of radiometric units to Chap. 10.

a scalar field or scalar-valued function of position, and the collection of three images is a 3D vector field.

Sometimes the components of a vector field are entirely different physical quantities. For example, objects encountered in magnetic resonance imaging (MRI) can be described in terms of three spatial maps: (1) spin density, (2) spin-lattice relaxation time and (3) spin-spin relaxation time. We can think of these maps as three separate spatial functions $f_j(\mathbf{r})$, $j = 1, \dots, 3$, or as three components of a single vector field $\mathbf{f}(\mathbf{r})$.

This concept can be extended further as needed. If J separate attributes are required to describe an object, and each attribute is a function of q variables, we can denote the object as $\mathbf{f}(\mathbf{r})$, where \mathbf{r} is a q D vector and $\mathbf{f}(\mathbf{r})$ for a fixed \mathbf{r} is a JD vector.

Complex functions In the examples given above, an object is described as a real-valued function, but complex-valued ones are also frequently required. In coherent imaging with ultrasound, microwaves or laser beams, the phase of the radiation plays a crucial role, and a complex notation is mathematically very convenient.

Consider, for example, a holographic imaging system in which an object is illuminated with a monochromatic plane wave of frequency ν . We might choose in this case to define the object by the amplitude of the reflected electric field in some plane near the object. This field is a function of two spatial variables and time, and we can denote it as $e(\mathbf{r}, t)$. This function is real, since it represents an actual physical field, and we can write it as

$$e(\mathbf{r}, t) = A(\mathbf{r}) \cos[\phi(\mathbf{r}) - 2\pi\nu t], \quad (7.1)$$

where $A(\mathbf{r})$ specifies the strength of the wave and $\phi(\mathbf{r})$ is the phase of its temporal oscillation at point \mathbf{r} . Note that we have assumed that both $A(\mathbf{r})$ and $\phi(\mathbf{r})$ are independent of time, which is appropriate if the object is not changing with time in any way and the illumination is constant except for the oscillation at frequency ν .

The real function in (7.1) can be expressed as

$$e(\mathbf{r}, t) = A(\mathbf{r}) \operatorname{Re}\{\exp[i\phi(\mathbf{r}) - 2\pi i\nu t]\}, \quad (7.2)$$

where $\operatorname{Re}\{\cdot\}$ denotes real part. Because the frequency ν is constant and known *a priori*, the factor $\exp(-2\pi i\nu t)$ is an unnecessary part of the specification of the wave. Therefore we can completely define the object in this case by the complex-valued function $f(\mathbf{r})$ given by

$$f(\mathbf{r}) = A(\mathbf{r}) \exp[i\phi(\mathbf{r})]. \quad (7.3)$$

The actual real field can be reconstituted by means of (7.2) if desired.

The complex form will prove to be very useful when we consider the effect of an imaging system. Any linear system operates on the real and imaginary parts of the input separately; the real part of the output is obtained by a linear transformation of the real part of the input, and similarly for the imaginary part. Therefore we can assume, quite unphysically, that the object is a complex wave, compute the image, and then take the real part. We caution the reader, however, that this approach presumes an imaging system that is strictly linear in wave amplitude.

Images as functions So far we have discussed objects, but images can also be treated as functions. Different imaging systems require different choices for the independent variables in these functions.

We need to distinguish variables that affect the response of the detector from ones that the detector *measures*. Photographic film, for example, responds to total energy per unit area to a first approximation. Although the response may depend on angle of arrival of the radiation or the time interval over which it is spread, film does not record these variables. Thus the natural description of an optical image in the film plane of a camera is $g(x_d, y_d)$, where x_d and y_d are spatial coordinates (d denotes *detector*), and the variable g itself denotes the exposure (joules/m²). If we wish to consider the developed film, the same independent variables can be used but then g will denote transmittance or optical density of the film.

One important variable that affects film response strongly, but is not measured by the film, is the wavelength. To illustrate how such a variable enters into the mathematical description of the image, we can define a spectral response function $R(\lambda)$ so that the effective exposure on the film is given by

$$g(\mathbf{r}_d) = \int_0^\infty d\lambda R(\lambda) g_\lambda(\mathbf{r}_d, \lambda), \quad (7.4)$$

where $g_\lambda(\mathbf{r}, \lambda)$ is the exposure per unit wavelength on the film. Thus the dependence on wavelength is integrated out, and λ does not appear in g . In order to calculate $g(\mathbf{r}_d)$ we must know $g_\lambda(\mathbf{r}_d, \lambda)$, but the final image is not a function of λ (for black-and-white film). On the other hand, if we consider a detector that does measure wavelength, such as an imaging spectrometer, then the λ variable must be included in the description of g .

7.1.2 Objects and images as infinite-dimensional vectors

As noted in Chap. 1, it is often fruitful to regard objects and images as vectors in linear vector spaces. If the basic description of the object or image is a function of one or more continuous variables, then the space will have an infinite number of dimensions.

In order to decide what vector spaces are most appropriate for imaging applications, we must inquire about the basic mathematical properties of the functions used for describing objects and images. We do not want to impose artificial and physically unrealistic conditions on the functions, but we do want to specify them as completely as possible.

One thing we should not assume is that the functions (especially object functions) are continuous or differentiable. Objects have abrupt edges, so they are not differentiable. Similarly, we do not want to assume that objects are bandlimited (see Sec. 3.5.1) because functions with finite bandwidth also cannot have sharp edges. It may sometimes be useful to approximate *images* as bandlimited, since the edges are blurred by the imaging system, but even there it cannot be an exact description.

One mathematical feature that we can take advantage of is compact support. Objects and images have finite size. An exception to this statement might appear to occur in astronomy — cosmological arguments aside, the universe is infinite. Nevertheless, astronomical objects can usefully be described as functions of finite support. The essentially infinite distances from the earth are no problem since the imaging systems don't measure that distance, so the object is described by angular

coordinates which are restricted to 4π steradians. Thus even the universe is, for our purposes, a function with finite support.

Moreover, functions that describe real objects and images do not have infinite values. A function with finite support and no infinite values is necessarily square-integrable and hence a vector in the Hilbert space $\mathbb{L}_2(\mathbf{S})$, where \mathbf{S} is the region of support of the function in terms of its independent variables (not including time).

Explicitly, if an object is described as a bounded function of q variables (or, equivalently, a q D vector \mathbf{r}), and $f(\mathbf{r})$ is zero outside some region \mathbf{S}_f in \mathbb{R}^q , then it is square-integrable:

$$\int_{\mathbf{S}_f} d^q r |f(\mathbf{r})|^2 < \infty. \quad (7.5)$$

Thus the object can be regarded as a vector in the Hilbert space $\mathbb{L}_2(\mathbf{S}_f)$. If the object is square-integrable over the infinite domain, it is a vector in $\mathbb{L}_2(\mathbb{R}^q)$. We shall denote an object as $f(\mathbf{r})$ when we want to emphasize its functional dependence, but we shall use \mathbf{f} when we wish to think of it as a vector in Hilbert space.

Similarly, if an image $g(\mathbf{r}_d)$ is defined as a function on \mathbb{R}^s and is zero outside a region \mathbf{S}_g , then it corresponds to the vector \mathbf{g} in the Hilbert space $\mathbb{L}_2(\mathbf{S}_g)$, which may be $\mathbb{L}_2(\mathbb{R}^s)$ if no support restriction is required.

If the function includes angles, it can still be regarded as a vector in a Hilbert space. For example, $f(x, y, z, \theta, \phi)$ or $f(\mathbf{r}, \hat{\mathbf{n}})$ is a vector in the Hilbert space with norm defined by

$$\|\mathbf{f}\|^2 = \int_{\mathbf{S}_f} d^3 \mathbf{r} \int_{4\pi} d\Omega |f(\mathbf{r}, \hat{\mathbf{n}})|^2, \quad (7.6)$$

where $d\Omega$ is the element of solid angle associated with $\hat{\mathbf{n}}$.

Vector-valued functions A Hilbert-space formalism is also applicable to vector-valued functions. As discussed in Sec. 7.1.1, we can think of a J -component object as J separate spatial functions $f_j(\mathbf{r})$ or as J components of a single vector field $\mathbf{f}(\mathbf{r})$ in \mathbb{R}^q . The norm of such a function can be defined by

$$\|\mathbf{f}\|^2 = \sum_{j=1}^J \int_{\mathbf{S}_f} d^q r |f_j(\mathbf{r})|^2. \quad (7.7)$$

This norm corresponds to a mixed Hilbert space, the direct product of the JD Euclidean space \mathbb{E}^J and $\mathbb{L}_2(\mathbb{R}^q)$. If the norm in (7.7) is finite, as it will be in real-world applications, the object $\mathbf{f}(\mathbf{r})$ is a vector in the Hilbert space $\mathbb{L}_2(\mathbb{R}^q) \times \mathbb{E}^J$.

Note that boldface \mathbf{f} in this context has two distinct meanings. When we write $\mathbf{f}(\mathbf{r})$, we mean a vector field with a small number of components, but \mathbf{f} without an argument refers to a vector in an infinite-dimensional Hilbert space. To avoid notational complications, we shall consider only scalar-valued functions for the remainder of this chapter, but all results are easily extended to the vector-valued case.

Is \mathbb{L}_2 too large? To summarize the considerations above, we shall always assume that object and image functions are square-integrable and hence vectors in an \mathbb{L}_2 Hilbert space with appropriate variables and support. No physically obtainable objects or images are ruled out by this assumption. For generality, we shall often denote the object Hilbert space as \mathbb{U} and the image space as \mathbb{V} , but \mathbb{L}_2 spaces will always be understood. Of course, not all vectors in these spaces correspond

to meaningful objects or images. As noted in Sec. 7.1.1, we may have additional restrictions, such as the fact that in many applications objects and images are real and nonnegative. Thus many of the vectors in the \mathbb{L}_2 spaces are ruled out for other reasons, but at least we can be assured that \mathbb{U} and \mathbb{V} are large enough to include all physically realizable objects and images, respectively.

Basis vectors The \mathbb{L}_2 Hilbert spaces are all *separable*, which means that they are spanned by denumerably infinite sets of basis vectors (see Sec. 1.1.5). Thus any object $f(\mathbf{r})$ can be represented exactly as an infinite series of the form

$$f(\mathbf{r}) = \sum_{n=1}^{\infty} \alpha_n \psi_n(\mathbf{r}), \quad (7.8)$$

where $\{\psi_n(\mathbf{r})\}$ is any orthonormal basis for the relevant Hilbert space. If the space is $\mathbb{L}_2(\mathbf{S}_f)$, the coefficients are given by

$$\alpha_n = (\psi_n(\mathbf{r}), f(\mathbf{r})) = \int_{\mathbf{S}_f} d^q r \psi_n^*(\mathbf{r}) f(\mathbf{r}), \quad (7.9)$$

where $(\psi_n(\mathbf{r}), f(\mathbf{r}))$ denotes a scalar product.

In the more abstract Hilbert-space notation, (7.8) and (7.9) can also be written as

$$\mathbf{f} = \sum_{n=1}^{\infty} \alpha_n \psi_n, \quad \alpha_n = (\psi_n, \mathbf{f}). \quad (7.10)$$

Fourier basis functions To illustrate the expansion (7.8), we shall discuss Fourier-series representations, first in one dimension and then in an arbitrary number of dimensions. For background material, see Secs. 3.2.1 and 3.4.6.

As discussed in Sec. 3.2.1, a 1D square-integrable function that vanishes outside $-\frac{1}{2}L < x < \frac{1}{2}L$ can be represented as

$$f(x) = \sum_{k=-\infty}^{\infty} F_k \exp(2\pi i \xi_k x) \text{rect}(x/L), \quad (7.11)$$

where ξ_k is a discrete spatial frequency given by $\xi_k = k/L$, and the Fourier coefficients $\{F_k\}$ can be computed from (3.19). Without the *rect* function, the right-hand side of (7.11) would represent a periodic function consisting of an infinite set of replicas of $f(x)$, but the *rect* function sets all replicas but one to zero. Thus the Fourier series (7.11) has the same structure² as (7.8), with $\psi_k(x) = \exp(2\pi i kx/L) \text{rect}(x/L)$. These functions form a basis for $\mathbb{L}_2(-\frac{1}{2}L, \frac{1}{2}L)$.

Next we consider a function $f(\mathbf{r})$, where \mathbf{r} is a q D vector. To generalize (7.11) to q dimensions, we need to replace k with a set of q indices. A convenient notation for this set is the multi-index \mathbf{k} (see Sec. 3.4.6), a set of q integers (k_1, \dots, k_q) where each integer specifies a component of the q D spatial-frequency

²One minor difference between (7.8) and (7.11) is that the index runs from 1 to ∞ in the former and from $-\infty$ to ∞ in the latter, but that is of no great import. A reparameterization, which we won't bother with, could easily solve this problem. If $f(x)$ is real, the negative k values in (7.11) are redundant anyway by dint of (3.45).

vector $\boldsymbol{\rho}_{\mathbf{k}} = (k_1\Delta\rho, \dots, k_q\Delta\rho)$. Thus the set of frequency vectors $\{\boldsymbol{\rho}_{\mathbf{k}}\}$ defines an infinite regular lattice of points in the q D frequency space. We shall adopt the convention that summation over the multi-index \mathbf{k} is equivalent to summing over all q of its components:

$$\sum_{\mathbf{k}=-\infty}^{\infty} = \sum_{k_1=-\infty}^{\infty} \sum_{k_2=-\infty}^{\infty} \cdots \sum_{k_q=-\infty}^{\infty} . \quad (7.12)$$

We assume that $f(\mathbf{r})$ vanishes identically unless \mathbf{r} is in a region \mathbf{S}_f of the q D space. This region is assumed to be bounded by a *cube of support*, a region defined by $-\frac{1}{2}L < r_j < \frac{1}{2}L$, $j = 1, \dots, q$. For $q = 3$ the cube of support is literally a cube in 3D space, but for $q = 2$ it is a square of side L , while for $q > 3$ it is a hypercube. The support region \mathbf{S}_f can be either the cube of support itself or any smaller region containing the object and lying entirely within the cube.

With this support constraint, an exact Fourier-series representation of $f(\mathbf{r})$ is possible if we choose $\Delta\rho \leq 1/L$ (see Sec. 3.5.4). If this condition is satisfied, then

$$f(\mathbf{r}) = \sum_{\mathbf{k}=-\infty}^{\infty} F_{\mathbf{k}} \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}) S_f(\mathbf{r}), \quad (7.13)$$

where $\boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}$ denotes a scalar product of the two q D Euclidean vectors, and $S_f(\mathbf{r})$ is a *support function* that equals 1 for \mathbf{r} in \mathbf{S}_f and 0 otherwise. The support function, like the rect function in (7.11), sets all replicas but one to zero.

A useful way to rewrite (7.13) is [cf. (3.279)]

$$f(\mathbf{r}) = \sum_{\mathbf{k}=-\infty}^{\infty} F_{\mathbf{k}} \Phi_{\mathbf{k}}(\mathbf{r}), \quad (7.14)$$

where $\Phi_{\mathbf{k}}(\mathbf{r})$ is a basis function defined by

$$\Phi_{\mathbf{k}}(\mathbf{r}) \equiv \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}) S_f(\mathbf{r}). \quad (7.15)$$

If the support region \mathbf{S}_f is the cube of support as discussed above, the set $\{\Phi_{\mathbf{k}}(\mathbf{r})\}$ is orthogonal³ and complete. For some smaller support region lying within the cube of support, the orthogonality is lost but the set is still complete. A few of the basis functions for the case of $q = 3$ and spherical support are shown in Fig. 7.1.

If we do not wish to assume that the object has finite support, we can take the object space to be $\mathbb{L}_2(\mathbb{R}^q)$. Fourier analysis can still be used, of course, but now the object is represented by its q D inverse Fourier transform rather than by a Fourier series. As discussed in Sec. 1.1.6, this approach amounts to using a continuous or nondenumerable basis for $\mathbb{L}_2(\mathbb{R}^q)$, where the basis functions themselves do not lie in the space they span. On the other hand, because $\mathbb{L}_2(\mathbb{R}^q)$ is a separable Hilbert space even without any restriction to finite support, we can also adopt some denumerable basis functions such as Hermite-Gauss functions (see Sec. 4.1.4) or eigenfunctions of some compact, Hermitian operator (see Sec. 1.4.4).

³As defined here, the basis functions are not normalized. They could be by inclusion of a factor $1/\sqrt{V}$, where V is the q D volume of the support region. This factor, corresponding to $1/|\det(\mathbf{P})|$ in (3.280), is omitted here for convenience.

Fig. 7.1 Illustration of the sine and cosine basis functions $\Phi_{\mathbf{k}}(\mathbf{r})$ for the case of spherical support. (Courtesy of Howard Gifford.)

Spatio-temporal basis functions If the object is explicitly a function of time, $f(\mathbf{r}, t)$, and if it is square-integrable over the spatial support for each time, then it can still be expanded in terms of purely spatial basis functions, but with the coefficients being functions of time; thus (7.8) becomes

$$f(\mathbf{r}, t) = \sum_{n=1}^{\infty} \alpha_n(t) \psi_n(\mathbf{r}). \quad (7.16)$$

If we consider a finite time interval, say $-T < t < T$, then $\alpha_n(t)$ must be square-integrable for any finite object, so it is a vector in $\mathbb{L}_2(-T, T)$, and the coefficients can be expanded in temporal basis functions as

$$\alpha_n(t) = \sum_{j=1}^{\infty} \alpha_{nj} \phi_j(t). \quad (7.17)$$

Combining (7.16) and (7.17), we have

$$f(\mathbf{r}, t) = \sum_{n=1}^{\infty} \sum_{j=1}^{\infty} \alpha_{nj} \phi_j(t) \psi_n(\mathbf{r}). \quad (7.18)$$

Thus, under the stated square-integrability conditions, the spatio-temporal function can be expanded in terms of separable⁴ basis functions, each a product of a function of time and a function of position.

7.1.3 Objects and images as finite-dimensional vectors

For numerical computations we must represent objects and images as finite sets of numbers. There is a key difference between objects and images in this respect. Objects are actually functions of continuous variables, so a finite discrete representation is necessarily an approximation. Digital images, on the other hand, are

⁴This usage of the term *separable* is distinct from the usage in describing Hilbert spaces; see Sec. 1.1.5.

inherently discrete sets of numbers. Thus a finite object vector *approximates* reality, whereas a finite image vector *is* reality, at least for digital images.

Since finite representations of images are virtually automatic in a digital setting and involve no approximation, we concentrate in this section on finite representations of objects.

Truncation of exact expansions Consider an object $f(\mathbf{r})$, a function of the q D vector \mathbf{r} , and assume that it is square-integrable over the support region \mathbf{S}_f in \mathbb{R}^q . Then, as in Sec. 7.1.2, $f(\mathbf{r})$ can be regarded as a vector in the Hilbert space $\mathbb{L}_2(\mathbf{S}_f)$, and it can be represented exactly by an infinite series like (7.8).

An approximate representation can be obtained by retaining a finite subset of the terms in this expansion and deleting all others. Often the index n can be chosen so that it ranges monotonically over the subset of terms we want to retain, so the approximation is obtained simply by truncating the series:

$$f_t(\mathbf{r}) = \sum_{n=1}^N \alpha_n \psi_n(\mathbf{r}), \quad (7.19)$$

where the subscript t stands for truncated and N is the number of terms retained. For example, in a truncated Fourier series, N specifies the highest frequency retained, and in an SVD expansion, N specifies the smallest singular value.

Representation space We can also describe the process of truncating the series in terms of a projection operator \mathcal{P}_N , defined such that

$$f_t(\mathbf{r}) = \mathcal{P}_N\{f(\mathbf{r})\}. \quad (7.20)$$

As discussed in Sec. 1.3.6, \mathcal{P}_N is idempotent ($\mathcal{P}_N^2 = \mathcal{P}_N$). It projects $f(\mathbf{r})$ from $\mathbb{L}_2(\mathbf{S}_f)$ onto the subspace spanned by $\{\psi_n, n = 1, \dots, N\}$. We shall refer to that space as *representation space*. Since the set of all $\psi_n(\mathbf{r})$, $n = 1, \dots, \infty$, spans the object space, we can say that representation space approaches object space as $N \rightarrow \infty$.

Representation space is a reproducing-kernel Hilbert space (see Sec. 1.8). Any function in the space satisfies

$$f_t(\mathbf{r}) = \int_{\mathbf{S}_f} d^q r' p_N(\mathbf{r}, \mathbf{r}') f_t(\mathbf{r}'), \quad (7.21)$$

where $p_N(\mathbf{r}, \mathbf{r}')$ is the reproducing kernel, given by

$$p_N(\mathbf{r}, \mathbf{r}') = \sum_{n=1}^N \psi_n(\mathbf{r}) \psi_n^*(\mathbf{r}'). \quad (7.22)$$

Since $p_N(\mathbf{r}, \mathbf{r}')$ is also the kernel for the projection operator \mathcal{P}_N , (7.21) says simply that once an infinite expansion is truncated, it does not matter if it is truncated again (with the same N).

Truncation as continuous-to-discrete mapping Since $f_t(\mathbf{r})$ is fully described by the set of coefficients $\{\alpha_n, n = 1, \dots, N\}$, another way to think about the truncation process is that it is a continuous-to-discrete mapping (see Sec. 1.2.4) from $\mathbb{L}_2(\mathbf{S}_f)$ to a finite-dimensional Euclidean space \mathbb{E}^N , where N is the total number of coefficients

in the set. Let α denote the vector in \mathbb{E}^N with components $\{\alpha_n\}$. Then we can define a *discretization operator* \mathcal{D}_ψ such that

$$\alpha = \mathcal{D}_\psi\{f(\mathbf{r})\}, \tag{7.23}$$

where the components of α are given by (7.9). We shall need several discretization operators in this chapter, so we distinguish them by subscripts indicating the basis functions used.

There is a simple relation between \mathcal{P}_N and \mathcal{D}_ψ if the finite set $\{\psi_n(\mathbf{r}), n = 1, \dots, N\}$ is orthonormal. From (1.45), we see that⁵

$$\left[\mathcal{D}_\psi^\dagger \alpha\right](\mathbf{r}) = \sum_{n=1}^N \alpha_n \psi_n(\mathbf{r}). \tag{7.24}$$

Hence,

$$\left[\mathcal{D}_\psi^\dagger \mathcal{D}_\psi f(\mathbf{r})\right](\mathbf{r}) = f_t(\mathbf{r}), \tag{7.25}$$

or

$$\mathcal{D}_\psi^\dagger \mathcal{D}_\psi = \mathcal{P}_N. \tag{7.26}$$

Thus, choice of the basis functions $\{\psi_n(\mathbf{r})\}$ and a value of N fully determines the representation space in which $f_t(\mathbf{r})$ lies. Specification of the ND vector of coefficients is equivalent to specifying the components of $f(\mathbf{r})$ in representation space. The space \mathbb{E}^N in which α lies is not identical to representation space, but it is isomorphic to it; each vector α in \mathbb{E}^N is uniquely associated with a vector \mathbf{f}_t in representation space and hence with a function $f_t(\mathbf{r})$. When we need to distinguish \mathbb{E}^N from representation space, we shall refer to the former as *coefficient space*. These spaces are illustrated schematically in Fig. 7.2.

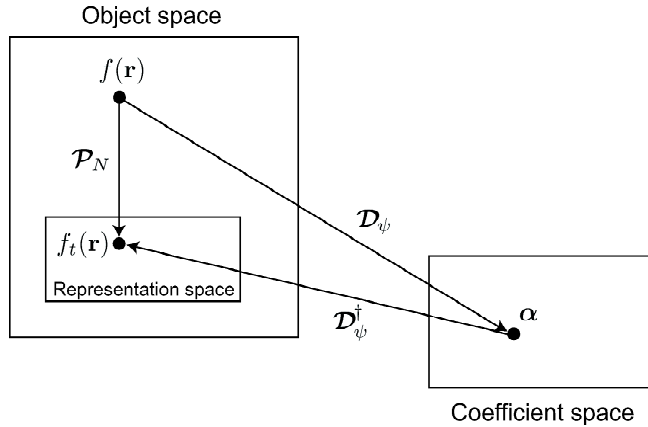

Fig. 7.2 The relationships among object space, representation space (here shown as a subspace of object space) and coefficient space.

⁵The lack of a complex conjugate in (7.24) may be puzzling when that equation is compared with (1.45). In defining \mathcal{D}_ψ to agree with (7.9), we included the conjugate in the forward operator, so we do not need it in the adjoint.

Approximate series expansions Rather than obtaining approximate series representations of $f(\mathbf{r})$ by truncating exact ones, we can also invent the approximations *de novo*. The generic form of a linear approximation to $f(\mathbf{r})$ is

$$f_a(\mathbf{r}) = \sum_{n=1}^N \theta_n \phi_n(\mathbf{r}), \quad (7.27)$$

where the subscript a stands for approximate. Though superficially similar, (7.27) differs from (7.19) in several important respects:

- (a) The functions $\{\phi_n(\mathbf{r})\}$ are not necessarily normalized;
- (b) The functions $\{\phi_n(\mathbf{r})\}$ are not necessarily orthogonal;
- (c) The coefficients $\{\theta_n\}$ are not necessarily computed as scalar products between $f(\mathbf{r})$ and $\phi_n(\mathbf{r})$;
- (d) The function $f_a(\mathbf{r})$ does not necessarily lie in $\mathbb{L}_2(\mathbf{S}_f)$.

Since the functions $\{\phi_n(\mathbf{r})\}$ do not form a basis for the object Hilbert space, we refrain from calling them basis functions (though this term is common in the literature). Instead we call them *expansion functions*. These functions do, however, span some ND space that we can still call representation space; now representation space is simply defined as the space of all functions that can be expressed as linear combinations of $\{\phi_n(\mathbf{r}), n = 1, \dots, N\}$. If the expansion functions are chosen to be orthonormal, they form an orthonormal basis for representation space. Moreover, if the expansion functions themselves lie in object space, then representation space is a subspace of object space.

Example—pixels We can illustrate some of the subtleties of (7.27) by considering the simple and familiar *pixel expansion* of a 2D function $f(\mathbf{r})$, where $\mathbf{r} = (x, y)$. We consider a regular lattice of points specified by the multi-index \mathbf{n} , a 2D vector with integer components (n_x, n_y) . Then a lattice point is denoted $\mathbf{r}_\mathbf{n} = (x_\mathbf{n}, y_\mathbf{n})$, where

$$x_\mathbf{n} = n_x \epsilon, \quad y_\mathbf{n} = n_y \epsilon, \quad (7.28)$$

and ϵ is the spacing between lattice points. With this notation, we can write the \mathbf{n}^{th} expansion function as

$$\phi_\mathbf{n}(\mathbf{r}) = \text{pix}_\mathbf{n}(\mathbf{r}) \equiv \text{rect}\left(\frac{x - x_\mathbf{n}}{\epsilon}\right) \text{rect}\left(\frac{y - y_\mathbf{n}}{\epsilon}\right). \quad (7.29)$$

This expansion function is not normalized (though it easily could be), but the set is orthogonal:

$$\int_{\infty} d^2 r \text{pix}_\mathbf{n}(\mathbf{r}) \text{pix}_\mathbf{m}(\mathbf{r}) = \epsilon^2 \delta_{\mathbf{nm}}, \quad (7.30)$$

where the Kronecker delta with vector indices is defined so that $\delta_{\mathbf{nm}} = 1$ if $n_x = m_x$ and $n_y = m_y$, and it is zero otherwise.

Choosing a set of expansion functions does not finish the job of constructing the approximation $f_a(\mathbf{r})$; we still have to choose the coefficients. One logical way to do so is by analogy to (7.9):

$$\theta_\mathbf{n} = \frac{1}{\epsilon^2} \int_{\infty} d^2 r \phi_\mathbf{n}(\mathbf{r}) f(\mathbf{r}). \quad (7.31)$$

This choice is, however, not mandated; we might also choose

$$\theta_{\mathbf{n}} = f(\mathbf{r}_{\mathbf{n}}) = \int_{\infty} d^2r \delta(\mathbf{r} - \mathbf{r}_{\mathbf{n}}) f(\mathbf{r}). \quad (7.32)$$

Comparing the integral form of (7.32) to (7.31), we see that they can both be written as

$$\theta_{\mathbf{n}} = \int_{\infty} d^2r \chi_{\mathbf{n}}^*(\mathbf{r}) f(\mathbf{r}), \quad (7.33)$$

where $\chi_{\mathbf{n}}(\mathbf{r}) = \epsilon^{-2} \text{pix}_{\mathbf{n}}(\mathbf{r})$ for (7.31) and $\delta(\mathbf{r} - \mathbf{r}_{\mathbf{n}})$ for (7.32).

Other choices are possible as well. We might, for example, reverse the roles of $\phi_{\mathbf{n}}$ and $\chi_{\mathbf{n}}$, letting $\chi_{\mathbf{n}}(\mathbf{r}) = \text{pix}_{\mathbf{n}}(\mathbf{r})$ and $\phi_{\mathbf{n}}(\mathbf{r}) = \delta(\mathbf{r} - \mathbf{r}_{\mathbf{n}})$, in which case our approximate representation would be

$$f_a(\mathbf{r}) = \sum_{n=1}^N \left[\frac{1}{\epsilon^2} \int_{\infty} d^2r' \text{pix}_{\mathbf{n}}(\mathbf{r}') f(\mathbf{r}') \right] \delta(\mathbf{r} - \mathbf{r}_{\mathbf{n}}). \quad (7.34)$$

While this form might be unappealing because the expansion functions are not square-integrable, there is no *a priori* reason to rule it out. Once we begin approximating, we have great flexibility in how we do so.

General operator treatment To formalize what we have learned from this discussion, we restate it in a general operator notation. Construction of a finite linear approximation to a q D function $f(\mathbf{r})$ is a two-step process. First we use a discretization operator \mathcal{D}_{χ} to form a vector of coefficients $\boldsymbol{\theta}$ given by

$$\boldsymbol{\theta} = \mathcal{D}_{\chi}\{f(\mathbf{r})\}. \quad (7.35)$$

The operator is defined by a modest generalization of (7.33):

$$\theta_n = [\mathcal{D}_{\chi}\{f(\mathbf{r})\}]_n = \int_{\infty} d^q r \chi_n^*(\mathbf{r}) f(\mathbf{r}), \quad n = 1, \dots, N, \quad (7.36)$$

where N is the total number of expansion functions used (and we have returned to a scalar index n). According to the Riesz representation theorem (see Sec. 1.2.1), (7.36) is the general form for a linear functional of $f(\mathbf{r})$. So long as we restrict attention to linear operators, the coefficients $\{\theta_n\}$ can always be written in the form of (7.36) for some choice of $\{\chi_n(\mathbf{r})\}$.

The second step is to use a (potentially different) discretization operator \mathcal{D}_{ϕ} to construct $f_a(\mathbf{r})$. By analogy to (7.24), we rewrite (7.27) as

$$f_a(\mathbf{r}) = \mathcal{D}_{\phi}^{\dagger} \boldsymbol{\theta} = \mathcal{D}_{\phi}^{\dagger} \mathcal{D}_{\chi}\{f(\mathbf{r})\} = \sum_{n=1}^N \theta_n \phi_n(\mathbf{r}). \quad (7.37)$$

Construction of a finite approximation to an object function thus requires choice of two sets of functions, $\{\phi_n(\mathbf{r})\}$ and $\{\chi_n(\mathbf{r})\}$, or equivalently, two discretization operators \mathcal{D}_{ϕ} and \mathcal{D}_{χ} . In much of the literature, the form of one or both of these function sets is simply left unspecified, and the precise relation between an object function and its discrete representation is not spelled out. When it is spelled out, the most common assumption is that $\mathcal{D}_{\phi} = \mathcal{D}_{\chi}$, but we shall maintain the distinction for the sake of generality. Taking $\{\phi_n(\mathbf{r})\}$ and $\{\chi_n(\mathbf{r})\}$ to be identical orthonormal function sets means that the coefficients $\{\theta_n\}$ are given by scalar products of the expansion functions and the object. Using distinct function sets means that the coefficients are calculated some other way.

Representation space and projection operators If the expansion functions are square-integrable and have the same support as the objects, then all functions in representation space are also in object space, and hence representation space is a subspace of object space. In that case we can define a projection operator \mathcal{P}_{rep} that projects a general object vector onto representation space as [cf. (1.166)]

$$\mathcal{P}_{rep} = \mathcal{D}_\phi^+ \mathcal{D}_\phi, \quad (7.38)$$

where \mathcal{D}_ϕ^+ is the Moore-Penrose pseudoinverse of \mathcal{D}_ϕ .

We can go a step further if the expansion functions are orthonormal; in that case, we know from Sec. 1.3.6 [cf. (1.51)] that

$$\mathcal{P}_{rep} f(\mathbf{r}) = \sum_{n=1}^N (\phi_n, \mathbf{f}) \phi_n(\mathbf{r}). \quad (7.39)$$

In operator form, we can write this relation as

$$\mathcal{P}_{rep} = \mathcal{D}_\phi^\dagger \mathcal{D}_\phi = \sum_{n=1}^N \phi_n \phi_n^\dagger, \quad (7.40)$$

where the second form makes use of the outer-product notation of (1.57).

Comparison of (7.38) and (7.40) shows that $\mathcal{D}_\phi^\dagger = \mathcal{D}_\phi^+$ if $\{\phi_n(\mathbf{r})\}$ is an orthonormal set. This statement can be proved independently from either the Penrose equations (see Sec. 1.6.1) or the singular-value decomposition of \mathcal{D}_ϕ and the results in Sec. 1.6.2.

To summarize, the approximate representation $f_a(\mathbf{r})$, defined generally as $\mathcal{D}_\phi^\dagger \mathcal{D}_\chi f(\mathbf{r})$, is given by $\mathcal{P}_{rep} f(\mathbf{r})$ if $\{\phi_n(\mathbf{r})\}$ and $\{\chi_n(\mathbf{r})\}$ are identical orthonormal sets of square-integrable functions. It also follows from the discussion in Sec. 1.8.2 that representation space is a reproducing-kernel Hilbert space in this case.

7.1.4 Representation accuracy

When constructing approximate representations of object functions, two important questions arise: How much error do we make in any particular representation? How do we choose the best representation? The answers to these questions depend on what we want to do with the representation.

There are several possible applications for finite object representations. One is to simulate images so that we can understand how an imaging system would perform without actually building it. This is the *forward problem*, where we are given an object and want to compute the image it produces. Solving the forward problem on a computer requires a finite object representation that leads to accurate data vectors.

Another application is the *inverse problem*, where we are given a noisy image or data vector and want to determine some information about the object that produced it. If we represent the object by a finite series, the inverse problem is to determine (or estimate) the coefficients in the series. The accuracy of the final estimate depends both on how well we can determine the coefficients from noisy data and how well the series would describe the actual object if the coefficients were known perfectly. We therefore distinguish *representation accuracy* from *es-*

timing accuracy; the former is discussed in this section, but discussion of the latter is postponed until we take up estimation theory in Chap. 13.

One application where representation accuracy can be assessed, unencumbered by questions of estimation accuracy, is image display. Suppose we have stored a digital representation of an object $f(\mathbf{r})$ as a set of digital values $\{\theta_n\}$ and later want to display the digital data as a luminance pattern on a cathode-ray tube. To do so, we have to convert the digital values to a function like $f_a(\mathbf{r})$, and we are naturally interested in the degree of agreement between the two functions $f(\mathbf{r})$ and $f_a(\mathbf{r})$.

Another way to answer questions about representation accuracy is in terms of objective measures of image quality. We shall argue in Chap. 14 that image quality cannot be defined in the abstract. It must be related to the particular purpose for which the image was acquired, which we refer to as the *task*. It must also be related to just how the task is performed, which we call the *observer*. In Chap. 14, we develop figures of merit for imaging systems for specific tasks and observers and relate these figures of merit to properties of the system and any data-processing algorithms that might be used. In addition, however, the figures of merit are sensitive to the mathematical representation chosen, which is the subject of this section.

One specific task we shall consider in Chap. 14 is the estimation of certain moments of the object, such as its integral over a specified region of interest. Another task is pattern recognition, which begins with estimation of functionals called features. In estimating either moments or features, a prerequisite is an object representation that accurately describes the quantities being estimated.

Object error If our goal is to represent an object as accurately as possible, we can examine the norm of the error between the actual object and any approximate representation of it. This error is defined by

$$\delta f(\mathbf{r}) \equiv f(\mathbf{r}) - f_a(\mathbf{r}). \quad (7.41)$$

From (7.37) we can also write

$$\delta f(\mathbf{r}) = f(\mathbf{r}) - \mathcal{D}_\phi^\dagger \mathcal{D}_\chi f(\mathbf{r}) = [\mathbf{I} - \mathcal{D}_\phi^\dagger \mathcal{D}_\chi] f(\mathbf{r}), \quad (7.42)$$

where \mathbf{I} is the identity operator (here simply multiplication by unity).

The error norm is thus given by

$$\|\delta f(\mathbf{r})\| = \left\| [\mathbf{I} - \mathcal{D}_\phi^\dagger \mathcal{D}_\chi] f(\mathbf{r}) \right\|. \quad (7.43)$$

This norm depends on the choice of the expansion functions and on the particular object function $f(\mathbf{r})$.

It is necessary that $f_a(\mathbf{r})$ be square-integrable for the error norm to be finite. For example, we cannot use a representation like (7.34) where $\phi_n(\mathbf{r}) = \delta(\mathbf{r} - \mathbf{r}_n)$ since that would make $\|\delta f(\mathbf{r})\|$ infinite. In what follows, we shall therefore usually assume that the functions $\{\phi_n(\mathbf{r})\}$ are square-integrable and hence $f_a(\mathbf{r})$ lies in object space. Representation space will be a subspace of object space unless otherwise stated.

Once we have chosen the set $\{\phi_n(\mathbf{r})\}$, and hence the representation space, the next step is to minimize $\|\delta f(\mathbf{r})\|$ through choice of the expansion coefficients $\{\theta_n\}$, or equivalently through choice of the set $\{\chi_n(\mathbf{r})\}$. This minimization is essentially least-squares fitting of $f_a(\mathbf{r})$ to $f(\mathbf{r})$. As discussed in Sec. 1.7 and illustrated graphically in Fig. 7.3, the optimal fitting is accomplished by making $f_a(\mathbf{r}) = \mathcal{P}_{rep} f(\mathbf{r})$,

where \mathcal{P}_{rep} is the projector onto representation space. Since $f_a(\mathbf{r})$ can also be expressed as $\mathcal{D}_\phi^\dagger \mathcal{D}_\chi f(\mathbf{r})$, the optimum (least-squares) choice of $\{\chi_n(\mathbf{r})\}$ implies the operator relation, $\mathcal{D}_\phi^\dagger \mathcal{D}_\chi = \mathcal{P}_{rep} = \mathcal{D}_\phi^+ \mathcal{D}_\phi$. Hence,

$$\delta f(\mathbf{r}) = [\mathbf{I} - \mathcal{P}_{rep}] f(\mathbf{r}) = [\mathbf{I} - \mathcal{D}_\phi^+ \mathcal{D}_\phi] f(\mathbf{r}). \quad (7.44)$$

From the idempotency ($\mathcal{P}_{rep}^2 = \mathcal{P}_{rep}$) and Hermiticity ($\mathcal{P}_{rep}^\dagger = \mathcal{P}_{rep}$) of the projector, the minimum achievable error norm is found to be

$$\|\delta f(\mathbf{r})\|^2 = \|f(\mathbf{r})\|^2 - \|\mathcal{P}_{rep} f(\mathbf{r})\|^2, \quad (7.45)$$

where the first norm on the right refers to object space, say $\mathbb{L}_2(\mathbf{R}^q)$, and the second refers to representation space.

Fig. 7.3 Graphical demonstration that $\|\delta f\|$ is minimized by choosing $\mathbf{f}_a = \mathcal{P}_{rep} \mathbf{f}$. Here \mathbf{f} is shown as a vector in a 3D Hilbert space, while its approximate representation \mathbf{f}_a lies in a 2D subspace called representation space, illustrated as the 1-2 plane. Thus $\mathcal{P}_{rep} \mathbf{f}$ is the projection of \mathbf{f} onto the 1-2 plane. Among all vectors \mathbf{f}_a in this plane, the one that minimizes $\|\mathbf{f} - \mathbf{f}_a\|$ is $\mathbf{f}_a = \mathcal{P}_{rep} \mathbf{f}$.

If $\{\phi_n(\mathbf{r})\}$ is an orthonormal set, then, as shown in Sec. 7.1.3, $\mathcal{D}_\phi^+ = \mathcal{D}_\phi^\dagger$ and

$$\mathcal{P}_{rep} f(\mathbf{r}) = \sum_{n=1}^N \theta_n \phi_n(\mathbf{r}), \quad \theta_n = (\phi_n(\mathbf{r}), f(\mathbf{r})). \quad (7.46)$$

In this case the norm in representation space is given by

$$\begin{aligned} \|\mathcal{P}_{rep} f(\mathbf{r})\|^2 &= \int_{\infty} d^q r \left| \sum_{n=1}^N \theta_n \phi_n(\mathbf{r}) \right|^2 \\ &= \sum_{n=1}^N \theta_n \sum_{n'=1}^N \theta_{n'}^* \int_{\infty} d^q r \phi_{n'}^*(\mathbf{r}) \phi_n(\mathbf{r}) = \sum_{n=1}^N |\theta_n|^2, \end{aligned} \quad (7.47)$$

and hence

$$\|\delta f(\mathbf{r})\|^2 = \int_{\infty} d^q r |f(\mathbf{r})|^2 - \sum_{n=1}^N |\theta_n|^2 = \|f(\mathbf{r})\|^2 - \|\boldsymbol{\theta}\|^2. \quad (7.48)$$

Thus, so long as we construct a representation by using identical orthonormal sets for $\{\chi_n(\mathbf{r})\}$ and $\{\phi_n(\mathbf{r})\}$, the error norm is simply the squared norm of the function minus the squared norm of its coefficient vector.

If $\{\phi_n(\mathbf{r})\}$ were a complete set on $\mathbb{L}_2(\mathbb{R}^q)$, this error norm would be immediately zero by the Parseval relation (4.6). Similarly, if $f(\mathbf{r})$ were entirely in the representation space, then the error norm would again be zero. Neither of these conditions is likely to prevail in practice since they imply that $f(\mathbf{r})$ can be represented exactly by a finite-dimensional vector.

If the approximate representation is obtained by truncating an exact infinite representation, as in (7.19), then we have

$$\|\delta f(\mathbf{r})\|^2 = \|f(\mathbf{r})\|^2 - \sum_{n=1}^N |\alpha_n|^2 = \sum_{n=N+1}^{\infty} |\alpha_n|^2 \quad (7.49)$$

and

$$\lim_{N \rightarrow \infty} \|\delta f(\mathbf{r})\|^2 = 0. \quad (7.50)$$

How rapidly this limit is approached depends on the specific basis functions and the object. For a truncated Fourier series and a differentiable object, for example, the coefficients $F_{\mathbf{k}}$ fall off rapidly as any component of the multi-index \mathbf{k} tends to infinity [see (3.49)].

Ensembles of objects We are rarely interested in the error norm just for one object; we want a representation that performs well for many objects. For this reason it is useful to consider a statistical ensemble of objects and average the error norms over that ensemble. In this view, each object is a sample function of a random process, a topic to be discussed in Chap. 8. For completeness in this section, however, we give expressions for the mean-square representation error (MSRE), averaged over the ensemble of objects.

The MSRE is defined by

$$\text{MSRE} = \langle \|\delta f(\mathbf{r})\|^2 \rangle, \quad (7.51)$$

where the angle brackets denote an average over the ensemble of objects. For representations derived from a single orthonormal function set, (7.48) holds, and the MSRE is given by

$$\text{MSRE} = \langle \|f(\mathbf{r})\|^2 \rangle - \langle \|\boldsymbol{\theta}\|^2 \rangle. \quad (7.52)$$

Since θ_n is obtained optimally as a scalar product with the expansion functions, $\langle \|\boldsymbol{\theta}\|^2 \rangle$ is given by

$$\begin{aligned} \langle \|\boldsymbol{\theta}\|^2 \rangle &= \sum_{n=1}^N \int_{\infty} d^q r \int_{\infty} d^q r' \phi_n^*(\mathbf{r}) \langle f^*(\mathbf{r}) f(\mathbf{r}') \rangle \phi_n(\mathbf{r}') \\ &= \sum_{n=1}^N \int_{\infty} d^q r \int_{\infty} d^q r' \phi_n^*(\mathbf{r}) R(\mathbf{r}, \mathbf{r}') \phi_n(\mathbf{r}'), \end{aligned} \quad (7.53)$$

where $R(\mathbf{r}, \mathbf{r}') = \langle f(\mathbf{r}) f^*(\mathbf{r}') \rangle$ is the autocorrelation function of the random process (see Sec. 8.2). The autocorrelation function can be regarded as the kernel of an integral operator \mathcal{R} called the autocorrelation operator, and we can rewrite (7.53) as a Hermitian form,

$$\langle \|\boldsymbol{\theta}\|^2 \rangle = \sum_{n=1}^N \phi_n^\dagger \mathcal{R} \phi_n. \quad (7.54)$$

To minimize the MSRE, we must maximize the sum in (7.54). The first term, $\phi_1^\dagger \mathcal{R} \phi_1$, is maximized (among vectors with unit norm) by choosing ϕ_1 to be the eigenvector of \mathcal{R} with the largest eigenvalue. Then the second term, $\phi_2^\dagger \mathcal{R} \phi_2$, is maximized (among vectors with unit norm that are orthogonal to ϕ_1) by choosing ϕ_2 to be the eigenvector of \mathcal{R} with the second largest eigenvalue. Continuing in this way, we see that the sum in (7.54) is maximized by choosing the orthonormal vectors $\{\phi_n, n = 1, \dots, N\}$ as the eigenvectors of \mathcal{R} corresponding to the N largest eigenvalues. This choice of expansion functions is called the *Karhunen-Loève* (KL) expansion, which we now see is optimal in terms of MSRE when a fixed number of terms is used in the expansion.

With the KL expansion functions, (7.54) simplifies to

$$\langle \|\boldsymbol{\theta}\|^2 \rangle = \sum_{n=1}^N \lambda_n \phi_n^\dagger \phi_n = \sum_{n=1}^N \lambda_n, \quad (7.55)$$

where λ_n is the n^{th} eigenvalue of \mathcal{R} , and the eigenvalues are all ordered by decreasing value. It will be left as an exercise to show that [cf. (7.49)]

$$\text{MSRE} = \sum_{n=N+1}^{\infty} \lambda_n. \quad (7.56)$$

In summary, if the objects are sample functions drawn from some ensemble, the KL expansion minimizes the MSRE (for a fixed number of terms), and all we need to know to compute this minimum MSRE is the set of eigenvalues of the covariance operator.

Moment errors In some imaging situations the task is to determine certain linear functionals of the object. As a simple example, in nuclear medicine we might be interested in the total amount of radioactive tracer inside some specified volume of the object. If we knew the actual object $f(\mathbf{r})$, we could simply perform the integral and get the desired number. In reality, we have available some noisy and imperfect data set, so we can only estimate the value. One common approach to this estimation is to adopt a finite representation like (7.19) or (7.27), estimate the coefficients, and then integrate the series term by term. Of course, if the series does not accurately represent the object in the first place, its integral will not accurately reflect the desired integral even if the coefficients are accurately estimated.

To formalize this idea, suppose the linear functional of interest is specified by a *template function* $t(\mathbf{r})$. In the notation of Chap. 2, this functional would be denoted as $\Phi_t\{\mathbf{f}\}$, but we are using Φ for other things in this chapter, so we shall call the functional $\tau(\mathbf{f})$, or just τ for short, and define it by

$$\tau = \int_{\mathbf{S}_f} d^q r t(\mathbf{r}) f(\mathbf{r}). \quad (7.57)$$

In the nuclear-imaging example mentioned above, $t(\mathbf{r})$ is unity in some region of interest and zero outside, and τ is the integral of the object over the region of interest. More generally, τ is referred to as a moment⁶ of the object.

⁶This usage of the word *moment* is more general than, but consistent with, the usage in statistics and mechanics. For example, if \mathbf{r} is a random vector and $f(\mathbf{r})$ is its probability density function

If the object is approximated by the finite series (7.27), then τ is approximated by

$$\tau_a = \int_{\mathbf{S}_f} d^q r t(\mathbf{r}) f_a(\mathbf{r}) = \sum_{n=1}^N \theta_n \int_{\mathbf{S}_f} d^q r t(\mathbf{r}) \phi_n(\mathbf{r}). \quad (7.58)$$

If we have obtained a set of estimates $\{\hat{\theta}_n\}$ of the coefficients, then one (not necessarily optimal) way of estimating τ is by

$$\hat{\tau} = \sum_{n=1}^N \hat{\theta}_n \int_{\mathbf{S}_f} d^q r t(\mathbf{r}) \phi_n(\mathbf{r}). \quad (7.59)$$

The estimation error is $\tau - \hat{\tau}$, but in this section we are concerned with the *moment error* $\delta\tau$, given by

$$\delta\tau \equiv \tau - \tau_a = \int_{\mathbf{S}_f} d^q r t(\mathbf{r}) \delta f(\mathbf{r}) = \int_{\mathbf{S}_f} d^q r t(\mathbf{r}) [\mathbf{I} - \mathcal{D}_\phi^\dagger \mathcal{D}_\chi] f(\mathbf{r}), \quad (7.60)$$

where we have used (7.41) in the last step. We can go a step further if $\mathcal{D}_\phi = \mathcal{D}_\chi$ and $\{\phi_n(\mathbf{r})\}$ is an orthonormal set. In this case $\mathcal{D}_\phi^\dagger \mathcal{D}_\chi$ is the projector onto representation space, and we have

$$\delta\tau = \int_{\mathbf{S}_f} d^q r t(\mathbf{r}) [\mathbf{I} - \mathcal{P}_{rep}] f(\mathbf{r}) = \int_{\mathbf{S}_f} d^q r f(\mathbf{r}) [\mathbf{I} - \mathcal{P}_{rep}] t(\mathbf{r}), \quad (7.61)$$

where the second step follows since the projector is Hermitian. Thus τ_a might be a good approximation to τ even if $f_a(\mathbf{r})$ is not a good approximation to $f(\mathbf{r})$, so long as $\mathcal{P}_{rep} t(\mathbf{r})$ is a good approximation to $t(\mathbf{r})$. It is the template rather than the object that has to be accurately approximated if we use the moment error as a figure of merit for the representation. Another way to state this conclusion is that components of $f(\mathbf{r})$ that lie in the orthogonal complement of representation space can greatly influence $\delta f(\mathbf{r})$, but they do not affect $\delta\tau$ at all if $t(\mathbf{r})$ lies entirely in representation space.

An immediate consequence of (7.61) is that $\delta\tau = 0$ if $t(\mathbf{r})$ is any linear combination of the representation functions $\{\phi_n(\mathbf{r})\}$. For example, if we choose to represent an object in pixels, then any moment obtained by integrating over regions defined by an integral number of pixels is exactly represented.

7.1.5 Uniform translates

In many practical situations, the functions $\phi_n(\mathbf{r})$ are chosen as uniform translates of a single function $\phi(\mathbf{r})$, such as a pixel function. In a slightly modified notation, we can write

$$\phi_{\mathbf{n}}(\mathbf{r}) = \phi(\mathbf{r} - \mathbf{r}_{\mathbf{n}}), \quad (7.62)$$

where \mathbf{n} is a multi-index as in Sec. 7.1.3, and the points $\mathbf{r}_{\mathbf{n}}$ form a regular lattice. For pixels in 2D for example, $\mathbf{r}_{\mathbf{n}} = (n_x \epsilon, n_y \epsilon)$ with n_x and n_y being integers.

More generally (see Sec. 3.4.6), we can construct the regular lattice by

$$\mathbf{r}_{\mathbf{n}} = \mathbf{P} \mathbf{n}, \quad (7.63)$$

(PDF), then the second moment of the component x can be obtained from (7.57) by letting $t(\mathbf{r}) = x^2$.

where \mathbf{P} is a real, nonsingular $q \times q$ matrix. For the 2D pixel example, $\mathbf{P} = \epsilon \mathbf{I}$, where \mathbf{I} is the 2×2 identity matrix. In q dimensions, the condition $\mathbf{P} = \epsilon \mathbf{I}$ generates a *generalized cubic lattice* where the sides of a unit cell are mutually orthogonal and of equal length.

In this section we shall analyze expansions based on functions of this form, first under the assumption that $\{\phi(\mathbf{r} - \mathbf{r}_n)\}$ is an orthonormal set and then more generally. For simplicity, we consider initially a generalized cubic lattice where $\mathbf{P} = \epsilon \mathbf{I}$, but this assumption will also be lifted shortly.

Orthonormal translates Consider an approximation to the object $f(\mathbf{r})$ in the form,

$$f_a(\mathbf{r}) = \sum_{\mathbf{n}=-\infty}^{\infty} \theta_{\mathbf{n}} \phi(\mathbf{r} - \mathbf{r}_{\mathbf{n}}). \quad (7.64)$$

If $\{\phi(\mathbf{r} - \mathbf{r}_n)\}$ is an orthonormal set, the coefficients are given optimally (in the sense of minimum $\|\delta f(\mathbf{r})\|$) by

$$\theta_{\mathbf{n}} = \int_{\infty} d^q r f(\mathbf{r}) \phi^*(\mathbf{r} - \mathbf{r}_{\mathbf{n}}). \quad (7.65)$$

If the object and the expansion function $\phi(\mathbf{r})$ both have finite support, then there are a finite number of terms in (7.64) even though the sums on all components of the multi-index run over $(-\infty, \infty)$; the coefficient $\theta_{\mathbf{n}} = 0$ when there is no overlap of $f(\mathbf{r})$ and $\phi^*(\mathbf{r} - \mathbf{r}_{\mathbf{n}})$ in the integrand of (7.65).

With this way of constructing $f_a(\mathbf{r})$, the error norm $\|\delta f(\mathbf{r})\|^2$ is given, from (7.48), by

$$\|\delta f(\mathbf{r})\|^2 = \int_{\infty} d^q r |f(\mathbf{r})|^2 - \sum_{\mathbf{n}=-\infty}^{\infty} \left| \int_{\infty} d^q r f(\mathbf{r}) \phi^*(\mathbf{r} - \mathbf{r}_{\mathbf{n}}) \right|^2. \quad (7.66)$$

With Parseval's relations (3.225) and (3.226) and the shift theorem (3.238), we have

$$\begin{aligned} \|\delta f(\mathbf{r})\|^2 &= \int_{\infty} d^q \rho |F(\rho)|^2 \\ &- \sum_{\mathbf{n}=-\infty}^{\infty} \int_{\infty} d^q \rho \int_{\infty} d^q \rho' F(\rho) F^*(\rho') \Phi^*(\rho) \Phi(\rho') \exp[-2\pi i(\rho - \rho') \cdot \mathbf{r}_{\mathbf{n}}], \end{aligned} \quad (7.67)$$

where, as usual, capital letters denote Fourier transforms. Interchanging sum and integral in (7.67) yields

$$\begin{aligned} \|\delta f(\mathbf{r})\|^2 &= \int_{\infty} d^q \rho |F(\rho)|^2 \\ &- \int_{\infty} d^q \rho \int_{\infty} d^q \rho' F(\rho) F^*(\rho') \Phi^*(\rho) \Phi(\rho') \sum_{\mathbf{n}=-\infty}^{\infty} \exp[-2\pi i(\rho - \rho') \cdot \mathbf{r}_{\mathbf{n}}] \\ &= \int_{\infty} d^q \rho |F(\rho)|^2 - \int_{\infty} d^q \rho \int_{\infty} d^q \rho' F(\rho) F^*(\rho') \Phi^*(\rho) \Phi(\rho') \text{comb}[\epsilon(\rho - \rho')], \end{aligned} \quad (7.68)$$

where we have assumed that $\mathbf{P} = \epsilon \mathbf{I}$. With this assumption, the multidimensional comb function (see Sec. 3.4.6) is given by

$$\text{comb}[\epsilon(\rho - \rho')] = \sum_{\mathbf{n}=-\infty}^{\infty} \delta[\epsilon(\rho - \rho') - \mathbf{n}] = \frac{1}{\epsilon^q} \sum_{\mathbf{n}=-\infty}^{\infty} \delta\left(\rho - \rho' - \frac{\mathbf{n}}{\epsilon}\right), \quad (7.69)$$

so we have

$$\|\delta f(\mathbf{r})\|^2 = \int_{\infty} d^q \rho |F(\boldsymbol{\rho})|^2 - \epsilon^{-q} \sum_{\mathbf{n}=-\infty}^{\infty} \int_{\infty} d^q \rho F(\boldsymbol{\rho}) F^*\left(\boldsymbol{\rho} - \frac{\mathbf{n}}{\epsilon}\right) \Phi^*(\boldsymbol{\rho}) \Phi\left(\boldsymbol{\rho} - \frac{\mathbf{n}}{\epsilon}\right). \quad (7.70)$$

The terms in the sum with $\mathbf{n} \neq 0$ result from aliasing. These terms can be neglected if the integrand is small at all $\boldsymbol{\rho}$ for nonzero \mathbf{n} , which is a valid assumption if *either* the object $f(\mathbf{r})$ or the expansion function $\phi(\mathbf{r})$ is smooth and nearly bandlimited. For this reason, several authors have advocated using smooth expansion functions; see, for example, Hanson and Wecksung (1985) and Lewitt (1990, 1992).

When aliasing can be neglected, the error norm is

$$\|\delta f(\mathbf{r})\|^2 = \int_{\infty} d^q \rho |F(\boldsymbol{\rho})|^2 [1 - \epsilon^{-q} |\Phi(\boldsymbol{\rho})|^2]. \quad (7.71)$$

If $f(\mathbf{r})$ is constant or very slowly varying, then $F(\boldsymbol{\rho})$ is small except near $\boldsymbol{\rho} = 0$. For such functions, aliasing can certainly be neglected, and the error norm is minimized when

$$|\Phi(0)| = \left| \int_{\infty} d^q r \phi(\mathbf{r}) \right| = \epsilon^{q/2}. \quad (7.72)$$

This condition is satisfied by pixels if they are properly normalized (with a factor of $\epsilon^{-q/2}$) and the rect functions fit together without gaps or overlap.

Non-orthonormal translates We assumed above that the set $\{\phi(\mathbf{r} - \mathbf{r}_{\mathbf{n}})\}$ was orthonormal, but this condition is often violated in practice. For example, it is violated if $\phi(\mathbf{r})$ is nonnegative and the translates are allowed to overlap. We now examine the error norm without the orthonormality assumption, and we also extend the treatment to more general lattices where $\mathbf{P} \neq \epsilon \mathbf{I}$.

Assume that a function $\phi(\mathbf{r})$ has been chosen so that the set $\{\phi(\mathbf{r} - \mathbf{r}_{\mathbf{n}})\}$ can be generated. The only remaining freedom we have is in the choice of the expansion coefficients, or equivalently the functions $\{\chi_{\mathbf{n}}(\mathbf{r})\}$. We know from the discussion in Sec. 7.1.4 that the object error is minimized if we choose $\{\chi_{\mathbf{n}}(\mathbf{r})\}$ such that

$$\mathcal{D}_{\phi}^{\dagger} \mathcal{D}_{\chi} = \mathcal{D}_{\phi}^{\dagger} \mathcal{D}_{\phi}. \quad (7.73)$$

The operator \mathcal{D}_{χ} , a linear mapping from a function of \mathbf{r} to a discrete vector, is given by (7.36), with the functions $\{\chi_{\mathbf{n}}(\mathbf{r})\}$ yet to be determined. The operator $\mathcal{D}_{\phi}^{\dagger} \mathcal{D}_{\chi}$ is then given by [cf. (7.37)]

$$\left[\mathcal{D}_{\phi}^{\dagger} \mathcal{D}_{\chi} \mathbf{f} \right] (\mathbf{r}) = \int_{\infty} d^q r' f(\mathbf{r}') \sum_{\mathbf{n}} \chi_{\mathbf{n}}^*(\mathbf{r}') \phi(\mathbf{r} - \mathbf{r}_{\mathbf{n}}). \quad (7.74)$$

Since $\mathcal{D}_{\phi}^{\dagger}$ is the Moore-Penrose pseudoinverse of \mathcal{D}_{ϕ} , it must satisfy the Penrose equations, (1.130a-d). In particular, the fourth Penrose equation requires that $\mathcal{D}_{\phi}^{\dagger} \mathcal{D}_{\phi}$ be Hermitian, so (7.73) implies that $\mathcal{D}_{\phi}^{\dagger} \mathcal{D}_{\chi} = [\mathcal{D}_{\phi}^{\dagger} \mathcal{D}_{\chi}]^{\dagger}$, or

$$\sum_{\mathbf{n}} \chi_{\mathbf{n}}(\mathbf{r}) \phi^*(\mathbf{r}' - \mathbf{r}_{\mathbf{n}}) = \sum_{\mathbf{n}} \chi_{\mathbf{n}}^*(\mathbf{r}') \phi(\mathbf{r} - \mathbf{r}_{\mathbf{n}}). \quad (7.75)$$

This condition holds if we choose

$$\chi_{\mathbf{n}}(\mathbf{r}) = \sum_{\mathbf{k}} B_{\mathbf{k}\mathbf{n}} \phi(\mathbf{r} - \mathbf{r}_{\mathbf{k}}), \quad (7.76)$$

with $B_{\mathbf{kn}}$ being an element (in multi-index notation) of a Hermitian matrix \mathbf{B} . In operator form, (7.76) is equivalent to

$$\mathcal{D}_\chi = \mathbf{B}\mathcal{D}_\phi. \quad (7.77)$$

If we multiply both sides of (7.73) by \mathcal{D}_ϕ and apply the first Penrose equation, (1.130a), we find

$$\mathcal{D}_\phi \mathcal{D}_\phi^\dagger \mathcal{D}_\chi = \mathcal{D}_\phi. \quad (7.78)$$

The operator $\mathcal{D}_\phi \mathcal{D}_\phi^\dagger$ is a Hermitian matrix, which we shall call \mathbf{A} , with elements given by the overlap integral,

$$A_{\mathbf{mn}} = \left[\mathcal{D}_\phi \mathcal{D}_\phi^\dagger \right]_{\mathbf{mn}} = \int_\infty d^q r \phi^*(\mathbf{r} - \mathbf{r}_\mathbf{m}) \phi(\mathbf{r} - \mathbf{r}_\mathbf{n}). \quad (7.79)$$

The indices \mathbf{m} and \mathbf{n} on $\mathbf{A}_{\mathbf{mn}}$ can, in principle, extend to infinity in each of q directions, so \mathbf{A} is an infinite matrix. In practice, however, $\mathcal{D}_\phi \mathcal{D}_\phi^\dagger$ will be applied to finite vectors, so infinite sums will not be required.

Combining (7.77) and (7.78), we find

$$\mathbf{A}\mathbf{B}\mathcal{D}_\phi = \mathcal{D}_\phi. \quad (7.80)$$

Multiplying from the right by \mathcal{D}_ϕ^\dagger gives

$$\mathbf{A}\mathbf{B}\mathbf{A} = \mathbf{A}. \quad (7.81)$$

This is again the first Penrose equation, so \mathbf{B} is a 1-inverse of \mathbf{A} (see Sec. 1.6.1). Solving (7.81) for \mathbf{B} is equivalent to finding \mathcal{D}_χ because of (7.77).

In practice, the function $\phi(\mathbf{r})$ will either have compact support or fall off rapidly with \mathbf{r} , so there will be very little overlap of the functions in the integrand of (7.79) unless \mathbf{m} is near \mathbf{n} . With this assumption, the matrix \mathbf{A} is diagonally dominant. Moreover, if $\mathbf{r}_\mathbf{m} = \mathbf{P}\mathbf{m}$, then

$$A_{\mathbf{mn}} = \int_\infty d^q r \phi^*(\mathbf{r} - \mathbf{P}\mathbf{m}) \phi(\mathbf{r} - \mathbf{P}\mathbf{n}) = \int_\infty d^q r' \phi^*[\mathbf{r}' - \mathbf{P}(\mathbf{m} - \mathbf{n})] \phi(\mathbf{r}'). \quad (7.82)$$

Thus $A_{\mathbf{mn}}$ is a function of $\mathbf{m} - \mathbf{n}$. In App. A we noted that a square matrix where each element is determined by the difference in the indices is called a Toeplitz matrix. We can extend the definition of a Toeplitz matrix to include the present case with vector indices, though it is more common in the literature to refer to matrices of this form as *block-Toeplitz*. See Sec. 7.4.4 or Andrews and Hunt (1977) for more discussion of block-Toeplitz matrices.

We can also argue from the discrete shift-invariance that \mathbf{B} must be Toeplitz as well. With these considerations on the structure of \mathbf{A} and \mathbf{B} , we can express $\mathbf{A}\mathbf{B}\mathbf{A}$ in component form as

$$[\mathbf{A}\mathbf{B}\mathbf{A}]_{\mathbf{mn}} = \sum_{\mathbf{k}=\mathbf{m}-\frac{1}{2}N}^{\mathbf{m}+\frac{1}{2}N-1} \sum_{\mathbf{k}'=\mathbf{n}-\frac{1}{2}N}^{\mathbf{n}+\frac{1}{2}N-1} A_{\mathbf{m}-\mathbf{k}} B_{\mathbf{k}-\mathbf{k}'} A_{\mathbf{k}'-\mathbf{n}}, \quad (7.83)$$

where the limits are specified component-wise (*e.g.*, $\mathbf{k} = \mathbf{m} - \frac{1}{2}N$ means that $k_i = m_i - \frac{1}{2}N$, $i = 1, \dots, q$), and N is any sufficiently large number such that no

significant nonzero elements of \mathbf{A} or \mathbf{B} are cut off by the limits. With this choice of N , (7.83) is essentially a discrete double convolution, and we do not need to worry about the modulo- N arithmetic usually involved in discrete convolutions (see Sec. 3.6.2). We know from (3.332) that the discrete Fourier transform (DFT) is a natural tool for solving problems involving discrete convolutions, and that is the approach we take here.

Though the DFT is usually defined on the interval $[0, N - 1]$ [cf. (3.363)], a symmetric definition is more convenient here, so we represent $A_{\mathbf{mn}}$ and $B_{\mathbf{mn}}$ as

$$A_{\mathbf{mn}} = A_{\mathbf{m-n}} = \sum_{\mathbf{j}=-\frac{1}{2}N}^{\frac{1}{2}N-1} a_{\mathbf{j}} \exp[-2\pi i(\mathbf{m} - \mathbf{n}) \cdot \mathbf{j}/N]; \quad (7.84)$$

$$B_{\mathbf{mn}} = B_{\mathbf{m-n}} = \sum_{\mathbf{j}=-\frac{1}{2}N}^{\frac{1}{2}N-1} b_{\mathbf{j}} \exp[-2\pi i(\mathbf{m} - \mathbf{n}) \cdot \mathbf{j}/N], \quad (7.85)$$

where the Fourier coefficients are given by

$$a_{\mathbf{j}} = N^{-q} \sum_{\mathbf{k}=-\frac{1}{2}N}^{\frac{1}{2}N-1} A_{\mathbf{k}} \exp(2\pi i\mathbf{k} \cdot \mathbf{j}/N), \quad (7.86)$$

and similarly for $b_{\mathbf{j}}$. We assume that N is large enough that no significant components are truncated by the limits in either the forward or inverse transform. The individual indices \mathbf{m} and \mathbf{n} , however, can still be allowed to run from $-\infty$ to ∞ .

With these representations, (7.81) becomes

$$\begin{aligned} [\mathbf{ABA}]_{\mathbf{mn}} &= \sum_{\mathbf{k}=\mathbf{m}-\frac{1}{2}N}^{\mathbf{m}+\frac{1}{2}N-1} \sum_{\mathbf{k}'=\mathbf{n}-\frac{1}{2}N}^{\mathbf{n}+\frac{1}{2}N-1} \sum_{\mathbf{j}=-\frac{1}{2}N}^{\frac{1}{2}N-1} \sum_{\mathbf{j}'=-\frac{1}{2}N}^{\frac{1}{2}N-1} \sum_{\mathbf{j}''=-\frac{1}{2}N}^{\frac{1}{2}N-1} a_{\mathbf{j}} b'_{\mathbf{j}} a''_{\mathbf{j}} \\ &\times \exp[-2\pi i(\mathbf{m} - \mathbf{k}) \cdot \mathbf{j}/N] \exp[-2\pi i(\mathbf{k} - \mathbf{k}') \cdot \mathbf{j}'/N] \exp[-2\pi i(\mathbf{k}' - \mathbf{n}) \cdot \mathbf{j}''/N] \\ &= A_{\mathbf{mn}} = \sum_{\mathbf{j}=-\frac{1}{2}N}^{\frac{1}{2}N-1} a_{\mathbf{j}} \exp[-2\pi i(\mathbf{m} - \mathbf{n}) \cdot \mathbf{j}/N]. \end{aligned} \quad (7.87)$$

The sum over \mathbf{k} yields $N^q \delta_{\mathbf{j}\mathbf{j}'}$ and the one over \mathbf{k}' yields $N^q \delta_{\mathbf{j}\mathbf{j}''}$, so (7.81) becomes

$$N^{2q} \sum_{\mathbf{j}=-\frac{1}{2}N}^{\frac{1}{2}N-1} a_{\mathbf{j}} b_{\mathbf{j}} a_{\mathbf{j}} \exp[-2\pi i(\mathbf{m} - \mathbf{n}) \cdot \mathbf{j}/N] = \sum_{\mathbf{j}=-\frac{1}{2}N}^{\frac{1}{2}N-1} a_{\mathbf{j}} \exp[-2\pi i(\mathbf{m} - \mathbf{n}) \cdot \mathbf{j}/N], \quad (7.88)$$

which can hold only if

$$N^{2q} a_{\mathbf{j}} b_{\mathbf{j}} a_{\mathbf{j}} = a_{\mathbf{j}}. \quad (7.89)$$

If $a_{\mathbf{j}} = 0$, $b_{\mathbf{j}}$ is arbitrary, but in the spirit of pseudoinverses, we take it to be zero as well (thereby making \mathbf{B} the Moore-Penrose pseudoinverse of \mathbf{A} , not just a 1-inverse). Thus we take

$$b_{\mathbf{j}} = \lim_{\eta \rightarrow 0^+} \frac{N^{-2q} a_{\mathbf{j}}}{a_{\mathbf{j}}^2 + \eta}, \quad (7.90)$$

and the solution for $B_{\mathbf{mn}}$ is

$$B_{\mathbf{mn}} = \lim_{\eta \rightarrow 0^+} \sum_{\mathbf{j}=-\frac{1}{2}N}^{\frac{1}{2}N-1} \frac{N^{-2q} a_{\mathbf{j}}}{a_{\mathbf{j}}^2 + \eta} \exp[-2\pi i(\mathbf{m} - \mathbf{n}) \cdot \mathbf{j}/N]. \quad (7.91)$$

If the translates are orthonormal, (7.91) reduces to $B_{\mathbf{mn}} = \delta_{\mathbf{mn}}$, which implies that $\chi_{\mathbf{n}}(\mathbf{r}) = \phi(\mathbf{r} - \mathbf{r}_{\mathbf{n}})$ as before. More generally, $\chi_{\mathbf{n}}(\mathbf{r})$ must be constructed from (7.76) and (7.91).

Biorthonormality In the discussions of Gabor expansions and wavelets in Chap. 5, we encountered examples of expansions in non-orthonormal functions where the expansion coefficients could be found by constructing a suitable family of biorthonormal functions [see, *e.g.*, (5.44) and (5.93)]. We shall now show that the family $\{\chi(\mathbf{r} - \mathbf{Pn})\}$ is biorthonormal to $\{\phi(\mathbf{r} - \mathbf{Pn})\}$ with a mild assumption.

Biorthonormality is related to the operator $\mathcal{D}_{\chi} \mathcal{D}_{\phi}^{\dagger}$, which by (7.77) is the same as the matrix \mathbf{BA} . This matrix has elements given by

$$[\mathcal{D}_{\chi} \mathcal{D}_{\phi}^{\dagger}]_{\mathbf{mn}} = [\mathbf{BA}]_{\mathbf{mn}} = \int_{\infty} d^q r \chi^*(\mathbf{r} - \mathbf{Pm}) \phi(\mathbf{r} - \mathbf{Pn}). \quad (7.92)$$

This matrix, like the others that occur in this problem, is Toeplitz and diagonally dominant. By analogy to (7.84), we can represent it as

$$[\mathcal{D}_{\chi} \mathcal{D}_{\phi}^{\dagger}]_{\mathbf{mn}} = \sum_{\mathbf{j}=-\frac{1}{2}N}^{\frac{1}{2}N-1} c_{\mathbf{j}} \exp[-2\pi i(\mathbf{m} - \mathbf{n}) \cdot \mathbf{j}/N]. \quad (7.93)$$

By algebra similar to that which led to (7.89), the second Penrose equation, $\mathbf{BAB} = \mathbf{B}$, can be written as

$$N^q c_{\mathbf{j}} b_{\mathbf{j}} = b_{\mathbf{j}}. \quad (7.94)$$

If the expansion functions are spatially compact, then the Fourier coefficient $a_{\mathbf{j}}$ extends to large \mathbf{j} . If we assume that $a_{\mathbf{j}}$ does not vanish identically for any \mathbf{j} , then (7.90) shows that $b_{\mathbf{j}}$ is also not zero, and (7.94) requires $c_{\mathbf{j}} = N^{-q}$ for all \mathbf{j} . Under this assumption (which is equivalent to replacing the pseudoinverse with a true inverse in the discussion above), we find

$$[\mathcal{D}_{\chi} \mathcal{D}_{\phi}^{\dagger}]_{\mathbf{mn}} = N^{-q} \sum_{\mathbf{j}=-\frac{1}{2}N}^{\frac{1}{2}N-1} \exp[-2\pi i(\mathbf{m} - \mathbf{n}) \cdot \mathbf{j}/N] = \delta_{\mathbf{mn}}, \quad (7.95)$$

which is the anticipated biorthonormality relation.

7.1.6 Other representations

So far in this chapter we have concentrated on linear representations, but nonlinear ones are often useful as well. In this section we briefly survey a few nonlinear representations that occur in the imaging literature.

Nonlinear parametric models The general approximate representation $f_a(\mathbf{r})$ defined in (7.27) is a linear representation since it results from a linear operator acting on $f(\mathbf{r})$. A nonlinear representation can be constructed in the form

$$f_p(\mathbf{r}) = \sum_{n=1}^N \Upsilon_n(\mathbf{r}, \Theta_n), \quad (7.96)$$

where subscript p connotes *parametric* and Θ_n is the parameter vector. This representation is nonlinear in two senses. First, the function $\Upsilon_n(\mathbf{r}, \Theta_n)$ depends nonlinearly on the free parameters Θ_n , so $f_p(\mathbf{r})$ does as well. Second, the parameters will be determined from $f(\mathbf{r})$ by a nonlinear computation.

The advantage of (7.96) is that it is often possible to use fewer terms than in a pixel representation and to use parameter vectors with few components. As a simple example, consider an astronomical image of a double star, where it is known *a priori* that the object consists of two point sources and the objective of the imaging is to determine the location and strength of each. In that case the object can be described by two terms:

$$f_p(\mathbf{r}) = \sum_{n=1}^2 A_n \delta(\mathbf{r} - \mathbf{r}_n). \quad (7.97)$$

Now each vector Θ_n has three components, A_n , x_n and y_n , and the expansion function depends nonlinearly on the latter two. Equation (7.97) is a more compact representation than any linear expansion $f_a(\mathbf{r})$ that we might construct, yet it is capable of being an exact representation for the given problem. With this object representation, the inverse problem is to estimate the six unknown parameters from some data set \mathbf{g} .

A simple extension of this example might be appropriate in x-ray astronomy if we know that the objects are point sources but do not know *a priori* how many point sources to expect. In that case the summation limit N in (7.96) can itself be one of the nonlinear parameters to be estimated in the inverse problem.

Shape parameters Sometimes it is valid to regard an object as a superposition of geometrical shapes such as circles, ellipses or polygons. The parameters in the representation can then include things like the center coordinates and semimajor axes of each ellipse or the vertices of each polygon, as well as an amplitude like A_n in (7.97) associated with each term.

Gray levels within a shape Shape alone is an incomplete object specification; functional values (gray levels) within the shape also influence the data. Often we are much more interested in the shape than in the functional values, however, so we can use a much coarser description of the latter than the former. For example, we might approximate a 2D object as

$$f_p(\mathbf{r}) = \left[\sum_{k=0}^K \sum_{j=-k}^k a_{jk} R_k^j(r) e^{ij\theta} \right] S_{\Theta}(\mathbf{r}), \quad (7.98)$$

where r and θ are the polar coordinates of \mathbf{r} (do not confuse θ and Θ), $R_k^j(r)$ is the Zernike polynomial (see Sec. 4.1.4) and $S_{\Theta}(\mathbf{r})$ is a function that is unity inside

some region defined by the parameter vector Θ and zero outside. The complete parametric description of the object thus consists of the coefficients $\{a_{jk}\}$ and the components of Θ (e.g., vertex positions). If the gray levels within this region are relatively unimportant to the eventual use of the image, then a small number of Zernike polynomials (small K) can be used. The extreme case is where we assume that the object is uniform within the shape outline, so only the $k = 0$ term is used. Representation of the object in this case requires specifying the shape parameters Θ and the overall gray level a_{00} .

Geometrical transformations For complex shapes such as the cerebral cortex, it may not be feasible to find an analytic expression, but we may have one or more exemplars that capture the essential features of the shape. Then representation of a particular object can be performed by warping each exemplar to fit to that object, and choosing the best fit if more than one exemplar is available. Once the best fit has been found, the warping parameters and an index identifying the exemplar constitute a nonlinear representation of the object. This method is sometimes called *atlas matching*.

The warping can be an affine transformation of the coordinate system of the form

$$\mathbf{r}' = \mathbf{W}\mathbf{r} + \mathbf{r}_0, \quad (7.99)$$

where \mathbf{W} and \mathbf{r}_0 are a matrix and vector, respectively, to be chosen by the fitting procedure. More complex nonlinear transformations can be also used; for example, the elements of \mathbf{W} and \mathbf{r}_0 can be functions of \mathbf{r} . Very complex transformations known as *morphing* have been developed for computer graphics.

Adaptive linear expansions In Sec. 7.1.3 we discussed finite representations obtained by truncating infinite, exact representations [see (7.19)]. Such truncations are useful if terms with higher values of the index n convey less information in some sense about the object being represented. An example is the Fourier series representation of (7.11) where the index codes spatial frequency. Truncating the series thus eliminates high frequencies or small structures, with the hazard that these components might be weak but of prime importance for the intended task.

An alternative approach is to start with an exact (and hence infinite) expansion and keep only the N largest terms in order to represent a particular object. This method is commonly used with wavelets. From (5.90) we know that a 1D function can be represented exactly as

$$f(x) = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} c_{jk} \psi_{jk}(x), \quad (7.100)$$

where $\psi_{jk}(x)$ is a wavelet. If this expansion is truncated, the resulting approximate representation $f_a(x)$ is linear in both senses: $f_a(x)$ is a linear function of the coefficients c_{jk} , and the coefficients are determined by a linear operation on $f(x)$ as in (5.92). If, on the other hand, we keep all terms for which $|c_{jk}|$ is greater than some threshold c_{th} , then linearity in the latter sense is lost, but perhaps many fewer terms will be needed to get a given representation accuracy.

We can think of the two methods of getting an approximate representation from (7.100) as thresholding on the horizontal axis or on the vertical axis of a

wavelet transform; this idea is illustrated in Fig. 7.4. An analysis of the mean-square representation error for thresholding on the vertical axis has been given by Cohen and d'Ales (1995, 1997).

Fig. 7.4 Illustration of two ways of deriving an approximate finite representation from the discrete wavelet transform.

7.2 LINEAR CONTINUOUS-TO-CONTINUOUS SYSTEMS

Having surveyed many different representations of objects and images, we turn now to imaging systems. In this section both the object and the image are described as scalar-valued functions as in Sec. 7.1.1, and we assume that the mapping from object to image is linear. The action of the imaging system is thus described by a linear integral transform (see Sec. 1.2.2). Since the input and output of the system are functions defined on continuous domains, we refer to this system description as the continuous-to-continuous (CC) model. There is, however, no implication that the functions themselves are continuous or even that the system is a continuous mapping as defined in Sec. 1.3.2.

As we shall see in Chap. 9, the linear CC model is valid for optical imaging in two important limits, complete coherence and complete incoherence, and it can be salvaged for partial coherence as well. The CC model also plays a role in indirect imaging. In that case the final image is unlikely to be a function of a continuous variable, since the reconstruction step is usually performed digitally, but the CC model may describe the mapping from an object to an intermediate data set prior to detection and digitization. We shall use the language of direct imaging in this section, but the mathematics is often applicable as well to the first stage in an indirect system.

7.2.1 General shift-variant systems

As in Sec. 7.1.1, we regard the object as a function $f(\mathbf{r})$, where \mathbf{r} is a vector in q dimensions, and the image as a function $g(\mathbf{r}_d)$, where \mathbf{r}_d is a vector in s dimensions. As in Sec. 7.1, the subscript d denotes *detector*, and we shall think of $g(\mathbf{r}_d)$ as a radiation pattern incident on some detector.

The object will be assumed to be supported within a region \mathbf{S}_f in \mathbb{R}^q and square-integrable over that region. Similarly, the image will be assumed to be supported within a region \mathbf{S}_g in \mathbb{R}^s and square-integrable over that region. One or both of these regions might be infinite in a particular problem.

With these assumptions, the imaging system is a mapping from $\mathbb{L}_2(\mathbf{S}_f)$ to $\mathbb{L}_2(\mathbf{S}_g)$, or from object space \mathbb{U} to image space \mathbb{V} . If this mapping is linear, the

Riesz representation theorem (see Sec. 1.2.2) tells us that it must have the form

$$g(\mathbf{r}_d) = \int_{\mathbf{S}_f} d^q r h(\mathbf{r}_d, \mathbf{r}) f(\mathbf{r}). \quad (7.101)$$

In a more abstract notation, we can express this integral as

$$\mathbf{g} = \mathcal{H}\mathbf{f}, \quad (7.102)$$

where \mathbf{f} and \mathbf{g} are Hilbert-space vectors and \mathcal{H} is the linear operator defined by (7.101). We shall also, on occasion, use the notation $[\mathcal{H}f(\mathbf{r})](\mathbf{r}_d)$ or $[\mathcal{H}\mathbf{f}](\mathbf{r}_d)$ to indicate that the function $f(\mathbf{r})$ has been transformed to a function of \mathbf{r}_d .

Since we have defined \mathbb{V} without reference to the characteristics of \mathcal{H} , it is a larger space than we need to encompass all vectors of the form $\mathbf{g} = \mathcal{H}\mathbf{f}$; the range of \mathcal{H} is a subspace of \mathbb{V} . Nevertheless, it is very convenient to choose a familiar \mathbb{L}_2 space as image space, and it will prove essential to do so when we consider noise. With noise, the mapping takes the form $\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}$, where \mathbf{n} is a random vector whose sample space may be all of \mathbb{V} .

Basis functions Because the system is linear, we can expand $f(\mathbf{r})$ in any basis we choose, and each basis function will be mapped independently. With the general expansion (7.8), we have

$$g(\mathbf{r}_d) = \sum_{n=1}^{\infty} \alpha_n \int_{\mathbf{S}_f} d^q r h(\mathbf{r}_d, \mathbf{r}) \psi_n(\mathbf{r}) = \sum_{n=1}^{\infty} \alpha_n [\mathcal{H}\psi_n](\mathbf{r}_d), \quad (7.103)$$

where $\mathcal{H}\psi_n$ is the vector in image space produced by the system in response to vector ψ_n in object space, and $[\mathcal{H}\psi_n](\mathbf{r}_d)$ is the same thing expressed as a function.

Thus, once we know the response of the system to the basis functions, we can obtain the response to an arbitrary object by performing the sum over n . The same conclusion holds for continuous bases (see Sec. 1.1.6), even though the basis functions themselves are not square-integrable.

Point response As discussed in Sec. 2.2.6, Dirac delta functions can be regarded as basis functions for \mathbb{L}_2 , even though they are not themselves in that space. The sifting property of delta functions can be used to express $f(\mathbf{r})$ as

$$f(\mathbf{r}) = \int_{\mathbf{S}_f} d^q r_0 \delta(\mathbf{r} - \mathbf{r}_0) f(\mathbf{r}_0). \quad (7.104)$$

When the right-hand side of this equation is substituted for $f(\mathbf{r})$ in (7.101), $f(\mathbf{r}_0)$ is simply a constant and the entire \mathbf{r} -dependence is carried by the delta function. Thus we obtain

$$g(\mathbf{r}_d) = \int_{\mathbf{S}_f} d^q r h(\mathbf{r}_d, \mathbf{r}) \int_{\mathbf{S}_f} d^q r_0 \delta(\mathbf{r} - \mathbf{r}_0) f(\mathbf{r}_0) = \int_{\mathbf{S}_f} d^q r_0 h(\mathbf{r}_d, \mathbf{r}_0) f(\mathbf{r}_0). \quad (7.105)$$

At first glance, the final form here is just a trivial change of variables in (7.101), but it provides an important insight into the meaning of the kernel. Equations (7.103) and (7.104) have the same structure if we think of the integral over \mathbf{r}_0 in the latter as equivalent to the sum over n in the former. In this view, $h(\mathbf{r}_d, \mathbf{r}_0)$

plays the same role as $[\mathcal{H}\psi_n](\mathbf{r}_d)$. That is, the kernel $h(\mathbf{r}_d, \mathbf{r}_0)$ is the response of the system at point \mathbf{r}_d in image space to a delta function at point \mathbf{r}_0 in object space. Since a delta function is frequently referred to as a *point source* in optics, $h(\mathbf{r}_d, \mathbf{r}_0)$ is called the *point response function* (PRF). Another common term, especially in electrical engineering is impulse response.⁷

Another way to see the interpretation of the kernel as a PRF is to treat the delta function as the limit of a Dirac sequence. If we write

$$\delta(\mathbf{r} - \mathbf{r}_0) = \lim_{k \rightarrow \infty} d_k(\mathbf{r} - \mathbf{r}_0), \quad (7.106)$$

where each function $d_k(\mathbf{r} - \mathbf{r}_0)$ is square-integrable and meets the criteria for a Dirac sequence (see Sec. 2.2.2), then we can investigate the effect of the system on each function and pass to the limit. If the operator \mathcal{H} is a continuous mapping (see Secs. 1.3.2 and 2.1.4), then

$$\lim_{k \rightarrow \infty} [\mathcal{H}d_k(\mathbf{r} - \mathbf{r}_0)](\mathbf{r}_d) = [\mathcal{H}\delta(\mathbf{r} - \mathbf{r}_0)](\mathbf{r}_d) = h(\mathbf{r}_d, \mathbf{r}_0), \quad (7.107)$$

where the last step uses the definition of \mathcal{H} and the sifting property of the delta function. This step can, in fact, be regarded as the definition of $\mathcal{H}\delta(\mathbf{r} - \mathbf{r}_0)$, which is otherwise undefined since the delta function is not strictly in the domain of \mathcal{H} .

Thus, if the term *point source* is interpreted in the sense of a Dirac sequence as the limit of a very small, very bright source at point \mathbf{r}_0 , then the kernel $h(\mathbf{r}_d, \mathbf{r}_0)$, regarded as a function of \mathbf{r}_d for a fixed \mathbf{r}_0 , is the limit of the corresponding image.

The concept of PRF is illustrated in Fig. 7.5 for a 2D imaging system ($q = s = 2$).

Fig. 7.5 Illustration of the point response function for a 2D CC imaging system. Three different input locations for a point object are shown on the left; the image on the right illustrates the location dependence of the response function.

Resolution measures The full PRF, $h(\mathbf{r}_d, \mathbf{r}_0)$ for all values of \mathbf{r}_d and \mathbf{r}_0 , is required for a complete specification of a general linear CC system. This specification is a

⁷The reader familiar with the imaging literature will notice that we are avoiding the term *point spread function* here; that term is being reserved for the special case of shift-invariant imaging, to be discussed shortly. Another expression with essentially the same meaning as PRF is *Green's function*, and that terminology will be used in the context of diffraction.

function of $q + s$ variables, in general, or 4 variables for the 2D imaging situation where $q = s = 2$. Since display of even a 4D function is difficult, there is some impetus for finding simpler, though less complete, descriptions of the system. One way to simplify the description is to report some scalar measure of the width of the function rather than the full function. This measure of the width of the PRF is often referred to as the *spatial resolution* of the system. Perversely, however, a system for which the width is *small* is often said to have *high* resolution.

One common width measure is the *full width at half maximum* (FWHM). This idea is best illustrated by assuming first that $q = s = 1$, so $h(\mathbf{r}_d, \mathbf{r}_0)$ becomes $h(x_d, x_0)$, which we shall assume to be real. Let $h_{max}(x_0)$ be the maximum value of $h(x_d, x_0)$ as a function of x_d for fixed x_0 , and assume that this maximum occurs at $x_d = x_{d0}$, as illustrated in Fig. 7.6. (The value of x_{d0} depends, of course, on x_0 .) If $h(x_d, x_0)$ falls off monotonically away from the peak, it is possible to identify two unique points $x_{d+} > x_{d0}$ and $x_{d-} < x_{d0}$ such that $h(x_{d\pm}, x_0) = \frac{1}{2}h_{max}(x_0)$. A simple measure of the width of the PRF, for a point source at x_0 , is then given by

$$\delta_{\text{FWHM}}(x_0) = x_{d+} - x_{d-}. \quad (7.108)$$

The FWHM definition can be extended straightforwardly to higher dimensions. If $s = 2$, for example, we can define a 2D vector $\delta_{\text{FWHM}}(\mathbf{r}_0)$ with components $x_{d+} - x_{d-}$ and $y_{d+} - y_{d-}$. If the object is also 2D (*i.e.*, $q = 2$), we can display the resolution by this definition in the form of two separate 2D images, one for each component of $\delta_{\text{FWHM}}(\mathbf{r}_0)$ as a function of the coordinates of the object point, x_0 and y_0 . If the PRF is well approximated by a specific functional form such as a Gaussian, then these images fully specify the PRF; otherwise they merely give an indication of general trends.

Fig. 7.6 Illustration of the FWHM measure of resolution.

Some authors argue that tails on the PRF are very important, so we should define additional resolution measures such as full width at one-tenth maximum or

even one-fiftieth, but these definitions require some strong constraints on the form of the PRF. If, for example, the function has low level ripples, there may be many points where it takes on the values $h_{max}/10$ or $h_{max}/50$. We could take the points closest to the maximum, but the resulting width measure is not very representative of the entire function.

Another way to define a width measure is to normalize the PRF as a probability density function and think of \mathbf{r}_d as a random vector (see Fig. 12.28). The width of the PRF in any direction can then be defined by the variance of the corresponding component of \mathbf{r}_d . If we assume that $h(\mathbf{r}_d, \mathbf{r}_0)$ is a real, nonnegative function, the required normalization is

$$p(\mathbf{r}_d, \mathbf{r}_0) = \frac{h(\mathbf{r}_d, \mathbf{r}_0)}{\int_{\mathbf{S}_g} d^s r' h(\mathbf{r}', \mathbf{r}_0)}. \quad (7.109)$$

The resolution width in the x direction is then defined by

$$\delta_x^2 = \int_{\mathbf{S}_g} d^2 r_d x_d^2 p(\mathbf{r}_d, \mathbf{r}_0) - \left[\int_{\mathbf{S}_g} d^2 r_d x_d p(\mathbf{r}_d, \mathbf{r}_0) \right]^2, \quad (7.110)$$

and the width in the y direction is defined analogously.

Other definitions of spatial resolution are appropriate in particular problems. In optics, for example, the PRF often has the form of a sinc or besinc function, and it is common to define a resolution width as the distance from the peak to the first zero. This definition is the *Rayleigh criterion* for resolution.

This discussion of resolution has focused on the dependence of the PRF $h(\mathbf{r}_d, \mathbf{r}_0)$ on the image position \mathbf{r}_d , with the object point \mathbf{r}_0 fixed. It is also useful to consider the dependence of $h(\mathbf{r}_d, \mathbf{r})$ on \mathbf{r} with \mathbf{r}_d fixed. This function of \mathbf{r} can be regarded as the PRF associated with \mathcal{H}^\dagger , and summary measures such as δ_{FWHM} can be defined by direct analogy to the ones discussed above. If the system has some magnification associated with it (see Sec. 7.2.7), the numerical values of the resolution measures in object space may be quite different from those in image space.

Flood images and point sensitivities In addition to providing a sharp image of a point, a good imaging system will exhibit good spatial uniformity in two distinct senses. It will produce a uniform image of a uniform object (often called a *flood source*), and its total response to a point source will be independent of where the point is in the field of view.

The first kind of uniformity is measured by the *flood image*, obtained from the basic imaging equation (7.101) with $f(\mathbf{r})$ set to a constant, which we may as well take to be unity. Thus the flood image is given by

$$g_{fld}(\mathbf{r}_d) = \int_{\mathbf{S}_f} d^q r h(\mathbf{r}_d, \mathbf{r}). \quad (7.111)$$

A common goal, at least in direct imaging, is to make $g_{fld}(\mathbf{r}_d)$ constant (independent of \mathbf{r}_d). If this condition cannot be achieved by design of the system, it always can be achieved by post-processing; we simply define a normalized image of any object by

$$g_{norm}(\mathbf{r}_d) = \frac{g(\mathbf{r}_d)}{g_{fld}(\mathbf{r}_d)}, \quad (7.112)$$

where $g(\mathbf{r}_d)$ is related to $f(\mathbf{r})$ by (7.101). It follows from the definition that $g_{norm}(\mathbf{r}_d)$ must be constant if $f(\mathbf{r})$ is constant. In addition, large uniform regions of a general object will also be rendered as uniform regions in the image (provided the regions are large compared to the width of the PRF).

Uniformity of response to point sources can be quantified by the *point sensitivity*, defined as

$$s_{pt}(\mathbf{r}_0) = \int_{\mathbf{S}_g} d^s r_d h(\mathbf{r}_d, \mathbf{r}_0). \quad (7.113)$$

If $g(\mathbf{r}_d)$ physically represents a mean number of photons per unit area on the detector, then $s_{pt}(\mathbf{r}_0)$ is interpreted as the total mean number of photons collected from a unit point source at \mathbf{r}_0 .

Constant point sensitivity does not imply constant flood uniformity since the latter depends on where the photons are recorded in the image plane, while the former depends only on the total number of photons recorded. Image distortion, for example, can degrade the flood image without affecting point sensitivity. This point is discussed further in Sec. 7.2.7.

7.2.2 Adjoint operators and SVD

As we saw in Chap. 1, singular-value decomposition (SVD) is a powerful tool for analyzing linear systems. If the system is described by a CC operator \mathcal{H} , SVD requires knowledge of the eigenfunctions of $\mathcal{H}^\dagger \mathcal{H}$ and $\mathcal{H} \mathcal{H}^\dagger$, denoted $u_n(\mathbf{r})$ and $v_n(\mathbf{r}_d)$, respectively. In this section we shall discuss the interpretation and uses of these eigenfunctions for CC systems, but first we need to discuss the interpretation of the adjoint operator.

Since \mathcal{H} is a mapping from object space \mathbb{U} to image space \mathbb{V} , the adjoint operator \mathcal{H}^\dagger maps from \mathbb{V} to \mathbb{U} . In a CC problem, the adjoint converts a function of image coordinates \mathbf{r}_d to a function of object coordinates \mathbf{r} . Specifically, for the operator \mathcal{H} defined in (7.102), the adjoint is given (see Sec. 1.3.5) by⁸

$$[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) = \int_{\mathbf{S}_g} d^s r_d g(\mathbf{r}_d) h^*(\mathbf{r}_d, \mathbf{r}). \quad (7.114)$$

If the PRF is real, the complex conjugate is not needed, but we shall maintain the generality.

Since (7.114) is a linear CC mapping like (7.102), it is again useful to discuss it in terms of a point response function. The adjoint PRF is the response in object space produced by a point source in image space. If that point is at the specific location \mathbf{r}_{d0} , then the response is $h^*(\mathbf{r}_{d0}, \mathbf{r})$. Thus there is no need for a separate characterization of the adjoint operator; its PRF is fully determined by the PRF for \mathcal{H} itself.

Figure 7.7 illustrates the adjoint PRF for a 2D system with a nonnegative, real kernel. If we think of \mathcal{H} as a blurring operation in this case, then \mathcal{H}^\dagger is a further blurring, but with $h(\mathbf{r}_d, \mathbf{r})$ replaced by $h(\mathbf{r}, \mathbf{r}_d)$.

⁸Note that we have *not* interchanged the two arguments in $h^*(\mathbf{r}_d, \mathbf{r})$. The interchange stated in (1.44) is implicit in (7.114) since the variable of integration is the first argument, not the second; see the discussion of this point in Sec. 1.3.5.

Fig. 7.7 Illustration of the point response function for \mathcal{H}^\dagger for a 2D CC imaging system. As in Fig. 7.5, 3 input points are shown on the left. The resulting image, shown in (b), illustrates that the PRF of the adjoint operator is position-dependent.

The adjoint operation is frequently called *backprojection* (especially in the tomography literature), since each point is, in a sense, projected back into the object space by the operation defined in (7.114). We caution the reader, however, that the word projection in this context does not imply idempotency.

The operator \mathcal{H} is Hermitian if $h(\mathbf{r}, \mathbf{r}_d) = h^*(\mathbf{r}_d, \mathbf{r})$, which cannot happen unless $q = s$. Even if $q = s$, it is rare to find that \mathcal{H} is Hermitian.

Eigenfunctions in object space The operator $\mathcal{H}^\dagger \mathcal{H}$ that forms the starting point for SVD is given by

$$[\mathcal{H}^\dagger \mathcal{H} \mathbf{f}](\mathbf{r}) = \int_{\mathbf{s}_f} d^q r' k(\mathbf{r}, \mathbf{r}') f(\mathbf{r}'), \quad (7.115)$$

where the kernel $k(\mathbf{r}, \mathbf{r}')$ is

$$k(\mathbf{r}, \mathbf{r}') = \int_{\mathbf{s}_g} d^s r_d h^*(\mathbf{r}_d, \mathbf{r}) h(\mathbf{r}_d, \mathbf{r}'). \quad (7.116)$$

This kernel can be interpreted as the PRF for the CC operator $\mathcal{H}^\dagger \mathcal{H}$ (see Fig. 7.8). It is necessarily symmetric, in the sense that $k(\mathbf{r}, \mathbf{r}') = k^*(\mathbf{r}', \mathbf{r})$, so $\mathcal{H}^\dagger \mathcal{H}$ is (not surprisingly) Hermitian.

If $\mathcal{H}^\dagger \mathcal{H}$ is compact (see Sec. 1.3.3), then the eigenvalues form a denumerable set. For a compact operator, the eigenvalue problem is

$$[\mathcal{H}^\dagger \mathcal{H} \mathbf{u}_n](\mathbf{r}) = \mu_n u_n(\mathbf{r}), \quad n = 1, \dots, \infty. \quad (7.117)$$

Since $\mathcal{H}^\dagger \mathcal{H}$ is Hermitian, all of the eigenvalues are real.

To clarify the interpretation of the eigenvalue equation, we again consider a 2D system with a nonnegative, real kernel. If an eigenfunction $u_n(\mathbf{r})$ is placed in the object plane of this system, the image $\mathcal{H} \mathbf{u}_n$ is a blurred version of it, and $\mathcal{H}^\dagger \mathcal{H} \mathbf{u}_n$ is blurred further. Since the input is an eigenfunction, however, the result of this double blurring must be the original function simply multiplied by a real number μ_n . It may seem surprising that any function would exist with this property, but from the theory of Hermitian operators, we know there must be an infinite number of them. The eigenfunctions may be complex, however, so they cannot represent

real, physical objects. In many imaging situations, the object is constrained to be real and perhaps nonnegative, but no such constraint applies to the eigenfunctions.

Fig. 7.8 Illustration of the point response function for $\mathcal{H}^\dagger \mathcal{H}$ for a CC imaging system.

From the discussion in Sec. 1.5.1, we know that the eigenfunctions can be chosen to form an orthonormal basis in \mathbb{U} . The orthonormality is expressed by

$$\int_{\mathbf{S}_f} d^q r u_n^*(\mathbf{r}) u_m(\mathbf{r}) = \delta_{nm} \quad (7.118)$$

and the completeness by

$$\sum_{n=1}^{\infty} u_n^*(\mathbf{r}) u_n(\mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}'). \quad (7.119)$$

Because of the completeness, any object can be expanded as

$$f(\mathbf{r}) = \sum_{n=1}^{\infty} \alpha_n u_n(\mathbf{r}). \quad (7.120)$$

From (7.118), the coefficients are given by

$$\alpha_n = \int_{\mathbf{S}_f} d^q r u_n^*(\mathbf{r}) f(\mathbf{r}). \quad (7.121)$$

Eigenfunctions in image space If we have solved (7.117) and found a $u_n(\mathbf{r})$ corresponding to a nonzero μ_n , then we can construct a function $v_n(\mathbf{r}_d)$ in image space by [cf. (1.116) and (1.117)]

$$v_n(\mathbf{r}_d) = \frac{1}{\sqrt{\mu_n}} [\mathcal{H} u_n](\mathbf{r}_d). \quad (7.122)$$

This function is easily shown to be a normalized eigenfunction of $\mathcal{H} \mathcal{H}^\dagger$. It satisfies

$$[\mathcal{H} \mathcal{H}^\dagger v_n](\mathbf{r}_d) = \int_{\mathbf{S}_g} d^s r_{d0} K(\mathbf{r}_d, \mathbf{r}_{d0}) v_n(\mathbf{r}_{d0}) = \mu_n v_n(\mathbf{r}_d), \quad (7.123)$$

where the kernel $K(\mathbf{r}_d, \mathbf{r}_{d0})$ is given by

$$K(\mathbf{r}_d, \mathbf{r}_{d0}) = \int_{\mathbf{S}_f} d^q r h^*(\mathbf{r}_{d0}, \mathbf{r}) h(\mathbf{r}_d, \mathbf{r}). \quad (7.124)$$

Note that the eigenvalues of $\mathcal{H}\mathcal{H}^\dagger$ are the same as those of $\mathcal{H}^\dagger\mathcal{H}$.

The full set of functions $\{v_n(\mathbf{r}_d)\}$ (not just the ones corresponding to nonzero μ_n) form an orthonormal basis in image space, satisfying relations analogous to (7.118)–(7.120). Any image $g(\mathbf{r}_d)$ can thus be expanded as

$$g(\mathbf{r}_d) = \sum_{n=1}^{\infty} \beta_n v_n(\mathbf{r}_d), \quad (7.125)$$

where the coefficients are given by

$$\beta_n = \int_{\mathbf{S}_g} d^s r_d v_n^*(\mathbf{r}_d) g(\mathbf{r}_d). \quad (7.126)$$

SVD of a CC operator Having discussed the eigenanalysis of $\mathcal{H}\mathcal{H}^\dagger$ and $\mathcal{H}^\dagger\mathcal{H}$, we are now in a position to treat the SVD of a CC operator. The generic form of the SVD representation of a compact linear operator is given in (1.120), repeated here for convenience:

$$\mathcal{H} = \sum_{n=1}^R \sqrt{\mu_n} \mathbf{v}_n \mathbf{u}_n^\dagger, \quad (7.127)$$

where R is the rank of the operator or the number of nonzero singular values. By the discussion in Sec. 1.4.4, the eigenvalues μ_n cannot be negative, so the singular values $\sqrt{\mu_n}$ are real and nonnegative. Thus we can assume that they are ordered by descending value as in (1.114) and hence the first R terms (where R may be infinite) encompass all nonzero terms in this expansion.

Transcribing (7.127) to the specific case of a CC operator and applying it to an arbitrary object, we obtain

$$\begin{aligned} g(\mathbf{r}_d) &= [\mathcal{H}\mathbf{f}](\mathbf{r}_d) = \sum_{n=1}^R \sqrt{\mu_n} [\mathbf{v}_n \mathbf{u}_n^\dagger \mathbf{f}](\mathbf{r}_d) = \sum_{n=1}^R \left[\sqrt{\mu_n} \int_{\mathbf{S}_f} d^q r u_n^*(\mathbf{r}) f(\mathbf{r}) \right] v_n(\mathbf{r}_d) \\ &= \sum_{n=1}^R \sqrt{\mu_n} \alpha_n v_n(\mathbf{r}_d). \end{aligned} \quad (7.128)$$

That is, given the singular system $\{u_n(\mathbf{r}), v_n(\mathbf{r}), \mu_n\}$, the procedure for computing $[\mathcal{H}\mathbf{f}](\mathbf{r}_d)$ is to form all of the scalar products of $f(\mathbf{r})$ with the object-space singular functions $u_n(\mathbf{r})$, weight these products with the singular values $\sqrt{\mu_n}$ and use the results as coefficients of the image-space singular functions $v_n(\mathbf{r}_d)$. Whenever we use the generic form (7.127) for a CC operator, the detailed implementation of (7.128) will be implied.

Equations (7.125) and (7.128) are two expansions for $g(\mathbf{r}_d)$ in terms of $\{v_n(\mathbf{r}_d)\}$. Since the expansion functions are orthogonal, the sums can be equal only if they are equal term by term, or

$$\beta_n = \sqrt{\mu_n} \alpha_n. \quad (7.129)$$

Thus SVD expansions reduce the imaging equation $\mathbf{g} = \mathcal{H}\mathbf{f}$ to a simple multiplication.

Null functions A CC operator does not necessarily have null functions. If it does, then the sum over n in (7.128) includes only terms for which $\mu_n \neq 0$. These terms define the *measurement space* \mathbb{U}_{meas} for the operator \mathcal{H} , which is a subspace of object space \mathbb{U} . The orthogonal complement of this space, spanned by singular functions $u_n(\mathbf{r})$ for which $\mu_n = 0$, is the *null space* \mathbb{U}_{null} . A vector in this space is called a null vector and denoted \mathbf{f}_{null} , and the corresponding function is called a null function and denoted $f_{null}(\mathbf{r})$.

7.2.3 Shift-invariant systems

Temporal filters In electrical engineering, linear filters are described by a temporal impulse response $p(t, t')$. The voltage on the output of the filter is related to the voltage on the input by

$$v_{out}(t) = \int_{-\infty}^{\infty} dt' p(t, t') v_{in}(t'). \quad (7.130)$$

As in the spatial case, $p(t, t_0)$ is the filter output when the input is $\delta(t' - t_0)$.

In spite of the analogy of $p(t, t')$ to the PRF $h(\mathbf{r}_d, \mathbf{r})$ introduced above, there are two crucial distinctions (other than dimensionality). First, temporal systems are *causal*, which means that there can be no output before there is an input. Causality imposes the following constraint on the impulse response of any temporal filter:

$$p(t, t') = 0 \quad \text{if } t < t'. \quad (7.131)$$

Other properties of causal systems have been discussed in Secs. 4.2.1 and 4.2.4. There is no requirement that spatial filters be causal, and they seldom are.

The second distinction applies to temporal filters in which the physical parameters of the filter (capacitances, inductances, etc.) are independent of time. This is the usual case in passive electrical filters, and it implies that $p(t, t')$ is a function of only the time difference $t - t'$. It is convenient to use the same letter to designate the new function of one variable as we used for the function of two variables, and we write

$$p(t, t') = p(t - t'). \quad (7.132)$$

A linear filter satisfying this condition is said to be *linear and shift-invariant* (LSIV), implying that there is no preferred origin in time; if input $v_{in}(t)$ produces output $v_{out}(t)$, then $v_{in}(t - \Delta t)$ will produce $v_{out}(t - \Delta t)$.

Spatial shift-invariance? Unlike temporal filters with constant parameters, spatial linear systems usually do have preferred origins. The optical axis of a rotationally symmetric lens system or the center of the field of view in a tomographic imager establishes a unique point in space. For such systems, the LSIV model is only an approximation, but it is more mathematically tractable than the general CC model, and it may capture the essential features of a real system, especially when deviations from shift-invariance are small or attention can be confined to a small spatial region.

In addition, there are a few linear systems in optics and imaging that can be described accurately as LSIV. One example is a linear scanner, where a detector and imaging optics are moved continuously over an object. In that case, a shift of the object causes a corresponding shift of the image with no other changes.

Another example of a spatial LSIV system is diffraction. In a typical diffraction problem, an open aperture in a planar screen is illuminated with a monochromatic plane wave, and the diffracted field is observed on a plane a distance z from the aperture. As we shall see in detail in Chap. 9, this problem can be formulated as a linear mapping of one 2D function (the field $u_0(\mathbf{r}_a)$ in the aperture) to another 2D function (the field $u_z(\mathbf{r})$ on the observation plane). This mapping is linear, and it is SIV since a joint translation of the aperture and the observation point has no effect; if field $u_0(\mathbf{r}_a)$ produces the diffracted field $u_z(\mathbf{r})$, then $u_0(\mathbf{r}_a - \Delta\mathbf{r})$ produces $u_z(\mathbf{r} - \Delta\mathbf{r})$. Free space has no preferred origin and the wave equations are linear, so diffraction is an LSIV system. We shall exploit this simple observation fully in developing diffraction theory in Chap. 9.

Convolution operator and its adjoint When a spatial system in q dimensions can be described as LSIV, its output is given by

$$g(\mathbf{r}_d) = \int_{\infty} d^q r h(\mathbf{r}_d - \mathbf{r}) f(\mathbf{r}). \quad (7.133)$$

By a change of variables, this integral can also be written as

$$g(\mathbf{r}_d) = \int_{\infty} d^q r h(\mathbf{r}) f(\mathbf{r}_d - \mathbf{r}). \quad (7.134)$$

Note that the range of integration is infinite in all variables; LSIV systems cannot have limited fields of view.

From (3.240) we recognize the integral in (7.133) or (7.134) as a convolution, which we can write in shorthand form as

$$g(\mathbf{r}_d) = [h * f](\mathbf{r}_d) = h(\mathbf{r}_d) * f(\mathbf{r}_d). \quad (7.135)$$

The 1D convolution operator was introduced in Sec. 3.3.6, and the multidimensional case was discussed in Sec. 3.4.3. Many properties of convolution were developed in those two sections, and we assume here that the reader is conversant with that material.

The kernel of the convolution operator can again be interpreted as the point response function, but it is now a function of one argument rather than two. We shall use the term *point spread function* or PSF instead of PRF when we want to imply the LSIV case.

The adjoint of the convolution operator can be obtained from (7.114), which now becomes

$$[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) = \int_{\infty} d^q r_d h^*(\mathbf{r}_d - \mathbf{r}) g(\mathbf{r}_d). \quad (7.136)$$

From (3.242) we recognize this integral as the correlation $[g \star h^*](\mathbf{r})$. Thus the adjoint of convolution with $h(\mathbf{r})$ is correlation with $h^*(\mathbf{r})$. If $h(-\mathbf{r}) = h^*(\mathbf{r})$, then these two operations are identical and \mathcal{H} is Hermitian.

Flood images and point sensitivities As in the general CC case, we can define flood images and point sensitivities for LSIV systems, but they are rather uninteresting. The flood image is given by [cf. (7.111)]

$$g_{fld}(\mathbf{r}_d) = \int_{\infty} d^q r h(\mathbf{r}_d - \mathbf{r}) = \int_{\infty} d^q r' h(\mathbf{r}'), \quad (7.137)$$

where the last form follows from a simple change of variables. It is evident from this form that $g_{fld}(\mathbf{r}_d)$ is necessarily independent of \mathbf{r}_d . Similarly, the point sensitivity is necessarily independent of \mathbf{r} . LSIV systems cannot suffer from either of these kinds of nonuniformity (which is another reason why LSIV models do not accurately describe real systems).

7.2.4 Eigenanalysis of LSIV systems

For an LSIV operator, \mathbf{r} and \mathbf{r}_d must have the same dimensionality (q must equal s), since otherwise the algebraic operation $\mathbf{r} - \mathbf{r}_d$ would make no sense. Furthermore, the object and image supports are both infinite ($\mathbf{S}_f = \mathbf{S}_g = \mathbb{R}^q$), so object space \mathbb{U} is identical to image space \mathbb{V} . Under these circumstances, it is possible to find eigenfunctions (not just singular functions) and eigenvalues of \mathcal{H} .

We do not expect, however, that the eigenvalues will form a denumerable set since the convolution operator is not compact. In Sec. 1.3.3 we introduced the Hilbert-Schmidt condition, (1.33), as a test for compactness. Convolution fails this test, even if the kernel is square-integrable. By a change of variables, the Hilbert-Schmidt integral for a q D convolution can be written

$$\int_{\infty} d^q r_d \int_{\infty} d^q r |h(\mathbf{r}_d - \mathbf{r})|^2 = \int_{\infty} d^q r_d \int_{\infty} d^q r' |h(\mathbf{r}')|^2 = \int_{\infty} d^q r_d \text{const} = \infty, \quad (7.138)$$

so we cannot show by this route that convolution is compact. We must expect that a general convolution operator will have a continuous spectrum.

The eigenvalue problem for an LSIV operator has the form

$$[\mathcal{H}\psi](\mathbf{r}_d) = [\psi * h](\mathbf{r}_d) = \lambda\psi, \quad (7.139)$$

where $\psi(\mathbf{r})$ is the eigenfunction and λ is the eigenvalue. From the convolution theorem, (3.132), we can write the Fourier transform of this equation as

$$H(\boldsymbol{\rho})\Psi(\boldsymbol{\rho}) = \lambda\Psi(\boldsymbol{\rho}), \quad (7.140)$$

where $H(\boldsymbol{\rho})$ is the Fourier transform of the PSF and $\Psi(\boldsymbol{\rho})$ is the Fourier transform of the eigenfunction.

At first glance it might seem impossible to find a solution to (7.140); we seek a function $\Psi(\boldsymbol{\rho})$ that can be multiplied by some other function, yet retain its functional form. The only function with this property is the Dirac delta function,

$$\Psi(\boldsymbol{\rho}) = \delta(\boldsymbol{\rho} - \boldsymbol{\rho}_0). \quad (7.141)$$

That this function satisfies (7.140) follows from (2.25), according to which

$$H(\boldsymbol{\rho})\delta(\boldsymbol{\rho} - \boldsymbol{\rho}_0) = H(\boldsymbol{\rho}_0)\delta(\boldsymbol{\rho} - \boldsymbol{\rho}_0). \quad (7.142)$$

Since $H(\boldsymbol{\rho}_0)$ is a constant, it is the eigenvalue λ in (7.140), and the delta function is the required $\Psi(\boldsymbol{\rho})$. Any choice of the constant vector $\boldsymbol{\rho}_0$ works, so $\boldsymbol{\rho}_0$ is the continuous index that distinguishes one eigenfunction from another.

An inverse transform of (7.141) shows that the eigenfunctions, now embellished with a subscript, are given by

$$\psi_{\boldsymbol{\rho}_0}(\mathbf{r}) = \exp(2\pi i \boldsymbol{\rho}_0 \cdot \mathbf{r}), \quad (7.143)$$

and the corresponding eigenvalue is

$$\lambda_{\rho_0} = H(\rho_0). \quad (7.144)$$

Since these equations hold for any spatial-frequency vector, the subscript on ρ_0 is superfluous and will be dropped.

Another way to see that (7.143) and (7.144) satisfy the eigenvalue equation is by direct substitution in (7.139):

$$\begin{aligned} [\mathcal{H}\psi_\rho](\mathbf{r}_d) &= \int_{-\infty}^{\infty} d^q r h(\mathbf{r}) \exp[2\pi i \boldsymbol{\rho} \cdot (\mathbf{r}_d - \mathbf{r})] \\ &= \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}_d) \int_{-\infty}^{\infty} d^q r h(\mathbf{r}) \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \end{aligned} \quad (7.145)$$

The last integral is $H(\boldsymbol{\rho})$, but the interesting point for the present discussion is that it is independent of \mathbf{r}_d . For the convolution operator, we can thus write

$$[\mathcal{H}\psi_\rho](\mathbf{r}_d) = \lambda_\rho \psi_\rho(\mathbf{r}_d), \quad (7.146)$$

where the eigenvalue is again $\lambda_\rho = H(\boldsymbol{\rho})$.

In summary, the eigenfunctions of an LSIV operator are the Fourier basis functions or complex exponentials, and the eigenvalues are obtained by Fourier-transforming the PSF. Note that the eigenfunctions are not square-integrable, so they are not contained in the space they span.

7.2.5 Singular-value decomposition of LSIV systems

We have just seen that convolution has eigenfunctions and eigenvalues; like any linear operator, it also has singular functions and singular values. In fact, the singular functions are precisely the eigenfunctions. It will be left as an exercise to show that

$$[\mathcal{H}^\dagger \mathcal{H}\psi_\rho](\mathbf{r}) = |\lambda_\rho|^2 \psi_\rho(\mathbf{r}) = |H(\boldsymbol{\rho})|^2 \psi_\rho(\mathbf{r}), \quad (7.147)$$

where \mathcal{H}^\dagger is given by (7.136). Hence the object-space singular function (or eigenfunction of $\mathcal{H}^\dagger \mathcal{H}$), which we denote by $u_\rho(\mathbf{r})$, is also equal in this case to the eigenfunction $\psi_\rho(\mathbf{r})$. The corresponding singular value is

$$\sqrt{\mu_\rho} = |\lambda_\rho| = |H(\boldsymbol{\rho})|. \quad (7.148)$$

As expected, the singular values are all nonnegative.

When $H(\boldsymbol{\rho}) \neq 0$, the singular functions in image space are given by (7.122) as

$$v_\rho(\mathbf{r}_d) = \frac{1}{|H(\boldsymbol{\rho})|} [\mathcal{H}u_\rho](\mathbf{r}_d) = \frac{H(\boldsymbol{\rho})}{|H(\boldsymbol{\rho})|} \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}_d). \quad (7.149)$$

The factor $H(\boldsymbol{\rho})/|H(\boldsymbol{\rho})|$ is a constant phase factor (± 1 if $H(\boldsymbol{\rho})$ is real); if it is omitted, $v_\rho(\mathbf{r}_d)$ is still an eigenfunction of $\mathcal{H}\mathcal{H}^\dagger$, but the factor is needed for consistency in our overall formalism.

The SVD representation of a convolution, applied to an arbitrary object, is given by (7.128) with the sum over n generalized to an integral over $\boldsymbol{\rho}$:

$$\begin{aligned}
g(\mathbf{r}_d) &= [\mathcal{H}\mathbf{f}](\mathbf{r}_d) = \int_{\infty} d^q\rho |H(\boldsymbol{\rho})| [\mathbf{v}_{\boldsymbol{\rho}}\mathbf{u}_{\boldsymbol{\rho}}^{\dagger}\mathbf{f}](\mathbf{r}_d) \\
&= \int_{\infty} d^q\rho |H(\boldsymbol{\rho})| \left[\int_{\infty} d^q\mathbf{r} u_{\boldsymbol{\rho}}^*(\mathbf{r}) f(\mathbf{r}) \right] v_{\boldsymbol{\rho}}(\mathbf{r}_d). \quad (7.150)
\end{aligned}$$

The integral in square brackets is just the Fourier transform of the object, denoted $F(\boldsymbol{\rho})$, and $v_{\boldsymbol{\rho}}(\mathbf{r}_d)$ is given by (7.149), so

$$g(\mathbf{r}_d) = \int_{\infty} d^q\rho H(\boldsymbol{\rho}) F(\boldsymbol{\rho}) \exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r}_d). \quad (7.151)$$

Taking Fourier transforms of both sides yields

$$G(\boldsymbol{\rho}) = H(\boldsymbol{\rho}) F(\boldsymbol{\rho}), \quad (7.152)$$

where $G(\boldsymbol{\rho}) = \mathcal{F}_q\{g(\mathbf{r}_d)\}$.

This result is the convolution theorem, (3.132), but now it acquires a new interpretation which we can elucidate by writing Fourier expressions beside their SVD counterparts:

$$\begin{aligned}
f(\mathbf{r}) &= \int_{\infty} d^q\rho F(\boldsymbol{\rho}) \exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r}) & \mathbf{f} &= \sum_{n=0}^{\infty} \alpha_n \mathbf{u}_n \\
g(\mathbf{r}_d) &= \int_{\infty} d^q\rho G(\boldsymbol{\rho}) \exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r}_d) & \mathbf{g} &= \sum_{n=0}^{\infty} \beta_n \mathbf{v}_n \\
g(\mathbf{r}_d) &= [h * f](\mathbf{r}_d) & \mathbf{g} &= \mathcal{H}\mathbf{f} \\
G(\boldsymbol{\rho}) &= H(\boldsymbol{\rho}) F(\boldsymbol{\rho}) & \beta_n &= \sqrt{\mu_n} \alpha_n.
\end{aligned}$$

Thus the Fourier transform of an object or image gives the coefficients in an SVD representation derived from a convolution operator. The lack of compactness of the convolution means that we have to use integrals rather than sums, but otherwise the familiar SVD results are obtained. In particular, SVD (or Fourier analysis) reduces the convolution operation to a simple multiplication.

7.2.6 Transfer functions

A complex exponential $\exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r})$ is transferred through an LSIV system unchanged except for multiplication by the eigenvalue $H(\boldsymbol{\rho})$; for this reason $H(\boldsymbol{\rho})$ is often called the *transfer function* of the system.

Of course, the transfer function is also the Fourier transform of the PSF. If the PSF is real, the transfer function must satisfy

$$H(-\boldsymbol{\rho}) = H^*(\boldsymbol{\rho}), \quad (7.153)$$

which shows that the real part of $H(\boldsymbol{\rho})$ is even and the imaginary part is odd (see Sec. 3.2.3). The transfer function is real and even if $h(\mathbf{r})$ is real and even. In any case, (7.153) ensures that $H(0)$ is real if $h(\mathbf{r})$ is real.

As noted in Chap. 3, many books refer to (7.153) as *Hermiticity* or *Hermitian symmetry*, but this terminology is unfortunate since $H(\boldsymbol{\rho})$ does not necessarily relate to a Hermitian operator. As noted in Sec. 7.2.3, the condition that an LSIV

operator be Hermitian is that $h(\mathbf{r}) = h^*(-\mathbf{r})$. This condition implies that $H(\boldsymbol{\rho})$ is real for all $\boldsymbol{\rho}$ (which must be the case for a Hermitian operator since its eigenvalues are real). To avoid confusion, we shall refer to (7.153) as *conjugate symmetry*.

For LSIV systems with real PSFs, it is common to define the *optical transfer function* (OTF) by

$$\text{OTF}(\boldsymbol{\rho}) = \frac{H(\boldsymbol{\rho})}{H(0)}. \quad (7.154)$$

Since $\text{OTF}(0)$ is unity, $\text{OTF}(\boldsymbol{\rho})$ gives the strength with which a complex exponential of frequency $\boldsymbol{\rho}$ is transferred through the system relative to the transferred strength of a constant, which can be regarded as an exponential of frequency zero.

Another normalized transfer function is the *modulation transfer function* (MTF) defined by

$$\text{MTF}(\boldsymbol{\rho}) = \frac{|H(\boldsymbol{\rho})|}{H(0)} = |\text{OTF}(\boldsymbol{\rho})|. \quad (7.155)$$

Many systems have the character of a low-pass-filter, which means that $\text{MTF}(\boldsymbol{\rho}) \leq 1$.

To see why $|H(\boldsymbol{\rho})|/H(0)$ is called MTF, consider as the input to the system not a complex exponential but a raised cosine of the form

$$f(\mathbf{r}) = A + B \cos(2\pi\boldsymbol{\rho} \cdot \mathbf{r} - \phi_f), \quad (7.156)$$

where A and B are real, with $A \geq B \geq 0$ and hence $f(\mathbf{r}) \geq 0$. This function has a *modulation* defined by

$$M_f \equiv \frac{f_{max} - f_{min}}{f_{max} + f_{min}} = \frac{B}{A}, \quad (7.157)$$

where f_{max} , the maximum value of $f(\mathbf{r})$, occurs when the cosine = 1 and is given by $f_{max} = A + B$. Similarly, $f_{min} = A - B$.

To see how this function is affected by an LSIV system, we decompose it as

$$f(\mathbf{r}) = A + \frac{1}{2}B \exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r} - \phi_f) + \frac{1}{2}B \exp(-2\pi i\boldsymbol{\rho} \cdot \mathbf{r} + \phi_f). \quad (7.158)$$

Each of the three terms is now an eigenfunction, so we can write down the image at once:

$$g(\mathbf{r}_d) = AH(0) + \frac{1}{2}BH(\boldsymbol{\rho}) \exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r}_d - \phi_f) + \frac{1}{2}BH(-\boldsymbol{\rho}) \exp(-2\pi i\boldsymbol{\rho} \cdot \mathbf{r}_d + \phi_f). \quad (7.159)$$

Now we assume that the PSF is real, so that (7.153) is satisfied, and write the transfer functions as

$$H(\boldsymbol{\rho}) = |H(\boldsymbol{\rho})| \exp[i\Phi_H(\boldsymbol{\rho})], \quad H(-\boldsymbol{\rho}) = |H(\boldsymbol{\rho})| \exp[-i\Phi_H(\boldsymbol{\rho})]. \quad (7.160)$$

Some easy algebra shows that

$$g(\mathbf{r}_d) = AH(0) + B|H(\boldsymbol{\rho})| \cos[2\pi\boldsymbol{\rho} \cdot \mathbf{r}_d - \phi_f + \Phi_H(\boldsymbol{\rho})]. \quad (7.161)$$

The modulation of $g(\mathbf{r}_d)$, defined analogously to (7.157), is given by

$$M_g = \frac{B|H(\boldsymbol{\rho})|}{AH(0)}. \quad (7.162)$$

Thus the modulation transfer function is aptly named since it is the ratio of output modulation to input modulation:

$$\text{MTF}(\boldsymbol{\rho}) = \frac{M_g}{M_f}. \quad (7.163)$$

This computation also provides an interpretation of the phase of $H(\boldsymbol{\rho})$. The cosine is not an eigenfunction unless $\Phi_H(\boldsymbol{\rho}) = 0$, but the change in form as it is transferred through the system is just a phase shift by an amount $\Phi_H(\boldsymbol{\rho})$. For this reason, $\Phi_H(\boldsymbol{\rho})$ is often referred to as the *phase transfer function*.

Fourier transformation as diagonalization Another way of looking at the process of Fourier transformation with an LSIV system is that it diagonalizes the system operator. The basic idea of diagonalization was introduced in Sec. 1.4.5; here we extend the argument specifically to a convolution operator.

Consider first a general linear CC operator as defined in (7.101), with no restriction other than that \mathbf{r} and \mathbf{r}_d have the same dimensionality ($q = s$). The object $f(\mathbf{r})$ can be expressed in terms of its qD inverse Fourier transform as

$$f(\mathbf{r}) = \int_{\infty} d^q \rho F(\boldsymbol{\rho}) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}), \quad (7.164)$$

or in abstract form,

$$\mathbf{f} = \mathcal{F}_q^{-1} \mathbf{F}. \quad (7.165)$$

A similar representation holds for the image, and the imaging equation becomes

$$\mathbf{g} = \mathcal{F}_q^{-1} \mathbf{G} = \mathcal{H} \mathcal{F}_q^{-1} \mathbf{F}. \quad (7.166)$$

Operating on both sides with \mathcal{F}_q yields

$$\mathbf{G} = \mathcal{F}_q \mathcal{H} \mathcal{F}_q^{-1} \mathbf{F}. \quad (7.167)$$

The kernel of the operator $\mathcal{F}_q \mathcal{H} \mathcal{F}_q^{-1}$ is given by

$$[\mathcal{F}_q \mathcal{H} \mathcal{F}_q^{-1}](\boldsymbol{\rho}_d, \boldsymbol{\rho}) = \int_{\infty} d^q r_d \int_{\infty} d^q r \exp(-2\pi i \boldsymbol{\rho}_d \cdot \mathbf{r}_d) h(\mathbf{r}_d, \mathbf{r}) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \quad (7.168)$$

So far this treatment is applicable to any linear CC system with $q = s$, but now we assume shift-invariance, so that $h(\mathbf{r}_d, \mathbf{r}) = h(\mathbf{r}_d - \mathbf{r})$. Then a change of variables and use of (3.217) shows that

$$[\mathcal{F}_q \mathcal{H} \mathcal{F}_q^{-1}](\boldsymbol{\rho}_d, \boldsymbol{\rho}) = H(\boldsymbol{\rho}) \delta(\boldsymbol{\rho} - \boldsymbol{\rho}_d). \quad (7.169)$$

If we think of $[\mathcal{F}_q \mathcal{H} \mathcal{F}_q^{-1}](\boldsymbol{\rho}_d, \boldsymbol{\rho})$ as a matrix, with continuous vector indices $\boldsymbol{\rho}$ and $\boldsymbol{\rho}_d$ replacing the usual integer indices, then (7.169) shows that the matrix is diagonal, in the sense that all elements with $\boldsymbol{\rho} \neq \boldsymbol{\rho}_d$ are zero. The diagonal elements are infinite, but the strength of the delta function along the diagonal is the transfer function $H(\boldsymbol{\rho})$. In this sense the Fourier domain is the representation in which the system operator is diagonal.

Diagonal operators, like ordinary diagonal matrices, simplify computations considerably. If we apply the operator $\mathcal{F}_q \mathcal{H} \mathcal{F}_q^{-1}$ to an arbitrary object, expressed in the Fourier domain by \mathbf{F} , we quickly find

$$[\mathcal{F}_q \mathcal{H} \mathcal{F}_q^{-1} \mathbf{F}] (\boldsymbol{\rho}_d) = \int_{\infty} d^q \rho H(\boldsymbol{\rho}) \delta(\boldsymbol{\rho} - \boldsymbol{\rho}_d) F(\boldsymbol{\rho}) = H(\boldsymbol{\rho}_d) F(\boldsymbol{\rho}_d). \quad (7.170)$$

Again we rediscover that convolution amounts to multiplication by the transfer function in the Fourier domain.

For later reference, we note that *all* LSIV operators are diagonalized by Fourier transformation. In particular, $\mathcal{H}^\dagger \mathcal{H}$ is LSIV if \mathcal{H} is, and it can be shown that

$$[\mathcal{F}_q \mathcal{H}^\dagger \mathcal{H} \mathcal{F}_q^{-1}] (\boldsymbol{\rho}_d, \boldsymbol{\rho}) = |H(\boldsymbol{\rho})|^2 \delta(\boldsymbol{\rho} - \boldsymbol{\rho}_d). \quad (7.171)$$

7.2.7 Magnifiers

An LSIV system necessarily has unit magnification; if two points on the object are separated by the vector $\Delta \mathbf{r}$, then the two corresponding points on the image must also be separated by $\Delta \mathbf{r}$. Optical systems, however, often function as magnifiers, with the size of the image scaled with respect to the object by a real number m , called the *magnification*. Negative m implies an inverted image, and $|m| < 1$ means that the image is smaller than the object. In this section we examine the effects of magnification from the viewpoint of SVD. Then we generalize the discussion to allow more general affine mappings and space-variant magnification.

Constant magnification An *ideal magnifier* has a PRF given by

$$h(\mathbf{r}_d, \mathbf{r}) = \delta(\mathbf{r}_d - m\mathbf{r}) = |m|^{-q} \delta\left(\frac{\mathbf{r}_d}{m} - \mathbf{r}\right), \quad (7.172)$$

so that

$$g(\mathbf{r}_d) = |m|^{-q} f(\mathbf{r}_d/m). \quad (7.173)$$

With the factor of $|m|^{-q}$, the integral of $g(\mathbf{r}_d)$ is equal to the integral of $f(\mathbf{r})$ for all objects, and hence the point sensitivity is unity. This conclusion follows also from the definition of point sensitivity, (7.113), and the sifting property of delta functions.

Next consider a magnifier with blur. If the form of the blur is independent of position in the object, the PRF is similar to (7.172) but with the delta function replaced by a blur function:

$$h(\mathbf{r}_d, \mathbf{r}) = h(\mathbf{r}_d - m\mathbf{r}). \quad (7.174)$$

Though this PRF is not strictly LSIV, a simple redefinition of the image converts it to LSIV form. The input–output relation can be written as

$$g(\mathbf{r}_d) = \int_{\infty} d^q r h(\mathbf{r}_d - m\mathbf{r}) f(\mathbf{r}) = \int_{\infty} d^q r h[m(\tilde{\mathbf{r}}_d - \mathbf{r})] f(\mathbf{r}), \quad (7.175)$$

where $\tilde{\mathbf{r}}_d = \mathbf{r}_d/m$. If we define $\tilde{g}(\tilde{\mathbf{r}}_d) = g(\mathbf{r}_d)$ and $h'(\mathbf{r}) = h(m\mathbf{r})$, then we have

$$\tilde{g}(\tilde{\mathbf{r}}_d) = \int_{\infty} d^q r h'(\tilde{\mathbf{r}}_d - \mathbf{r}) f(\mathbf{r}) = [h' * f](\tilde{\mathbf{r}}_d). \quad (7.176)$$

Thus, after we refer both the image and the PRF back to the scale of the object, a magnifier with shift-invariant blur is described by a convolution operator.

SVD of a magnifier with blur Another way to salvage the LSIV model with a magnifier is to look at $\mathcal{H}^\dagger \mathcal{H}$ rather than \mathcal{H} . From (7.116) and (7.174), the kernel for $\mathcal{H}^\dagger \mathcal{H}$ is given by

$$\begin{aligned} k(\mathbf{r}, \mathbf{r}') &= \int_{\infty} d^q r_d h^*(\mathbf{r}_d - m\mathbf{r}) h(\mathbf{r}_d - m\mathbf{r}') \\ &= \int_{\infty} d^q r_0 h^*(\mathbf{r}_0) h[\mathbf{r}_0 + m(\mathbf{r} - \mathbf{r}')], \end{aligned} \quad (7.177)$$

where $\mathbf{r}_0 = \mathbf{r}_d - m\mathbf{r}$.

By inspection, $k(\mathbf{r}, \mathbf{r}')$ is a function of $\mathbf{r} - \mathbf{r}'$, so $\mathcal{H}^\dagger \mathcal{H}$ is LSIV (and hence has unit magnification). Its eigenfunctions $u_{\boldsymbol{\rho}}(\mathbf{r})$, which are also the singular functions of \mathcal{H} in object space, are therefore the complex exponentials $\psi_{\boldsymbol{\rho}}(\mathbf{r})$. With a little algebra it can be shown that

$$[\mathcal{H}^\dagger \mathcal{H} u_{\boldsymbol{\rho}}](\mathbf{r}) = \int_{\infty} d^q r' k(\mathbf{r}, \mathbf{r}') \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}') = \mu_{\boldsymbol{\rho}} \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}), \quad (7.178)$$

where the eigenvalues are [cf. (7.147)]

$$\mu_{\boldsymbol{\rho}} = |m|^{-q} |H(\boldsymbol{\rho}/m)|^2. \quad (7.179)$$

The scale factor occurs since the blur function $h(\mathbf{r}_d)$ was originally defined in image space.

When $H(\boldsymbol{\rho}) \neq 0$, the singular functions in image space are given by [cf. (7.149)]

$$v_{\boldsymbol{\rho}}(\mathbf{r}_d) = \frac{1}{\sqrt{\mu_{\boldsymbol{\rho}}}} [\mathcal{H} u_{\boldsymbol{\rho}}](\mathbf{r}_d) = \frac{H(\boldsymbol{\rho}/m)}{|m^{q/2} H(\boldsymbol{\rho}/m)|} \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}_d/m). \quad (7.180)$$

Thus, with minor insertions of factors of m , magnifiers with shift-invariant blur and constant magnification have the same SVD as LSIV systems.

Affine mapping Next we consider systems where the mapping between a point in the object and the corresponding point in the image is an affine transformation. For simplicity, we neglect blur and take the PRF as [cf. (7.172)]

$$h(\mathbf{r}_d, \mathbf{r}) = \delta(\mathbf{r}_d - \mathbf{M}\mathbf{r} - \mathbf{r}_{d0}) = |\det(\mathbf{M})|^{-1} \delta(\mathbf{M}^{-1}\mathbf{r}_d - \mathbf{r} - \mathbf{M}^{-1}\mathbf{r}_{d0}), \quad (7.181)$$

where \mathbf{M} is a nonsingular $q \times q$ matrix and $\det(\mathbf{M})$ is its determinant. With this PRF, the point \mathbf{r} in the object maps to $\mathbf{M}\mathbf{r} + \mathbf{r}_{d0}$ in the image, and the origin in the object ($\mathbf{r} = 0$) maps to the point $\mathbf{r}_d = \mathbf{r}_{d0}$ in the image. If $\mathbf{M} = m\mathbf{I}$ and $\mathbf{r}_{d0} = 0$, then (7.181) reduces to (7.172).

The point sensitivity, defined by (7.113), is a constant for this system since the integral of $h(\mathbf{r}_d, \mathbf{r})$ over \mathbf{r}_d is unity for all \mathbf{r} , as we can see by applying the sifting property of delta functions to the first form of (7.181). Similarly, the flood image is also constant, as we can see by integrating the second form over \mathbf{r} .

SVD for this system is simple since the kernel for $\mathcal{H}^\dagger \mathcal{H}$ is given by

$$\begin{aligned} k(\mathbf{r}, \mathbf{r}') &= \int_{\infty} d^q r_d \delta(\mathbf{r}_d - \mathbf{M}\mathbf{r} - \mathbf{r}_{d0}) \delta(\mathbf{r}_d - \mathbf{M}\mathbf{r}' - \mathbf{r}_{d0}) \\ &= \delta(\mathbf{M}\mathbf{r} - \mathbf{M}\mathbf{r}') = |\det(\mathbf{M})|^{-1} \delta(\mathbf{r} - \mathbf{r}'). \end{aligned} \quad (7.182)$$

Thus $\mathcal{H}^\dagger \mathcal{H}$ is a constant times the identity operator. The SVD basis functions can be any orthonormal basis for the object space, including complex exponentials and space-domain delta-functions.

We can modify this discussion to apply to a system with affine mapping and shift-invariant blur. The delta function in (7.181) is replaced by $h(\mathbf{r}_d - \mathbf{M}\mathbf{r} - \mathbf{r}_{d0})$, and $\mathcal{H}^\dagger \mathcal{H}$ is readily shown to be LSIV. Then the SVD analysis of (7.177)–(7.180) holds simply by replacing the scalar magnification m with the matrix \mathbf{M} and $|m|^q$ with $|\det(\mathbf{M})|$.

Shift-variant magnification Now suppose the magnification varies with position in the object field. Again neglecting blur, and setting \mathbf{r}_{d0} to zero for simplicity, we write the PRF as

$$h(\mathbf{r}_d, \mathbf{r}) = \delta\{\mathbf{r}_d - [\mathbf{M}(\mathbf{r})] \mathbf{r}\}. \quad (7.183)$$

Now point \mathbf{r} in the object maps to $[\mathbf{M}(\mathbf{r})]\mathbf{r}$ in the image.

Since the argument of the delta function vanishes if $\mathbf{r} = [\mathbf{M}(\mathbf{r})]^{-1}\mathbf{r}_d$, we see that $h(\mathbf{r}_d, \mathbf{r}) \propto \delta\{\mathbf{r} - [\mathbf{M}(\mathbf{r})]^{-1}\mathbf{r}_d\}$, but the proportionality factor is a function of \mathbf{r} . To compute it rigorously, we would need to apply the multidimensional counterpart of the transformation rule (2.33), which requires computing derivatives of $[\mathbf{M}(\mathbf{r})]\mathbf{r}$ with respect to each of the components of \mathbf{r} . A reasonable approximation is available, however, if $\mathbf{M}(\mathbf{r})$ varies slowly with \mathbf{r} , in which case

$$h(\mathbf{r}_d, \mathbf{r}) \approx \frac{1}{|\det[\mathbf{M}(\mathbf{r})]|} \delta\{\mathbf{r} - [\mathbf{M}(\mathbf{r})]^{-1}\mathbf{r}_d\}. \quad (7.184)$$

For this system, the point sensitivity is still independent of \mathbf{r} , as we can see by integrating (7.183) over \mathbf{r}_d , but now the flood image is not constant. To compute the flood image, we need to integrate (7.184) over \mathbf{r} . For a specific \mathbf{r}_d , the argument of the delta function vanishes at $\mathbf{r} = \mathbf{r}_0$, where $\mathbf{r}_0 = [\mathbf{M}(\mathbf{r}_0)]^{-1}\mathbf{r}_d$. Actually finding \mathbf{r}_0 may require numerical methods or a specific analytic model for $\mathbf{M}(\mathbf{r})$. If $\mathbf{M}(\mathbf{r})$ is slowly varying in the vicinity of \mathbf{r}_0 , then the delta function can be integrated, with the result

$$g_{fld}(\mathbf{r}_d) \simeq \frac{1}{|\det[\mathbf{M}(\mathbf{r}_0)]|}. \quad (7.185)$$

Thus the flood image at point \mathbf{r}_d is the reciprocal of the determinant of the transformation matrix evaluated at the point \mathbf{r}_0 that solves $[\mathbf{M}(\mathbf{r}_0)]\mathbf{r}_0 = \mathbf{r}_d$. The distortion associated with the space-variant mapping results in a nonuniform flood image.

By analogy to (7.182), the kernel of $\mathcal{H}^\dagger \mathcal{H}$ for a non-blurring, shift-variant magnifier is given by

$$\begin{aligned} k(\mathbf{r}, \mathbf{r}') &= \int_{-\infty}^{\infty} d^q r_d \delta\{\mathbf{r}_d - [\mathbf{M}(\mathbf{r})] \mathbf{r}\} \delta\{\mathbf{r}_d - [\mathbf{M}(\mathbf{r}')] \mathbf{r}'\} \\ &= \delta\{[\mathbf{M}(\mathbf{r})] \mathbf{r} - [\mathbf{M}(\mathbf{r}')] \mathbf{r}'\} \simeq \frac{1}{|\det[\mathbf{M}(\mathbf{r})]|} \delta(\mathbf{r} - \mathbf{r}'), \end{aligned} \quad (7.186)$$

where the last step again assumes $\mathbf{M}(\mathbf{r})$ is slowly varying.

The SVD domain in this case is the space domain since

$$\mathcal{H}^\dagger \mathcal{H} \delta(\mathbf{r} - \mathbf{a}) = \frac{1}{|\det[\mathbf{M}(\mathbf{a})]|} \delta(\mathbf{r} - \mathbf{a}). \quad (7.187)$$

Thus the eigenvectors and eigenvalues of $\mathcal{H}^\dagger \mathcal{H}$ are indexed by a vector \mathbf{a} , and we have

$$u_{\mathbf{a}}(\mathbf{r}) = \delta(\mathbf{r} - \mathbf{a}), \quad \mu_{\mathbf{a}} = \frac{1}{|\det[\mathbf{M}(\mathbf{a})]|}. \quad (7.188)$$

This result illustrates a general rule: the SVD domain for *any* invertible point-to-point mapping without blur is the space domain. The reader is invited to extend the calculation above to an operator \mathcal{H} with kernel $\delta[\mathbf{r}_d - \Phi(\mathbf{r})]$, where $\Phi(\mathbf{r})$ is an arbitrary, invertible, vector-valued function. It will be seen that the eigenvectors of $\mathcal{H}^\dagger \mathcal{H}$ are delta functions; the assumption that $\Phi(\mathbf{r})$ is slowly varying will be needed only to determine the eigenvalues.

7.2.8 Approximately shift-invariant systems

In this section we examine several other systems where the LSIV model is useful but not exact.

Systems with finite field A real imaging system has a finite field of view (FOV) in object space and records an image of finite size. The image field is the same thing as the support of the image, which we denoted as \mathbf{S}_g in Sec. 7.1.2, but we have to be more careful for the FOV in object space. The object may be known *a priori* to fit within support \mathbf{S}_f , but there is no guarantee that the imaging system can respond to all points in this region.

For direct imaging, the main physical effects that limit the fields are finite detector size and vignetting (obscuration of one part of the imaging system by another). The effect of detector size is simply to multiply the image by a function $b_g(\mathbf{r}_d)$, which is 1 for \mathbf{r}_d in \mathbf{S}_g and 0 otherwise. It may be valid to account for vignetting or other field limitations in object space by defining a similar function $b_f(\mathbf{r})$. We shall refer to $b_f(\mathbf{r})$ and $b_g(\mathbf{r}_d)$ as *FOV functions*.

If the blur is shift-invariant except for the FOV functions, the PRF will have the form

$$h(\mathbf{r}_d, \mathbf{r}) = h(\mathbf{r}_d - \mathbf{r}) b_g(\mathbf{r}_d) b_f(\mathbf{r}). \quad (7.189)$$

The kernel for $\mathcal{H}^\dagger \mathcal{H}$ is given by [cf. (7.116)]

$$k(\mathbf{r}, \mathbf{r}') = b_f(\mathbf{r}) b_f(\mathbf{r}') \int_{\infty} d^q r_d b_g(\mathbf{r}_d) h^*(\mathbf{r}_d - \mathbf{r}) h(\mathbf{r}_d - \mathbf{r}'), \quad (7.190)$$

where we have used the fact that $b_f(\mathbf{r})$ is either 0 or 1, hence it is equal to its square.

Because $k(\mathbf{r}, \mathbf{r}')$ is not a function of $\mathbf{r} - \mathbf{r}'$ alone, the singular functions are not complex exponentials; nevertheless, it is interesting to see what happens if $\mathcal{H}^\dagger \mathcal{H}$ operates on $\psi_{\boldsymbol{\rho}}(\mathbf{r}) = \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r})$. With the kernel from (7.190), we have

$$\begin{aligned} & [\mathcal{H}^\dagger \mathcal{H} \psi_{\boldsymbol{\rho}}](\mathbf{r}) \\ &= b_f(\mathbf{r}) \int_{\infty} d^q r_d b_g(\mathbf{r}_d) h^*(\mathbf{r}_d - \mathbf{r}) \int_{\infty} d^q r' b_f(\mathbf{r}') h(\mathbf{r}_d - \mathbf{r}') \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}'). \end{aligned} \quad (7.191)$$

If we represent each of the functions in the double integral by its Fourier transform, we obtain

$$\begin{aligned} & [\mathcal{H}^\dagger \mathcal{H} \psi_\rho](\mathbf{r}) \\ &= b_f(\mathbf{r}) \int_{-\infty}^{\infty} d^q r_d \int_{-\infty}^{\infty} d^q r' \int_{-\infty}^{\infty} d^q \rho_d \int_{-\infty}^{\infty} d^q \rho'_d \int_{-\infty}^{\infty} d^q \rho' \int_{-\infty}^{\infty} d^q \rho'' B_g(\rho_d) H^*(\rho'_d) B_f(\rho') H(\rho'') \\ & \quad \times \exp\{2\pi i [\boldsymbol{\rho} \cdot \mathbf{r}' + \boldsymbol{\rho}_d \cdot \mathbf{r}_d - \boldsymbol{\rho}'_d \cdot (\mathbf{r}_d - \mathbf{r}) + \boldsymbol{\rho}' \cdot \mathbf{r}' + \boldsymbol{\rho}'' \cdot (\mathbf{r}_d - \mathbf{r}')]\}. \end{aligned} \quad (7.192)$$

Though this expression may appear frightening, it simplifies readily. By (3.217), the integral over \mathbf{r}_d yields $\delta(\boldsymbol{\rho}_d - \boldsymbol{\rho}'_d + \boldsymbol{\rho}'')$ and the one over \mathbf{r}' yields $\delta(\boldsymbol{\rho} + \boldsymbol{\rho}' - \boldsymbol{\rho}'')$. These two delta functions let us perform two other integrals, and we find

$$\begin{aligned} & [\mathcal{H}^\dagger \mathcal{H} \psi_\rho](\mathbf{r}) \\ &= b_f(\mathbf{r}) \int_{-\infty}^{\infty} d^q \rho_d \int_{-\infty}^{\infty} d^q \rho' B_g(\rho_d) H^*(\rho_d + \boldsymbol{\rho} + \boldsymbol{\rho}') B_f(\rho') H(\boldsymbol{\rho} + \boldsymbol{\rho}') \\ & \quad \times \exp[2\pi i(\boldsymbol{\rho} + \boldsymbol{\rho}_d + \boldsymbol{\rho}') \cdot \mathbf{r}]. \end{aligned} \quad (7.193)$$

So far this development has been exact, but now we make a reasonable approximation. We assume that the FOV functions $b_f(\mathbf{r})$ and $b_g(\mathbf{r}_d)$ cover a large area so that their Fourier transforms, $B_f(\boldsymbol{\rho}')$ and $B_g(\boldsymbol{\rho}_d)$, respectively, are peaked in a narrow range around the origin. For example, if an FOV function covers a region of width L in each dimension, then its Fourier transform is small when any component of the spatial frequency exceeds about $1/L$. If the transfer function $H(\boldsymbol{\rho})$ is slowly varying on this scale, it may be valid to replace $\boldsymbol{\rho}'$ and $\boldsymbol{\rho}_d$ with zero in the arguments of $H^*(\boldsymbol{\rho}_d + \boldsymbol{\rho} + \boldsymbol{\rho}')$ and $H(\boldsymbol{\rho} + \boldsymbol{\rho}')$. Doing so gives

$$\begin{aligned} [\mathcal{H}^\dagger \mathcal{H} \psi_\rho](\mathbf{r}) &\simeq b_f(\mathbf{r}) |H(\boldsymbol{\rho})|^2 \int_{-\infty}^{\infty} d^q \rho_d \int_{-\infty}^{\infty} d^q \rho' B_g(\rho_d) B_f(\rho') \exp[2\pi i(\boldsymbol{\rho} + \boldsymbol{\rho}_d + \boldsymbol{\rho}') \cdot \mathbf{r}] \\ &= b_f(\mathbf{r}) b_g(\mathbf{r}) |H(\boldsymbol{\rho})|^2 \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \end{aligned} \quad (7.194)$$

We can also define $b_{tot}(\mathbf{r}) = b_f(\mathbf{r}) b_g(\mathbf{r})$, which is a function that is unity for points inside both fields and zero elsewhere.

Thus the truncated exponential function $b_{tot}(\mathbf{r}) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r})$ is a useful approximate singular function for systems described by (7.189); a large but finite field of view does not rule out Fourier analysis so long as the transfer function is relatively slowly varying on a scale given by the reciprocal of the width of the field. Roughly speaking, the errors made with this approximation will be concentrated within about δ of the edge of the field, where δ is one of the resolution measures defined in Sec. 7.2.1.

Weak shift-variance For a shift-variant linear system, the PRF must be a function of two variables. In Sec. 7.2.1 we chose those variables as \mathbf{r}_d and \mathbf{r}_0 (where \mathbf{r}_0 is the location of the point in the object domain), but if $q = s$ we can equally well choose $\mathbf{r}_d - \mathbf{r}_0$ and \mathbf{r}_0 , writing

$$h(\mathbf{r}_d, \mathbf{r}_0) = p(\mathbf{r}_d - \mathbf{r}_0; \mathbf{r}_0). \quad (7.195)$$

The form on the right is particularly useful if $p(\mathbf{r}_d - \mathbf{r}_0; \mathbf{r}_0)$ is a slowly varying function of its second argument.

To clarify this idea, we need to consider two characteristic distances. One is the full width at half maximum of the PRF, $\delta_{FWHM}(\mathbf{r}_0)$ [see (7.108)]. The other is

a *variation distance*, defined loosely as a scalar $\Delta(\mathbf{r}_0)$ such that $p(\mathbf{r}_d - \mathbf{r}_0; \mathbf{r}_0) \simeq p(\mathbf{r}_d - \mathbf{r}_1; \mathbf{r}_1)$ if $|\mathbf{r}_1 - \mathbf{r}_0| < \Delta(\mathbf{r}_0)$. A system is said to be *weakly shift-variant* if $\delta_{\text{FWHM}}(\mathbf{r}_0) \ll \Delta(\mathbf{r}_0)$.

One way to analyze a weakly shift-variant system is via the continuous form of Gabor's signal expansion, introduced in Sec. 5.1.4. Generalizing (5.40) to q dimensions, we can express an object $f(\mathbf{r})$ as

$$f(\mathbf{r}) = \int_{\infty} d^q \rho \int_{\infty} d^q r_0 F_b(\boldsymbol{\rho}; \mathbf{r}_0) b(\mathbf{r} - \mathbf{r}_0) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}), \quad (7.196)$$

where we have assumed that the window function $b(\mathbf{r})$ is real and has unit norm. With these assumptions, the inverse of (7.196) is the multidimensional local Fourier transform [cf. (5.1)]:

$$F_b(\boldsymbol{\rho}; \mathbf{r}_0) = \int_{\infty} d^q r b(\mathbf{r} - \mathbf{r}_0) f(\mathbf{r}) \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \quad (7.197)$$

If we apply the operator with kernel (7.195) to (7.196), we obtain

$$\begin{aligned} g(\mathbf{r}_d) &= [\mathcal{H}f](\mathbf{r}_d) \\ &= \int_{\infty} d^q \rho \int_{\infty} d^q r_0 F_b(\boldsymbol{\rho}; \mathbf{r}_0) \int_{\infty} d^q r b(\mathbf{r} - \mathbf{r}_0) p(\mathbf{r}_d - \mathbf{r}; \mathbf{r}) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \end{aligned} \quad (7.198)$$

For this expression to be useful, we must be able to choose the width δ_b of the window function so that

$$\delta_{\text{FWHM}}(\mathbf{r}_0) \ll \delta_b \ll \Delta(\mathbf{r}_0) \quad (7.199)$$

for all \mathbf{r}_0 . If this condition is satisfied, $b(\mathbf{r} - \mathbf{r}_0) \simeq b(\mathbf{r}_d - \mathbf{r}_0)$ and $p(\mathbf{r}_d - \mathbf{r}; \mathbf{r}) \simeq p(\mathbf{r}_d - \mathbf{r}; \mathbf{r}_0)$, and we can write

$$\begin{aligned} g(\mathbf{r}_d) &= \int_{\infty} d^q \rho \int_{\infty} d^q r_0 F_b(\boldsymbol{\rho}; \mathbf{r}_0) b(\mathbf{r}_d - \mathbf{r}_0) \int_{\infty} d^q r p(\mathbf{r}_d - \mathbf{r}; \mathbf{r}_0) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) \\ &= \int_{\infty} d^q \rho \int_{\infty} d^q r_0 F_b(\boldsymbol{\rho}; \mathbf{r}_0) P(\boldsymbol{\rho}; \mathbf{r}_0) b(\mathbf{r}_d - \mathbf{r}_0) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}_d), \end{aligned} \quad (7.200)$$

where $P(\boldsymbol{\rho}; \mathbf{r}_0)$ is the Fourier transform (with respect to \mathbf{r}_d) of $p(\mathbf{r}_d; \mathbf{r}_0)$.

The similarity between (7.200) and (7.151) should be noted. The latter equation shows that the output of an LSIV system can be computed by multiplying the Fourier transform of the input by the transfer function and then taking an inverse Fourier transform; the former equation shows that the same thing holds true for weakly shift-variant systems if *local* Fourier transforms are used and the conditions (7.199) can be satisfied.

Under the same conditions, the windowed exponentials $b(\mathbf{r} - \mathbf{r}_0) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r})$ are approximately eigenfunctions (hence also singular functions) of \mathcal{H} and the eigenvalues are $P(\boldsymbol{\rho}; \mathbf{r}_0)$. Though the eigenfunctions and eigenvalues are characterized here by two continuous indices, it follows from the discussion in Sec. 5.1.4 that a countably infinite complete set can be obtained by sampling $\boldsymbol{\rho}$ and \mathbf{r}_0 on a Gabor lattice.

7.2.9 Rotationally symmetric systems

A CC system may have rotational symmetry, whether or not it is shift-invariant. A simple example is a rotationally symmetric lens with aberrations. As we shall see in Chap., the aberrations usually spoil the shift-invariance, but the rotational invariance remains and has a strong effect on the allowable forms of \mathcal{H} and $\mathcal{H}^\dagger\mathcal{H}$. In this section we shall discuss the effects of rotational symmetry specifically for systems that map a 2D object to a 2D image. For essential background material, see Chap. 6.

Symmetry group To give a precise definition of rotational symmetry, we need to introduce a Lie group of rotation operators. This group, denoted \mathbf{C}_∞ in Sec. 6.5, can describe either geometric rotations in the plane \mathbb{R}^2 or transformations of functions in the Hilbert space \mathbb{U} . As in Chap. 6 we make a notational distinction between these two kinds of operators by using \mathcal{T} with various subscripts to denote the functional operator. We denote a geometric rotation through angle ϕ by the operator \mathcal{R}_ϕ and the corresponding functional transformation by \mathcal{T}_ϕ . Specifically, if the 2D vectors \mathbf{r} and \mathbf{r}' are given in polar coordinates by (r, θ) and (r', θ') , respectively, and $\mathbf{r}' = \mathcal{R}_\phi\mathbf{r}$, then $r' = r$ and $\theta' = \theta + \phi$. The functional operator \mathcal{T}_ϕ is defined by (6.24) as

$$[\mathcal{T}_\phi\mathbf{f}](\mathbf{r}) = f[\mathcal{R}_\phi^{-1}\mathbf{r}] = f[\mathcal{R}_{-\phi}\mathbf{r}] = f(r, \theta - \phi), \quad (7.201)$$

where \mathbf{f} is an arbitrary vector in \mathbb{U} , corresponding to the function $f(r, \theta)$ in polar coordinates.

As discussed in Sec. 6.7, rotational symmetry means that all rotation operators, \mathcal{T}_ϕ for all ϕ , commute with $\mathcal{H}^\dagger\mathcal{H}$, so that

$$\mathcal{H}^\dagger\mathcal{H}\mathcal{T}_\phi = \mathcal{T}_\phi\mathcal{H}^\dagger\mathcal{H}. \quad (7.202)$$

In the language of group theory, this equation says that the symmetry group of the system is \mathbf{C}_∞ . In more intuitive terms, it says that we can either rotate the object in its plane by ϕ and then image it and backproject the result into object space, or we can first image and backproject and then rotate, and the result must be the same if the system has rotational symmetry.

Eigenfunctions The eigenfunctions of $\mathcal{H}^\dagger\mathcal{H}$ have been denoted by $u_n(\mathbf{r})$, but in this problem it is natural to express the 2D vector \mathbf{r} in polar coordinates as (r, θ) . In addition, it will prove useful to use two indices, j and k , in place of n , so we shall denote the eigenfunctions by $u_{jk}(r, \theta)$, and we shall use \mathbf{u}_{jk} to denote the corresponding Hilbert-space vector. With these notational changes, the eigenvalue equation (7.117) becomes

$$[\mathcal{H}^\dagger\mathcal{H}\mathbf{u}_{jk}](r, \theta) = \mu_{jk} u_{jk}(r, \theta). \quad (7.203)$$

It follows from (7.202) and (7.203) that

$$\mathcal{H}^\dagger\mathcal{H}\mathcal{T}_\phi\mathbf{u}_{jk} = \mathcal{T}_\phi\mathcal{H}^\dagger\mathcal{H}\mathbf{u}_{jk} = \mu_{jk}\mathcal{T}_\phi\mathbf{u}_{jk}. \quad (7.204)$$

Looking at the first and third forms in this equation, we see that $\mathcal{T}_\phi\mathbf{u}_{jk}$ is an eigenvector of $\mathcal{H}^\dagger\mathcal{H}$ with eigenvalue μ_{jk} if \mathbf{u}_{jk} is such an eigenvector (see Sec. 6.7.4). If the eigenvalue μ_{jk} is not degenerate, then $\mathcal{T}_\phi\mathbf{u}_{jk}$ can only be a constant

times \mathbf{u}_{jk} . In other words, \mathbf{u}_{jk} must be simultaneously an eigenvector of \mathcal{T}_ϕ and $\mathcal{H}^\dagger \mathcal{H}$.

To discover the structure of these eigenvectors, we note from (7.201) that $u_{jk}(r, \theta)$ is an eigenvector of \mathcal{T}_ϕ if

$$u_{jk}(r, \theta - \phi) = \text{const} \cdot u_{jk}(r, \theta). \quad (7.205)$$

The solution to this functional equation is

$$u_{jk}(r, \theta) = u_{jk}(r) e^{ik\theta}, \quad (7.206)$$

where $u_{jk}(r)$ is an arbitrary function of r .

The constant in (7.205) (the eigenvalue of \mathcal{T}_ϕ) is given by

$$\chi^{(k)}(\phi) = e^{-ik\phi}, \quad k = 0, \pm 1, \pm 2, \dots \quad (7.207)$$

Comparison with (6.23) reveals the reason for the notation chosen: $\chi^{(k)}(\phi)$ is the character associated with \mathcal{T}_ϕ in the k^{th} irreducible representation of \mathbf{C}_∞ . Since \mathbf{C}_∞ is an Abelian group, all of its irreducible representations are 1D, so all operators in the (infinite) group are represented by 1×1 matrices and act on 1D subspaces of the Hilbert space \mathbb{U} . The k^{th} subspace consists of all scalar multiples of $e^{ik\theta}$ (times an arbitrary function of r), and the matrix corresponding to the operator \mathcal{T}_ϕ in this representation is the scalar $e^{-ik\phi}$. Since the matrices are 1×1 , the character (trace of the matrix) and the eigenvalue of \mathcal{T}_ϕ are identical.

The conclusion from this discussion is that the nondegenerate eigenfunctions of $\mathcal{H}^\dagger \mathcal{H}$ for a rotationally symmetric system must have the form,

$$u_{jk}(r, \theta) = u_{jk}(r) e^{ik\theta}. \quad (7.208)$$

The utility of the double index jk is now apparent: the index k specifies the angular dependence, while different eigenvectors with the same angular dependence are distinguished by j . Since k also indexes the irreducible representation, we can say that \mathbf{u}_{jk} transforms under rotation according to the k^{th} irreducible representation of \mathbf{C}_∞ .

A similar argument shows that nondegenerate eigenfunctions of $\mathcal{H} \mathcal{H}^\dagger$ have the form,

$$v_{jk}(r_d, \theta_d) = v_{jk}(r_d) e^{ik\theta_d}. \quad (7.209)$$

This function also transforms under rotation according to the k^{th} irreducible representation of \mathbf{C}_∞ , but now the rotation operator is defined in image space \mathbb{V} .

Form of the operators We can use (7.208) along with the spectral decomposition (see Sec. 1.4.5) to discuss the structure of the operators $\mathcal{H}^\dagger \mathcal{H}$ and \mathcal{H} . In the present notation, the spectral decomposition of $\mathcal{H}^\dagger \mathcal{H}$ is

$$\mathcal{H}^\dagger \mathcal{H} = \sum_{j,k} \mu_{jk} \mathbf{u}_{jk} \mathbf{u}_{jk}^\dagger. \quad (7.210)$$

In polar coordinates, where $\mathbf{r} = (r, \theta)$ and $\mathbf{r}' = (r', \theta')$, the kernel of this operator is

$$k(\mathbf{r}, \mathbf{r}') = k(r, \theta, r', \theta') = \sum_{j,k} \mu_{jk} u_{jk}(r) u_{jk}^*(r') e^{ik(\theta - \theta')}. \quad (7.211)$$

By inspection, the kernel is a function of only the three variables, r , r' and $\theta - \theta'$. Angular shift-invariance results from rotational symmetry in the same way that the usual positional shift-invariance results from translational symmetry. The angular shift-invariance can also be stated as

$$k[\mathcal{R}_\phi \mathbf{r}, \mathcal{R}_\phi \mathbf{r}'] = k(\mathbf{r}, \mathbf{r}'). \quad (7.212)$$

A similar argument can be used to determine the structure of the operator \mathcal{H} . From the SVD expansion (7.127) and the forms (7.208) and (7.209), the kernel for \mathcal{H} is given by [cf. (7.127)]

$$h(\mathbf{r}_d, \mathbf{r}) = h(r_d, \theta_d, r, \theta) = \sum_{j,k} \sqrt{\mu_{jk}} v_{jk}(r_d) u_{jk}^*(r) e^{ik(\theta_d - \theta)}. \quad (7.213)$$

This kernel is a function of only r_d , r and $\theta_d - \theta$. We shall make use of this structure in Chap. 9 when we discuss aberrations of rotationally symmetric optical systems.

Mirror symmetry and degeneracy We assumed above that $\mathcal{H}^\dagger \mathcal{H}$ has no degeneracies, so each eigenvalue μ_{jk} corresponds uniquely to an eigenvector \mathbf{u}_{jk} . This assumption may not hold if the system has other symmetries (see Sec. 6.7.5) so that \mathbf{C}_∞ is just a subgroup of the full symmetry group of the system. An important additional symmetry, which often accompanies \mathbf{C}_∞ , is mirror-reflection symmetry. As a geometric transformation in \mathbb{R}_2 , mirror reflection about the x axis transforms point (x, y) to $(x, -y)$. We denote this operator by \mathcal{M}_0 , where the subscript indicates that the mirror axis is the line $\phi = 0$, or the x axis. Since \mathcal{M}_0 is its own inverse, the corresponding functional transformation, denoted $\mathcal{T}_{\mathcal{M}_0}$, satisfies $[\mathcal{T}_{\mathcal{M}_0} \mathbf{f}](x, y) = f(x, -y)$.

An immediate consequence of mirror symmetry is that the kernel of $\mathcal{H}^\dagger \mathcal{H}$ must satisfy $k[\mathcal{M}_0 \mathbf{r}, \mathcal{M}_0 \mathbf{r}'] = k(\mathbf{r}, \mathbf{r}')$ [cf. (7.212)]. Since mirror reflection about the x axis transforms θ to $-\theta$, it follows (for a system with rotational and mirror symmetry) that $k(r, r', \theta - \theta') = k(r, r', \theta' - \theta)$, where $k(r, r', \theta - \theta')$ is the same function as $k(r, \theta, r', \theta')$ but with the angular shift-invariance displayed explicitly. Thus the kernel can only be an even function of $\theta - \theta'$.

To examine the degeneracies of the eigenvalues, we must first determine the full symmetry group of the system. If a rotationally symmetric $\mathcal{H}^\dagger \mathcal{H}$ is invariant under $\mathcal{T}_{\mathcal{M}_0}$, it is also invariant under all other mirror reflections obtained by rotating the mirror axis by an arbitrary angle. The full symmetry group of the system thus consists of all rotations \mathcal{T}_ϕ and all mirror transformations of the form $\mathcal{T}_{\mathcal{M}_\phi} \equiv \mathcal{T}_\phi^{-1} \mathcal{T}_{\mathcal{M}_0} \mathcal{T}_\phi$. This group is isomorphic to the group of geometric operators that leave a uniform disc invariant. It will be denoted \mathbf{D}_∞ since it can be regarded as the limit as $N \rightarrow \infty$ of the dihedral group \mathbf{D}_N (the symmetry group of an N -sided regular polygon), which is discussed in Sec. 6.4.2. The group \mathbf{D}_∞ has two 1D irreducible representations and a denumerable infinity of 2D ones. A 2D irreducible representation of the symmetry group of the system leads to two-fold degeneracy of the eigenvectors of $\mathcal{H}^\dagger \mathcal{H}$.

Specifically, $u_{jk}(r, \theta)$ and $[\mathcal{T}_{\mathcal{M}_0} \mathbf{u}_{jk}](r, \theta)$ must be degenerate if $\mathcal{T}_{\mathcal{M}_0}$ commutes with $\mathcal{H}^\dagger \mathcal{H}$. Since the eigenfunctions have the form of (7.206) by rotational symmetry, and mirror reflection about the x axis merely reverses the sign of θ , we have

$$[\mathcal{T}_{\mathcal{M}_0} \mathbf{u}_{jk}](r, \theta) = u_{jk}(r) e^{-ik\theta}, \quad (7.214)$$

and the eigenfunctions $u_{jk}(r) \exp(ik\theta)$ and $u_{jk}(r) \exp(-ik\theta)$ must be degenerate. If $k = 0$, the two functions are identical, so $k = 0$ corresponds to a 1D irreducible representation. For any other k , however, the two functions are linearly independent and the irreducible representation is 2D.

We can always choose the eigenfunctions to have the form $u_{jk}(r) \exp(ik\theta)$, in spite of the degeneracy. Suppose P linearly independent eigenvectors $\mathbf{u}_{jk}^{(p)}$, $p = 1, \dots, P$, have the same eigenvalue μ_{jk} . These vectors define a P -dimensional subspace, and any linear combination of vectors in the space is an eigenvector of $\mathcal{H}^\dagger \mathcal{H}$ with eigenvalue μ_{jk} . Moreover, we know from (7.204) that this subspace is invariant under \mathbf{C}_∞ if $\mathcal{H}^\dagger \mathcal{H}$ is rotationally symmetric. That is, the action of \mathcal{T}_ϕ on any vector in the space yields another vector in the space. Following (6.68), we can construct a representation of \mathbf{C}_∞ on this space by forming the $P \times P$ matrices $\mathbf{M}(\mathcal{T}_\phi)$, with elements given by

$$[\mathbf{M}(\mathcal{T}_\phi)]_{p'p} = \left(\mathbf{u}_{jk}^{(p')}, \mathcal{T}_\phi \mathbf{u}_{jk}^{(p)} \right). \quad (7.215)$$

Since \mathbf{C}_∞ is Abelian, it has only 1D irreducible representations, so the P -dimensional representation defined by (7.215) is necessarily reducible if $P > 1$. We can therefore find a $P \times P$ unitary transformation that will diagonalize each of the P matrices of (7.215), and each diagonal element will be one of the characters defined in (7.207). That is, we can choose the basis of the subspace to consist of eigenvectors of the rotation operators. Since the unitary transformation leaves us within the space of degenerate eigenvectors, the resulting basis vectors are also eigenvectors of $\mathcal{H}^\dagger \mathcal{H}$, and the corresponding eigenfunctions have the form $u_{jk}(r) \exp(ik\theta)$.

Rotational and translational symmetry: The kernels Next we consider systems that are invariant under both rotations and translations. We saw in (7.213) that the kernel of a rotationally symmetric \mathcal{H} is a function of r , r_d and $\theta - \theta_d$, and we know that the kernel (PSF) of a shift-invariant system is a function of $\mathbf{r}_d - \mathbf{r}$. Here we examine the form of the kernel when both symmetries are present.

A system is rotationally and translationally symmetric if $h(\mathbf{r}_d, \mathbf{r}) = p(|\mathbf{r}_d - \mathbf{r}|)$, where $p(\cdot)$ is a scalar-valued function. This form satisfies both conditions in the paragraph above. Any function of $|\mathbf{r}_d - \mathbf{r}|$ is also a function of $\mathbf{r}_d - \mathbf{r}$ as required by translational symmetry and, since $|\mathbf{r}_d - \mathbf{r}| = [r^2 + r_d^2 + 2rr_d \cos(\theta - \theta_d)]^{1/2}$, $p(|\mathbf{r}_d - \mathbf{r}|)$ can be rewritten as a function of r , r_d and $\theta - \theta_d$ as required by rotational symmetry.

Thus any LSIV system where the PSF $p(\mathbf{r})$ is a function of only the magnitude of r is rotationally symmetric, but the converse does not necessarily hold. Since we have defined rotational symmetry by the condition that $\mathcal{T}_\phi \mathcal{H}^\dagger \mathcal{H} = \mathcal{H}^\dagger \mathcal{H} \mathcal{T}_\phi$, it is possible for an LSIV system to have rotational symmetry but for the PSF to depend on θ . A simple example is when $p(\mathbf{r})$ is a function of $|\mathbf{r} - \mathbf{a}|$. The offset \mathbf{a} makes $p(\mathbf{r})$ a function of θ , but $k(\mathbf{r})$, the PSF associated with $\mathcal{H}^\dagger \mathcal{H}$, is the autocorrelation of $p(\mathbf{r})$ and hence insensitive to offset. Thus $k(\mathbf{r}) = k(r)$. The same conclusion emerges in the Fourier domain when we recognize that the transfer function $H(\boldsymbol{\rho})$ has a factor $\exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{a})$ resulting from the offset, but the transfer function associated with $\mathcal{H}^\dagger \mathcal{H}$ is $|H(\boldsymbol{\rho})|^2$. Since the phase factor disappears when we take the squared modulus, we can have $|H(\boldsymbol{\rho})|^2 = |H(\boldsymbol{\rho})|^2$ even though $H(\boldsymbol{\rho}) \neq H(\boldsymbol{\rho})$.

We could remove this peculiarity by defining rotational symmetry differently. If object space \mathbb{U} and image space \mathbb{V} are the same, we could require that \mathcal{H} itself, and not just $\mathcal{H}^\dagger \mathcal{H}$, commute with each \mathcal{T}_ϕ . Then the kernel of \mathcal{H} would have

angular shift-invariance and the eigenfunctions of \mathcal{H} would vary as $\exp(ik\theta)$. The advantage of working with $\mathcal{H}^\dagger\mathcal{H}$, however, is that we can define rotational and other symmetries even when \mathbb{U} and \mathbb{V} are different spaces. An example where this feature is useful will be seen in Sec. 7.2.10.

Rotational and translational symmetry: The eigenfunctions We know from Sec. 7.2.4 that the eigenfunctions of $\mathcal{H}^\dagger\mathcal{H}$ for LSIV systems are the complex exponentials, $\exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r})$, and this statement must still hold true if the system also has rotational symmetry. We have also argued, however, that the eigenfunctions of rotationally symmetric systems should vary as $e^{ik\theta}$. To reconcile these statements, we must recognize that the translation-rotation group, like the affine group, has only infinite-dimensional irreducible representations (see Sec. 6.8.5). That means that all eigenfunctions have infinite degeneracy for an LSIV system with rotational symmetry.

Though this conclusion may be surprising as a mathematical proposition, there is actually a simple physical explanation. We saw in Sec. 7.2.5 that the eigenvalues of $\mathcal{H}^\dagger\mathcal{H}$, now indexed by the continuous vector variable $\boldsymbol{\rho}$, are given by $|H(\boldsymbol{\rho})|^2$, where $H(\boldsymbol{\rho})$ is the transfer function [see (7.147)]. If the system is rotationally symmetric, $|H(\boldsymbol{\rho})|^2 = |H(\rho)|^2$. All points on a circle around the origin in the 2D frequency plane have the same transfer function and hence the same eigenvalue. The subspace associated with a set of degenerate eigenvectors now has infinite dimensionality.

We are free to choose as the basis for this subspace either functions of the form $\exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r})$ (with $\boldsymbol{\rho}$ constant and the functions indexed by θ_ρ) or functions proportional to $e^{ik\theta}$ for integer k . A function from either set can be expanded in terms of the other set. For example, a Fourier basis function, rewritten in polar coordinates, can be expressed as

$$\begin{aligned} u_\rho(\mathbf{r}) &= \exp(2\pi i\boldsymbol{\rho} \cdot \mathbf{r}) = \exp[2\pi i\rho r \cos(\theta - \theta_\rho)] \\ &= \sum_{k=-\infty}^{\infty} A_k(r, \rho, \theta_\rho) e^{ik\theta}. \end{aligned} \quad (7.216)$$

The coefficients can be found by the usual formula for Fourier-series coefficients, with the result,

$$A_k(r, \rho, \theta_\rho) = J_k(2\pi\rho r) \exp(-2\pi ik\theta_\rho), \quad (7.217)$$

where $J_k(\cdot)$ is a Bessel function.

7.2.10 Axial systems

Many real-world imaging systems (including our eyes) produce 2D images of 3D objects, so $q = 3$ and $s = 2$. These systems may have a preferred axis, often referred to as the *optic axis*. For a rotationally symmetric system, the axis of rotational symmetry is the optic axis, but rotational symmetry is not the only way to establish a preferred axis. For a pinhole or coded-aperture system, for example, it is natural to take the optic axis to be normal to the plane of the aperture and detector. We shall refer to such imaging systems as *axial systems*, and the optic axis will consistently be taken as the z axis.

It may be a good approximation to model an axial system as LSIV in each plane normal to the axis and as a simple integrator over z . With this model, the system operator is specified by

$$g(\mathbf{r}_d) = [\mathcal{H}\mathbf{f}](\mathbf{r}_d) = \int_{-\infty}^{\infty} d^2r \int_0^{\infty} dz h(\mathbf{r}_d - \mathbf{r}; z) f(\mathbf{r}, z), \quad (7.218)$$

where \mathbf{r} and \mathbf{r}_d are both 2D vectors but (\mathbf{r}, z) specifies location in 3D. This model is appropriate for emissive objects that are not opaque to their own radiation (as in fluorescent microscopy). It works also for reflective objects (as in ordinary photography) if structures close to the imaging system do not obscure more distant ones.

By the methods developed in Sec. 1.3.5, the adjoint operator is given by

$$[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}, z) = \int_{-\infty}^{\infty} d^2r_d h^*(\mathbf{r}_d - \mathbf{r}; z) g(\mathbf{r}_d), \quad (7.219)$$

and hence

$$\begin{aligned} [\mathcal{H}^\dagger \mathcal{H}\mathbf{f}](\mathbf{r}, z) &= \int_{-\infty}^{\infty} d^2r' \int_0^{\infty} dz' f(\mathbf{r}', z') \int_{-\infty}^{\infty} d^2r_d h^*(\mathbf{r}_d - \mathbf{r}; z) h(\mathbf{r}_d - \mathbf{r}'; z') \\ &= \int_{-\infty}^{\infty} d^2r' \int_0^{\infty} dz' f(\mathbf{r}', z') p(\mathbf{r} - \mathbf{r}'; z, z'), \end{aligned} \quad (7.220)$$

where $p(\mathbf{r} - \mathbf{r}'; z, z')$ is just the indicated integral over \mathbf{r}_d , which is the complex cross-correlation (see Sec. 3.3.6) of $h(\mathbf{r}; z)$ and $h(\mathbf{r}; z')$. The physical picture is that a point source at (\mathbf{r}', z') produces an image value of $p(\mathbf{r} - \mathbf{r}'; z, z')$ at point (\mathbf{r}, z) after projection (\mathcal{H}) and backprojection (\mathcal{H}^\dagger).

As usual, to perform an SVD we must first find the eigenfunctions of $\mathcal{H}^\dagger \mathcal{H}$. Since the system is LSIV in the lateral dimensions, a 2D Fourier transform is indicated. Denoting the eigenfunctions as

$$u_{\boldsymbol{\rho}, j}(\mathbf{r}, z) = \tilde{u}_{\boldsymbol{\rho}, j}(z) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}), \quad (7.221)$$

we can write the eigenvalue equation as

$$\begin{aligned} [\mathcal{H}^\dagger \mathcal{H} u_{\boldsymbol{\rho}, j}](\mathbf{r}, z) &= \int_{-\infty}^{\infty} d^2r' \int_0^{\infty} dz' \tilde{u}_{\boldsymbol{\rho}, j}(z') \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}') p(\mathbf{r} - \mathbf{r}'; z, z') \\ &= \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) \int_0^{\infty} dz' \tilde{u}_{\boldsymbol{\rho}, j}(z') P(\boldsymbol{\rho}; z, z') \\ &= \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) H(-\boldsymbol{\rho}; z) \int_0^{\infty} dz' \tilde{u}_{\boldsymbol{\rho}, j}(z') H(\boldsymbol{\rho}; z'), \end{aligned} \quad (7.222)$$

where $P(\boldsymbol{\rho}; z, z')$ is the 2D Fourier transform of $p(\mathbf{r}; z, z')$, and we have used (3.134) to factor it as $P(\boldsymbol{\rho}; z, z') = H(-\boldsymbol{\rho}; z)H(\boldsymbol{\rho}; z')$.

Because the kernel factors, the integral on the middle line in (7.222) is a rank-one operator and hence has only a single nonzero eigenvalue; by our conventions, we denote that eigenvalue with $j = 1$. The measurement space of $\mathcal{H}^\dagger \mathcal{H}$ is thus spanned by the set $\{u_{\boldsymbol{\rho}, 1}(\mathbf{r}, z)\}$ for all $\boldsymbol{\rho}$, and there is also a null space spanned by $\{u_{\boldsymbol{\rho}, j}(\mathbf{r}, z)\}$ for all $\boldsymbol{\rho}$ and $j > 1$.

We can obtain the eigenfunction and eigenvalue for $j = 1$ by inspection of (7.222). The integral on the last line is a constant, independent of \mathbf{r} and z , and

it is therefore the eigenvalue. If this integral is not zero, the only possible spatial dependence of the eigenfunction is

$$u_{\boldsymbol{\rho},1}(\mathbf{r}, z) \propto \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) H(-\boldsymbol{\rho}; z). \quad (7.223)$$

The corresponding eigenvalue is

$$\mu_{\boldsymbol{\rho},1} = \int_{S_z} dz' |H(\boldsymbol{\rho}; z')|^2, \quad (7.224)$$

where the integral is now over the object support in the z direction. (The object support in x and y is infinite since the system is shift-invariant in those directions.) To complete the story, the reader may show that the required normalizing constant in (7.223) is just $1/\sqrt{\mu_{\boldsymbol{\rho},1}}$ and that the singular functions in image space are given by $v_{\boldsymbol{\rho},1}(\mathbf{r}_d) = \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}_d)$.

To summarize, axial systems with lateral shift-invariance have very simple SVDs; all object-space singular functions corresponding to nonzero singular values have the form $\exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) H(-\boldsymbol{\rho}; z)$. We shall see an example of the usefulness of this result in Sec. 16.2.6.

7.3 LINEAR CONTINUOUS-TO-DISCRETE SYSTEMS

Digital imaging systems view objects defined on a continuous domain and produce finite vectors as their output. A simple example, introduced in the Prologue, is a digital video camera using a charge-coupled device. Each of the M discrete detector elements in this device performs a spatial and temporal integration of the image irradiance.⁹ As a result, the image output from this detector in one video frame is simply M numbers $\{g_m, m = 1, \dots, M\}$, and we can order these numbers as an $M \times 1$ column vector \mathbf{g} .

In the digital-camera example and many other digital imaging systems, it is an excellent approximation to say that each output datum g_m is linearly related to the object, so the correct system description is a linear continuous-to-discrete mapping as introduced in Sec. 1.2.4. It is the goal of this section to describe that mapping in more detail.

7.3.1 System operator

As in Sec. 7.2, we assume that the object is square-integrable and supported within a region \mathbf{S}_f in \mathbb{R}^q , so object space \mathbb{U} is $\mathbb{L}_2(\mathbf{S}_f)$. The image vector \mathbf{g} is a finite set of finite numbers, so image space \mathbb{V} is the M -dimensional Euclidean space \mathbb{E}^M . Thus the imaging system is a mapping from $\mathbb{L}_2(\mathbf{S}_f)$ to \mathbb{E}^M . If this mapping is linear, then, by a generalization of (1.30), it must have the form

$$g_m = \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}) f(\mathbf{r}). \quad (7.225)$$

⁹Irradiance is simply the radiant power per unit area incident on a surface. For more discussion, see Chap. 10.

As usual, we shall express this relation in operator form as

$$\mathbf{g} = \mathcal{H}\mathbf{f}, \quad (7.226)$$

where now \mathcal{H} indicates a linear continuous-to-discrete (CD) mapping.

The index m can have a variety of meanings, depending on the system being considered. A digital camera has a regular array of detectors, which we describe with a single index by lexicographic ordering. Alternatively, we might choose to use a multi-index as in Sec. 7.1.3 and then denote an element of \mathbf{g} as $g_{\mathbf{m}}$. In tomography, for another example, m is a composite index specifying projection angle and location of a particular detector element in an array that measures the projection.

The function $h_m(\mathbf{r})$ specifies how sensitive the m^{th} detector is to radiation originating at point \mathbf{r} in the object. It can be called the *detector sensitivity function* when we wish to consider a single detector and describe how its output varies with location of a point source. As in Sec. 7.2, however, we shall also use the term *point response function* or PRF for $h_m(\mathbf{r})$, especially when we wish to think of \mathbf{r} as fixed and the discrete index m as the variable. If $f(\mathbf{r}) = \delta(\mathbf{r} - \mathbf{r}_0)$, then $g_m = h_m(\mathbf{r}_0)$, so the set $\{h_m(\mathbf{r}_0)\}$ is the digital image of a point at \mathbf{r}_0 . Fig. 7.9 illustrates the PRF for a CD imaging system.

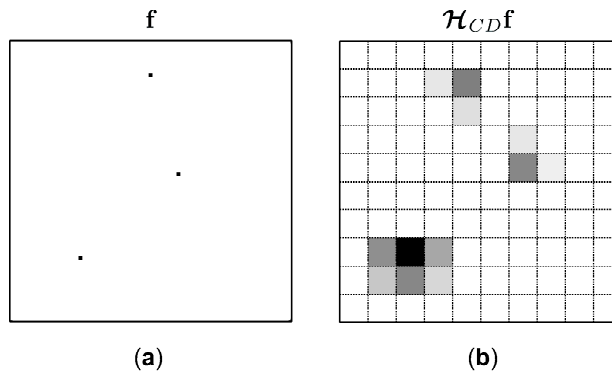

Fig. 7.9 Illustration of the PRF for a CD operator for three input locations.

Continuous imaging followed by sampling In most applications of the CD operator to imaging, we can separate the imaging process into two stages: continuous imaging followed by sampling or discretization. In the digital-camera example, the first stage is accomplished by the imaging lens, and the output of this stage is the continuous irradiance pattern on the detector face. The discretization step arises since the detector integrates the irradiance over each pixel area.

In more mathematical terms, a CC operator \mathcal{H}_{CC} followed by a discretization operator \mathcal{D}_w is equivalent to a composite CD operator:

$$\mathbf{g} = \mathcal{D}_w \mathcal{H}_{CC} \mathbf{f} = \mathcal{H}\mathbf{f}. \quad (7.227)$$

By analogy to (7.33), the general form¹⁰ of \mathcal{D}_w (if it is linear) is

$$[\mathcal{D}_w \mathbf{g}]_m = \int_{\mathbf{S}_g} d^s r_d g(\mathbf{r}_d) w_m(\mathbf{r}_d). \quad (7.228)$$

The general form of \mathcal{H}_{CC} is given by (7.101), so we can write (7.227) in general as

$$g_m = \int_{\mathbf{S}_g} d^s r_d w_m(\mathbf{r}_d) \int_{\mathbf{S}_f} d^q r h(\mathbf{r}_d, \mathbf{r}) f(\mathbf{r}). \quad (7.229)$$

We see that this form agrees with (7.225) if we set

$$h_m(\mathbf{r}) = \int_{\mathbf{S}_g} d^s r_d w_m(\mathbf{r}_d) h(\mathbf{r}_d, \mathbf{r}). \quad (7.230)$$

In a digital camera with an ideal detector array, $h(\mathbf{r}_d, \mathbf{r})$ accounts for blur arising from the imaging lens, and $w_m(\mathbf{r})$ is real and equal to a constant whenever \mathbf{r} is within the m^{th} detector pixel. In the terminology of Sec. 3.5.6, $w_m(\mathbf{r})$ is the *sampling aperture*.

Flood uniformity and point sensitivity Flood uniformity and point sensitivity for a CD system can be defined as in Sec. 7.2, but now \mathbf{g}_{fld} is a vector, given by [cf. (7.111)]

$$[\mathbf{g}_{fld}]_m = \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}). \quad (7.231)$$

The point sensitivity is, however, still a function, and (7.113) is modified to

$$s_{pt}(\mathbf{r}_0) = \sum_m h_m(\mathbf{r}_0). \quad (7.232)$$

If we decompose the CD operator as a CC operator followed by a discretization operator and use (7.230), the flood image becomes

$$\begin{aligned} [\mathbf{g}_{fld}]_m &= \int_{\mathbf{S}_f} d^q r \int_{\mathbf{S}_g} d^s r_d w_m(\mathbf{r}_d) h(\mathbf{r}_d, \mathbf{r}) \\ &= \int_{\mathbf{S}_g} d^s r_d w_m(\mathbf{r}_d) g_{fld}(\mathbf{r}_d), \end{aligned} \quad (7.233)$$

where $g_{fld}(\mathbf{r}_d)$ is the flood image for the underlying CC system as defined in (7.111).

We saw in (7.137) that $g_{fld}(\mathbf{r}_d)$ is constant if the CC system is shift-invariant. In that case,

$$[\mathbf{g}_{fld}]_m = \text{const} \cdot \int_{\mathbf{S}_g} d^s r_d w_m(\mathbf{r}_d). \quad (7.234)$$

The integral accounts for detector nonuniformities; it is a constant if the detectors

¹⁰To agree strictly with the notation used in Sec. 7.1.3, we would either have to write $w_m^*(\mathbf{r}_d)$ in the integrand of (7.228) or denote the operator by \mathcal{D}_{w^*} . This minor notational inconsistency disappears if $w_m(\mathbf{r}_d)$ is real.

are identical, so that $w_m(\mathbf{r}_d) = w(\mathbf{r}_d - \mathbf{r}_{dm})$, where \mathbf{r}_{dm} is the center of the m^{th} detector pixel.

The point sensitivity for a general CD system decomposed as a CC system plus discretization is

$$s_{pt}(\mathbf{r}_0) = \sum_m \int_{\mathbf{S}_g} d^s r_d w_m(\mathbf{r}_d) h(\mathbf{r}_d, \mathbf{r}_0) = \int_{\mathbf{S}_g} d^s r_d \eta(\mathbf{r}_d) h(\mathbf{r}_d, \mathbf{r}_0), \quad (7.235)$$

where

$$\eta(\mathbf{r}_d) = \sum_m w_m(\mathbf{r}_d). \quad (7.236)$$

This function is proportional to the probability that radiation incident at point \mathbf{r}_d on the detector will contribute to the final image. For an ideal digital camera, $\eta(\mathbf{r}_d)$ is unity whenever \mathbf{r}_d lies in any one of the detector pixels, and it is zero if \mathbf{r}_d lies in a gap between pixels. Because of the blur associated with the CC component, however, gaps in the detector do not necessarily cause $s_{pt}(\mathbf{r}_0)$ to fall to zero.

7.3.2 Adjoint operator and singular-value decomposition

The adjoint of a continuous-to-discrete operator is a discrete-to-continuous operator. That is, if \mathcal{H} maps from the infinite-dimensional object space \mathbb{U} to a finite-dimensional image space \mathbb{V} , then \mathcal{H}^\dagger maps from \mathbb{V} to \mathbb{U} . Specifically, for the operator \mathcal{H} defined in (7.225), the adjoint is given by [cf. (1.45)]

$$[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}) = \sum_{m=1}^M g_m h_m^*(\mathbf{r}). \quad (7.237)$$

If the PRFs $h_m(\mathbf{r})$ are real, the function $[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r})$ is a linear superposition of the PRFs, with components of \mathbf{g} serving as weights. This operation is illustrated in Fig. 7.10. As in the CC case (see Sec. 7.2.2), this adjoint operator is often referred to as backprojection.

Since the spaces \mathbb{U} and \mathbb{V} have different dimensionalities, a CD operator \mathcal{H} cannot have eigenfunctions. Nevertheless, we can make good use of singular-value decomposition, which is based on eigenanalysis of the Hermitian operators $\mathcal{H}^\dagger \mathcal{H}$ and $\mathcal{H} \mathcal{H}^\dagger$.

Fig. 7.10 Illustration of the adjoint of a CD operator.

Eigenfunctions in object space The operator $\mathcal{H}^\dagger \mathcal{H}$ maps object space \mathbb{U} to itself. From (7.225) and (7.237), it is given explicitly by

$$\begin{aligned} [\mathcal{H}^\dagger \mathcal{H} \mathbf{f}] (\mathbf{r}) &= \sum_{m=1}^M h_m^*(\mathbf{r}) \int_{\mathbf{S}_f} d^q r' h_m(\mathbf{r}') f(\mathbf{r}') \\ &= \int_{\mathbf{S}_f} d^q r' k(\mathbf{r}, \mathbf{r}') f(\mathbf{r}'), \end{aligned} \quad (7.238)$$

where the kernel is given by

$$k(\mathbf{r}, \mathbf{r}') = \sum_{m=1}^M h_m^*(\mathbf{r}) h_m(\mathbf{r}'). \quad (7.239)$$

Comparing this result to the corresponding expression for a CC system, (7.116), we see that the only difference is that the integral over the continuous detector space in the CC case has been replaced by a sum over discrete image components here. Figure 7.11 illustrates the meaning of $k(\mathbf{r}, \mathbf{r}')$.

Fig. 7.11 Illustration of the operator $\mathcal{H}^\dagger \mathcal{H}$ when \mathcal{H} is a CD operator.

Compact operators and eigenanalysis The operator $\mathcal{H}^\dagger \mathcal{H}$ is compact (see Sec. 1.3.3) if its kernel satisfies the Hilbert-Schmidt condition [*cf.* (7.138)],

$$\int_{\mathbf{S}_f} d^q r \int_{\mathbf{S}_f} d^q r' |k(\mathbf{r}, \mathbf{r}')|^2 < \infty. \quad (7.240)$$

This condition is satisfied if $k(\mathbf{r}, \mathbf{r}')$ is bounded and \mathbf{S}_f is finite, as they will be with all physically realizable imaging systems.

We know from Sec. 1.4.4 that a compact Hermitian operator on an infinite-dimensional Hilbert space has a countably infinite set of eigenvectors and real eigenvalues. The eigenvectors of $\mathcal{H}^\dagger \mathcal{H}$ are a set of functions $\{u_n(\mathbf{r})\}$ or, equivalently, a set of vectors $\{\mathbf{u}_n\}$ in the object Hilbert space.

The eigenvalue equation is

$$\mathcal{H}^\dagger \mathcal{H} \mathbf{u}_n = \mu_n \mathbf{u}_n, \quad n = 1, \dots, \infty, \quad (7.241)$$

which is equivalent to (7.117). The structure of the eigenvalue problem here is exactly the same as in the CC case since in both cases $\mathcal{H}^\dagger \mathcal{H}$ is a Hermitian operator

mapping \mathbb{U} to \mathbb{U} ; the intermediate stop at \mathbb{V} does not invalidate any of the key properties of the eigenfunctions or eigenvalues. In particular, the eigenvalues $\{\mu_n\}$ are real and nonnegative, and $\{\mathbf{u}_n\}$ can be chosen as a complete, orthonormal set in \mathbb{U} (*i.e.*, (7.118) and (7.119) still hold). Thus any object in \mathbb{U} can be expanded as in (7.120) with coefficients given by (7.121):

$$\mathbf{f} = \sum_{n=1}^{\infty} \alpha_n \mathbf{u}_n, \quad \alpha_n = \mathbf{u}_n^\dagger \mathbf{f} = \int_{\mathbf{S}_f} d^q r \, u_n^*(\mathbf{r}) f(\mathbf{r}). \quad (7.242)$$

Eigenvectors in image space Though the eigenvalue problems for $\mathcal{H}^\dagger \mathcal{H}$ have the same structure for CC and CD systems, the corresponding problems for $\mathcal{H} \mathcal{H}^\dagger$ are quite different. The operator $\mathcal{H} \mathcal{H}^\dagger$ maps image space \mathbb{V} to itself, and for a CD system \mathbb{V} has a finite dimension.

The action of the operator $\mathcal{H} \mathcal{H}^\dagger$ can be expressed as

$$\begin{aligned} [\mathcal{H} \mathcal{H}^\dagger \mathbf{g}]_m &= \int_{\mathbf{S}_f} d^q r \, h_m(\mathbf{r}) \sum_{k=1}^M g_k h_k^*(\mathbf{r}) \\ &= \sum_{k=1}^M \left[\int_{\mathbf{S}_f} d^q r \, h_m(\mathbf{r}) h_k^*(\mathbf{r}) \right] g_k. \end{aligned} \quad (7.243)$$

In other words, $\mathcal{H} \mathcal{H}^\dagger$ is an $M \times M$ Hermitian matrix with elements given by

$$[\mathcal{H} \mathcal{H}^\dagger]_{mk} = \int_{\mathbf{S}_f} d^q r \, h_m(\mathbf{r}) h_k^*(\mathbf{r}). \quad (7.244)$$

The eigenvalue problem is thus

$$\mathcal{H} \mathcal{H}^\dagger \mathbf{v}_n = \mu_n \mathbf{v}_n, \quad n = 1, \dots, M, \quad (7.245)$$

where \mathbf{v}_n is an $M \times 1$ column vector. Since $\mathcal{H} \mathcal{H}^\dagger$ is a matrix, this eigenvalue problem can be solved by standard algorithms (Golub and van Loan, 1989; Press *et al.*, 1992) or by various software packages.

From the general discussion in Sec. 1.4.4, we know that the eigenvectors of $\mathcal{H} \mathcal{H}^\dagger$ can be chosen to form a complete, orthonormal set in \mathbb{V} , so that

$$\mathbf{v}_k^\dagger \mathbf{v}_n = \delta_{kn}; \quad (7.246)$$

$$\sum_{n=1}^M \mathbf{v}_n \mathbf{v}_n^\dagger = \mathbf{I}_M, \quad (7.247)$$

where \mathbf{I}_M is the $M \times M$ unit matrix. From these equations it follows that any data vector \mathbf{g} can be expressed as

$$\mathbf{g} = \sum_{n=1}^M \beta_n \mathbf{v}_n, \quad \beta_n = \mathbf{v}_n^\dagger \mathbf{g}. \quad (7.248)$$

Rank and null space To establish that the eigenvalues for $\mathcal{H}\mathcal{H}^\dagger$ are the same as those for $\mathcal{H}^\dagger\mathcal{H}$, we operate on both sides of (7.245) with \mathcal{H}^\dagger and add some brackets for clarity; we find

$$\mathcal{H}^\dagger\mathcal{H}[\mathcal{H}^\dagger\mathbf{v}_n] = \mu_n [\mathcal{H}^\dagger\mathbf{v}_n], \quad (7.249)$$

so $\mathcal{H}^\dagger\mathbf{v}_n$ is an eigenvector of $\mathcal{H}^\dagger\mathcal{H}$ with eigenvalue μ_n . Similarly, by operating on both sides of (7.241) with \mathcal{H} we can show that $\mathcal{H}\mathbf{u}_n$ is an eigenvector of $\mathcal{H}\mathcal{H}^\dagger$ with eigenvalue μ_n . Thus the two operators $\mathcal{H}\mathcal{H}^\dagger$ and $\mathcal{H}^\dagger\mathcal{H}$ share the same eigenvalue spectrum. But $\mathcal{H}\mathcal{H}^\dagger$ is a finite matrix, so its rank R cannot exceed its dimension M (see Sec. 1.2.3). Moreover, from Sec. 1.4.3 the rank is the number of nonzero eigenvalues. The operator $\mathcal{H}^\dagger\mathcal{H}$ has an infinite number of eigenvalues, since it operates in an infinite-dimensional space, but at most M of them are nonzero.

An important consequence of this discussion is that $\mathcal{H}^\dagger\mathcal{H}$ necessarily has an infinite-dimensional null space if \mathcal{H} itself is a CD operator. If we order the eigenvalues by descending value as in (1.114), so that μ_R is the last non-vanishing eigenvalue, then the measurement space of $\mathcal{H}^\dagger\mathcal{H}$ is the subspace of \mathbb{U} spanned by $\{\mathbf{u}_n, n = 1, \dots, R\}$, and the null space is the infinite-dimensional orthogonal complement of the measurement space (see Secs. 1.5.2 and 1.5.3).

Thus an arbitrary object vector \mathbf{f} can be uniquely decomposed into measurement and null functions as follows:

$$\mathbf{f} = \mathbf{f}_{meas} + \mathbf{f}_{null}, \quad (7.250)$$

where

$$\mathbf{f}_{meas} = \mathcal{P}_{meas}\mathbf{f} = \sum_{n=1}^R \alpha_n \mathbf{u}_n, \quad (7.251)$$

$$\mathbf{f}_{null} = \mathcal{P}_{null}\mathbf{f} = \sum_{n=R+1}^{\infty} \alpha_n \mathbf{u}_n. \quad (7.252)$$

In these expressions, \mathcal{P}_{meas} and \mathcal{P}_{null} are the projectors onto measurement and null space, respectively, and in both spaces the coefficients α_n are given by $\mathbf{u}_n^\dagger\mathbf{f}$ as in (7.242).

Relation between eigenvectors in object and image space Comparison of (7.249) and (7.241) provides a relation between \mathbf{v}_n and \mathbf{u}_n . In fact, the reader's first impulse might be simply to equate $\mathcal{H}^\dagger\mathbf{v}_n$ with \mathbf{u}_n , but that would not necessarily produce a properly normalized eigenvector in object space. We can, however, multiply an eigenvector by any constant and it remains an eigenvector with the same eigenvalue. We shall now show that an appropriate choice for the constant is $1/\sqrt{\mu_n}$.

Suppose we have solved the eigenvalue problem for the matrix $\mathcal{H}\mathcal{H}^\dagger$ and found a set of orthonormal eigenvectors $\{\mathbf{v}_n, n = 1, \dots, M\}$ and that we form the functions $\{u_n(\mathbf{r})\}$ by

$$\frac{1}{\sqrt{\mu_n}} [\mathcal{H}^\dagger\mathbf{v}_n](\mathbf{r}) = u_n(\mathbf{r}), \quad n = 1, \dots, R. \quad (7.253)$$

That is, we backproject each vector \mathbf{v}_n and then divide by $\sqrt{\mu_n}$. By (7.249), the resulting functions are eigenfunctions of $\mathcal{H}^\dagger\mathcal{H}$.

The following manipulations show that the set of eigenfunctions is orthonormal:

$$\begin{aligned} (\mathbf{u}_n, \mathbf{u}_k) &= \frac{1}{\sqrt{\mu_n \mu_k}} (\mathcal{H}^\dagger \mathbf{v}_n, \mathcal{H}^\dagger \mathbf{v}_k) = \frac{1}{\sqrt{\mu_n \mu_k}} (\mathcal{H} \mathcal{H}^\dagger \mathbf{v}_n, \mathbf{v}_k) \\ &= \frac{\mu_n}{\sqrt{\mu_n \mu_k}} (\mathbf{v}_n, \mathbf{v}_k) = \frac{\mu_n}{\sqrt{\mu_n \mu_k}} \delta_{nk} = \delta_{nk}. \end{aligned} \quad (7.254)$$

Similar arguments show that

$$\frac{1}{\sqrt{\mu_n}} \mathcal{H} \mathbf{u}_n = \mathbf{v}_n, \quad n = 1, \dots, R. \quad (7.255)$$

Thus, for $n \leq R$, the eigenvectors of $\mathcal{H}^\dagger \mathcal{H}$ are uniquely determined from those of $\mathcal{H} \mathcal{H}^\dagger$ and vice versa.

SVD and the imaging equation The general form for the SVD of a compact linear operator is (1.120) or (7.127):

$$\mathcal{H} = \sum_{n=1}^R \sqrt{\mu_n} \mathbf{v}_n \mathbf{u}_n^\dagger. \quad (7.256)$$

For the specific case of a CD operator, the action of this expansion on an arbitrary object is [cf. (7.128)]

$$\begin{aligned} g_m = [\mathcal{H} \mathbf{f}]_m &= \sum_{n=1}^R \sqrt{\mu_n} [\mathbf{v}_n \mathbf{u}_n^\dagger \mathbf{f}]_m = \sum_{n=1}^R \left[\sqrt{\mu_n} \int_{\mathbf{S}_f} d^q r u_n^*(\mathbf{r}) f(\mathbf{r}) \right] v_{nm} \\ &= \sum_{n=1}^R \sqrt{\mu_n} \alpha_n v_{nm}, \end{aligned} \quad (7.257)$$

where v_{nm} is the m^{th} component of vector \mathbf{v}_n . Note especially that only the object components with $n \leq R$ contribute to \mathbf{g} ; the operator \mathcal{H} has the same infinite-dimensional null space as $\mathcal{H}^\dagger \mathcal{H}$.

Applying the same arguments as used above (7.129) to (7.248) and (7.257), we see that

$$\beta_n = \sqrt{\mu_n} \alpha_n. \quad (7.258)$$

Thus SVD again reduces the imaging equation $\mathbf{g} = \mathcal{H} \mathbf{f}$ to a simple multiplication.

7.3.3 Fourier description

The theoretical advantage of SVD is that it reduces the complicated integral operator to a simple multiplication, just as a Fourier transform reduces convolution to multiplication. (In fact, as we saw in Sec. 7.2.4, Fourier transformation *is* SVD for a convolution operator.) The SVD representation is very attractive for this reason, but it has some drawbacks as well, as we shall now enumerate.

The basis functions used in Fourier analysis have a simple analytical form, but it is often impossible to express SVD basis functions analytically. The singular functions corresponding to nonzero singular values can be found numerically by solving

the eigenvalue problem for the matrix $\mathcal{H}\mathcal{H}^\dagger$, but this matrix has size $M \times M$, where M is the number of measurements. In practice, even this numerical approach is not tractable for M greater than a few thousand.

Moreover, if one wants to compare two different imaging systems, or even two variants on the same system, it is convenient to use the same basis functions for both. LSIV systems can be compared by SVD since the basis functions for all LSIV systems are plane waves of infinite extent, but with this exception different systems have different SVD basis functions.

Another drawback to SVD analysis is that it is difficult to develop any intuition about the basis functions. With Fourier analysis, the spatial frequency has a simple physical interpretation, and we have no difficulty in visualizing the basis function or the action of an LSIV system on it. It would appear, however, that there is little benefit to using Fourier transforms with systems that are not at least approximately shift-invariant.

In fact, we can develop a fruitful Fourier theory for an arbitrary CD system by employing the Fourier *series* as in (7.14) [see also (3.279)]. A Fourier representation of the system can be obtained by substituting (7.14) into (7.226), yielding

$$\mathbf{g} = \sum_{\mathbf{k}} F_{\mathbf{k}} \mathcal{H}\{\Phi_{\mathbf{k}}(\mathbf{r})\} \equiv \Psi \mathbf{F}, \quad (7.259)$$

where Ψ is a complex matrix with element $\psi_{m\mathbf{k}}$. In component form, (7.259) is

$$g_m = \sum_{\mathbf{k}} \psi_{m\mathbf{k}} F_{\mathbf{k}}. \quad (7.260)$$

Recall from Sec. 7.1.2 that \mathbf{k} is a multi-index, a q D vector with integer components. Since each of the q components of \mathbf{k} ranges over $(-\infty, \infty)$, \mathbf{F} has a q -fold infinity of elements and Ψ is a matrix with M rows and a q -fold infinity of columns.

The matrix elements of Ψ are given explicitly by

$$\psi_{m\mathbf{k}} = [\mathcal{H}\Phi_{\mathbf{k}}]_m = \int_{-\infty}^{\infty} d^q r \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}) h_m(\mathbf{r}) S_f(\mathbf{r}). \quad (7.261)$$

The integral is the Fourier transform of the product $h_m(\mathbf{r}) S_f(\mathbf{r})$ evaluated at the specific spatial frequency $\boldsymbol{\rho}_{\mathbf{k}}$. Except for the normalizing constant $1/\sqrt{V}$ [see (7.15)], the integral can also be interpreted as a coefficient in the Fourier-series expansion of the same product. If $h_m(\mathbf{r})$ is real and the multi-index \mathbf{k} is constructed so that $\boldsymbol{\rho}_{-\mathbf{k}} = -\boldsymbol{\rho}_{\mathbf{k}}$, then it follows from (7.261) that

$$\psi_{m(-\mathbf{k})} = \psi_{m\mathbf{k}}^*. \quad (7.262)$$

This is the so-called Hermiticity property of Fourier coefficients, (3.227), but Ψ is definitely not a Hermitian matrix; it cannot be since it is not square.

The complex matrix Ψ is completely equivalent to the operator \mathcal{H} ; the latter maps the object \mathbf{f} to the discrete data set \mathbf{g} , while the former maps the infinite set of object Fourier coefficients \mathbf{F} to \mathbf{g} , but of course \mathbf{f} is uniquely related to \mathbf{F} . Since Ψ has an infinite number of columns, there is no loss of information in using it rather than \mathcal{H} .

Fourier crosstalk matrix With the system representation of (7.259), it is natural to investigate the operator $\Psi^\dagger \Psi$, where Ψ^\dagger is the adjoint of the matrix Ψ , *i.e.*,

$[\Psi^\dagger]_{\mathbf{k}m} = \psi_{m\mathbf{k}}^*$. Since Ψ maps a vector of Fourier coefficients to a finite-dimensional vector in image space, Ψ^\dagger maps from image space back to the space of Fourier coefficients; in this sense it is another backprojection operator. Thus $\Psi^\dagger\Psi$ maps a vector in the space of Fourier coefficients to another vector in the same space.

Since $\Psi^\dagger\Psi$ maps an infinite vector to another infinite vector, it can be regarded as a square matrix with an infinite number of rows and columns. For reasons discussed below, this matrix will be referred to as the *Fourier crosstalk matrix*, or simply crosstalk matrix for short. We denote the crosstalk matrix itself as \mathbf{B} (capital beta) and its elements by $\beta_{\mathbf{k}\mathbf{k}'}$. The elements are given by

$$\beta_{\mathbf{k}\mathbf{k}'} = \sum_{m=1}^M \psi_{m\mathbf{k}}^* \psi_{m\mathbf{k}'} = \sum_{m=1}^M [\mathcal{H}\Phi_{\mathbf{k}}]_m^* [\mathcal{H}\Phi_{\mathbf{k}'}]_m = (\mathcal{H}\Phi_{\mathbf{k}}, \mathcal{H}\Phi_{\mathbf{k}'}), \quad (7.263)$$

where (\cdot, \cdot) here denotes a scalar product in image space.

From this definition, it follows that the crosstalk matrix is Hermitian:

$$\mathbf{B}^\dagger = \mathbf{B} \quad \text{or} \quad \beta_{\mathbf{k}\mathbf{k}'} = \beta_{\mathbf{k}'\mathbf{k}}^*. \quad (7.264)$$

In addition, if $h_m(\mathbf{r})$ is real, it follows from (7.262) that

$$\beta_{(-\mathbf{k})(-\mathbf{k}')} = \beta_{\mathbf{k}\mathbf{k}'}^*. \quad (7.265)$$

Without any restriction on the form of \mathcal{H} or Ψ , \mathbf{B} is positive-semidefinite (see Sec. 1.4.4).

Interpretation of the crosstalk matrix The scalar product in (7.263) is zero if the two M -dimensional vectors $\mathcal{H}\Phi_{\mathbf{k}}$ and $\mathcal{H}\Phi_{\mathbf{k}'}$ are orthogonal to each other. If that is the case, the two Fourier components \mathbf{k} and \mathbf{k}' make linearly independent contributions to the data and can be easily separated by any inversion algorithm. On the other hand, if $\mathcal{H}\Phi_{\mathbf{k}}$ is parallel to $\mathcal{H}\Phi_{\mathbf{k}'}$ in data space, the two Fourier components produce identical data patterns and cannot be separated by any algorithm. Frequencies $\rho_{\mathbf{k}}$ and $\rho_{\mathbf{k}'}$ are fully aliased.

Even if this extreme case does not occur, $\beta_{\mathbf{k}\mathbf{k}'}$ with $\mathbf{k} \neq \mathbf{k}'$ is a useful measure of the *degree* of aliasing or crosstalk between two different frequencies. When we discussed aliasing in Sec. 3.5.3, we presented it as a binary concept—either the Nyquist condition is satisfied or it is not. A little reflection reveals the inadequacy of this approach for anything other than regular sampling schemes. Figure 3.8 in Chap. 3 shows how two different cosines are indistinguishable if one knows only their values at a set of evenly spaced points, but all we have to do to make them distinguishable in principle is to displace one of the sampling points slightly.

As a quantitative measure of degree of aliasing, we define the angle $\theta_{\mathbf{k}\mathbf{k}'}$ between $\mathcal{H}\Phi_{\mathbf{k}}$ and $\mathcal{H}\Phi_{\mathbf{k}'}$ by (see Sec. 1.1.4)

$$\cos \theta_{\mathbf{k}\mathbf{k}'} \equiv \frac{(\mathcal{H}\Phi_{\mathbf{k}}, \mathcal{H}\Phi_{\mathbf{k}'})}{\|\mathcal{H}\Phi_{\mathbf{k}}\| \cdot \|\mathcal{H}\Phi_{\mathbf{k}'}\|} = \frac{\beta_{\mathbf{k}\mathbf{k}'}}{\sqrt{\beta_{\mathbf{k}\mathbf{k}}\beta_{\mathbf{k}'\mathbf{k}'}}}. \quad (7.266)$$

For complete aliasing, $|\cos \theta_{\mathbf{k}\mathbf{k}'}| = 1$, and for no aliasing at all, $\cos \theta_{\mathbf{k}\mathbf{k}'} = 0$.

The diagonal elements of the crosstalk matrix also have a neat interpretation. If $\mathbf{k} = \mathbf{k}'$, (7.263) becomes

$$\beta_{\mathbf{k}\mathbf{k}} = \|\mathcal{H}\Phi_{\mathbf{k}}\|^2. \quad (7.267)$$

Thus a diagonal element of the crosstalk matrix is a measure of the strength (norm) of the data when the object consists of a single truncated plane wave. It specifies how strongly a particular spatial frequency is transferred through the system to the data. In this sense, the set of diagonal elements $\{\beta_{\mathbf{k}\mathbf{k}}\}$ constitutes a kind of transfer function, even though the Fourier-series basis functions are not eigenfunctions of the system.

Eigenanalysis of the crosstalk matrix The eigenvalue equation for $\Psi^\dagger \Psi$ is

$$\Psi^\dagger \Psi \mathbf{U}_n = \mu_n \mathbf{U}_n, \quad (7.268)$$

where \mathbf{U}_n has the same structure as \mathbf{F} , namely, an infinite vector of Fourier coefficients.

The eigenfunctions of $\Psi^\dagger \Psi$ are related to the eigenfunctions of $\mathcal{H}^\dagger \mathcal{H}$ (which are also the singular functions in object space). If we denote by \mathcal{F}_s the operator that converts a function $f(\mathbf{r})$ to its Fourier-series coefficients, then Ψ and \mathcal{H} are related by

$$\mathcal{H} = \Psi \mathcal{F}_s, \quad (7.269)$$

so

$$\mathcal{H}^\dagger \mathcal{H} \mathbf{u}_n = \mathcal{F}_s^\dagger \Psi^\dagger \Psi \mathcal{F}_s \mathbf{u}_n = \mu_n \mathbf{u}_n. \quad (7.270)$$

As discussed below (7.15), we can choose the support region so that the basis set $\{\Phi_{\mathbf{k}}(\mathbf{r})\}$ is orthogonal. In that case $\mathcal{F}_s^\dagger = \mathcal{F}_s^{-1}$, and the eigenvalue equation for $\mathcal{H}^\dagger \mathcal{H}$, (7.241), becomes

$$\Psi^\dagger \Psi \mathcal{F}_s \mathbf{u}_n = \mu_n \mathcal{F}_s \mathbf{u}_n. \quad (7.271)$$

Comparison with (7.268) shows that \mathbf{U}_n is just the Fourier-series representation of \mathbf{u}_n .

7.3.4 Sampled LSIV systems

To gain more insight into the crosstalk matrix, we return to a problem introduced in Sec. 7.3.1. We consider a CD system decomposed into a CC system followed by sampling or discretization, but now we add the additional restriction that the CC system be shift-invariant.

Specifically, we assume that $h(\mathbf{r}_d, \mathbf{r}) = h(\mathbf{r}_d - \mathbf{r})$ and that the discretization functions are translates of a single function, so that $w_m(\mathbf{r}_d) = w(\mathbf{r}_d - \mathbf{r}_{dm})$. Next we make a change of variables and recognize that we can always take \mathbf{S}_g large enough that the limits of integration do not need to be changed. The kernel specified in (7.230) then becomes

$$h_m(\mathbf{r}) \equiv p(\mathbf{r}_{dm} - \mathbf{r}) = \int_{\mathbf{S}_g} d^q r_d h(\mathbf{r}_d + \mathbf{r}_{dm} - \mathbf{r}) w(\mathbf{r}_d). \quad (7.272)$$

Thus $p(\mathbf{r})$, the cross-correlation of $h(\mathbf{r})$ and $w(\mathbf{r})$, serves as an overall shift-invariant PSF prior to point sampling.

With this form for the PRF and (7.261), elements of the system matrix Ψ are given by

$$\psi_{m\mathbf{k}} = \int_{\infty} d^q r \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}) S_f(\mathbf{r}) p(\mathbf{r}_{dm} - \mathbf{r}). \quad (7.273)$$

If $p(\mathbf{r})$ is spatially compact and we choose the region of support large enough, we can replace the support function $S_f(\mathbf{r})$ by unity. Then a change of variables yields

$$\psi_{m\mathbf{k}} = \int_{\infty} d^q r \exp[-2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot (\mathbf{r} - \mathbf{r}_{dm})] p(\mathbf{r}) = \exp(2\pi i \boldsymbol{\rho}_{\mathbf{k}} \cdot \mathbf{r}_{dm}) P(\boldsymbol{\rho}_{\mathbf{k}}), \quad (7.274)$$

where $P(\boldsymbol{\rho})$, the Fourier transform of $p(\mathbf{r})$, is the transfer function of the overall LSIV system (including the sampling aperture).

The elements of the crosstalk matrix, defined in (7.263), are now given by

$$\beta_{\mathbf{k}\mathbf{k}'} = P(\boldsymbol{\rho}_{\mathbf{k}}) P^*(\boldsymbol{\rho}_{\mathbf{k}'}) \sum_{m=1}^M \exp[2\pi i (\boldsymbol{\rho}_{\mathbf{k}} - \boldsymbol{\rho}_{\mathbf{k}'}) \cdot \mathbf{r}_{dm}]. \quad (7.275)$$

The diagonal elements,

$$\beta_{\mathbf{k}\mathbf{k}} = M |P(\boldsymbol{\rho}_{\mathbf{k}})|^2, \quad (7.276)$$

are completely determined by the transfer function $P(\boldsymbol{\rho})$ of the underlying LSIV system, independent of the location of the samples.

It is interesting to compare (7.276) to (7.147), where we saw that the squared modulus of the transfer function, $|H(\boldsymbol{\rho})|^2$, is the eigenvalue of $\mathcal{H}^\dagger \mathcal{H}$ for an LSIV system. Equivalently, $|H(\boldsymbol{\rho})|^2$ is the transfer function of $\mathcal{H}^\dagger \mathcal{H}$, which is also an LSIV system if \mathcal{H} is. In (7.276) we see that the squared modulus of a transfer function (now including a sampling aperture) recurs in the diagonal elements of the crosstalk matrix when the output of an LSIV system is sampled, even though the sampling spoils the shift-invariance.

Aliasing effects can be expressed in terms of $\cos \theta_{\mathbf{k}\mathbf{k}'}$, defined in (7.266). In the present problem, we have

$$|\cos \theta_{\mathbf{k}\mathbf{k}'}| = \frac{1}{M} \left| \sum_{m=1}^M \exp[2\pi i (\boldsymbol{\rho}_{\mathbf{k}} - \boldsymbol{\rho}_{\mathbf{k}'}) \cdot \mathbf{r}_{dm}] \right|. \quad (7.277)$$

Note that $|\cos \theta_{\mathbf{k}\mathbf{k}'}|$ is determined solely by the location of the sample points $\{\mathbf{r}_{dm}\}$ and is independent of $P(\boldsymbol{\rho})$.

1D Example To understand these results better, consider a 1D problem in which the object $f(x)$ is contained in the interval $-\frac{1}{2}L < x \leq \frac{1}{2}L$ and the sample points are spaced by ϵ . It is convenient to replace the index m with another index n , chosen to run symmetrically from $-N$ to N , so that $M = 2N + 1$. Then we can specify the sample points by

$$x_{dn} = n\epsilon, \quad -N \leq n \leq N, \quad \epsilon = \frac{L}{M} = \frac{L}{2N + 1}. \quad (7.278)$$

In 1D, k is an ordinary integer index instead of a multi-index, and the spatial frequency is a scalar ξ_k given by

$$\xi_k = k/L, \quad -\infty < k < \infty. \quad (7.279)$$

Thus (7.277) becomes

$$\cos \theta_{kk'} = \frac{1}{M} \sum_{n=-N}^N \exp[2\pi i (\xi_k - \xi_{k'}) x_{dn}] = \frac{1}{M} \sum_{n=-N}^N \exp[2\pi i (k - k') n/M]. \quad (7.280)$$

A geometric progression of this form was discussed in Chap. 2; using (2.49), we find that

$$\cos \theta_{kk'} = \frac{1}{M} \frac{\sin [\pi(k - k')]}{\sin [\pi(k - k')/M]} = \frac{1}{M} \frac{\sin [\pi M \epsilon (\xi_k - \xi_{k'})]}{\sin [\pi \epsilon (\xi_k - \xi_{k'})]}. \quad (7.281)$$

This function is plotted in Fig. 7.12, and the crosstalk matrix for this problem is depicted in Fig. 7.13 for the case where $p(x) = \text{rect}(x/\epsilon)$. Both figures show that frequencies ξ_k and $\xi_{k'}$ are fully aliased if $\xi_k - \xi_{k'}$ is an integer multiple of the sampling frequency $1/\epsilon$.

Fig. 7.12 Plot of the function $\sin(\pi M u)/\sin(\pi u)$.

In the limit of very fine sampling ($\epsilon \rightarrow 0$), a finite frequency ξ_k is not aliased with any other finite frequency. In this limit, $\cos \theta_{kk'} \rightarrow \delta_{kk'}$, so the crosstalk matrix is diagonal and given by

$$\lim_{\epsilon \rightarrow 0} \beta_{kk'} = M |P(\xi_k)|^2 \delta_{kk'}. \quad (7.282)$$

In this limit, the frequencies ξ_k become arbitrarily close together, so ξ_k can be replaced by the continuous variable ξ . The squared modulus of the transfer function of the underlying LSIV system then lies along the diagonal, but multiplied by the number of samples M , which has to go to ∞ as ϵ goes to 0. We have already encountered (7.282); in (7.171) we showed that $\mathcal{H}^\dagger \mathcal{H}$ for an LSIV system is diagonalized by Fourier transformation, and (7.282) reiterates that conclusion.

Another special case of this formalism is when the LSIV system is bandlimited (see Sec. 3.5.1) so that $P(\xi) = 0$ if $|\xi| \geq \xi_{max}$. This means that the crosstalk matrix is zero outside a submatrix of dimension $2\xi_{max}L \times 2\xi_{max}L$. Moreover, if the Nyquist condition (3.291) is satisfied, then there is no aliasing and this submatrix is diagonal. Note that two distinct Nyquist conditions are operative here. We assume that the object is spatially limited to extent L so that we can represent it by a Fourier series with sample spacing $1/L$, and we assume that the LSIV system is bandlimited so that its output can be sampled without aliasing by a discrete detector array. These conditions are not contradictory; we do not need to assume that the object is bandlimited or that the system impulse response is spatially limited.

Fig. 7.13 Low-frequency portion of the crosstalk matrix for a 1D CD system with uniformly spaced sampling apertures (Gifford, 1997). (a) Point sampling, no presampling blur. (b) Sampling with rect functions, low-pass presampling blur, Nyquist condition not satisfied. (c) Same as (b) but lower cutoff frequency in presampling blur, so Nyquist is satisfied.

7.3.5 Mixed CC-CD systems

So far we have treated CC and CD systems separately, but sometimes it is useful to mix continuous and discrete variables in the description of the object, the image or both.

One example is a linear system that acquires multiple images of the same object. We can denote the j^{th} image by the vector \mathbf{g}_j , with components given by

$$g_j(\mathbf{r}_d) = \int_{\mathbf{S}_f} d^q r h_j(\mathbf{r}_d, \mathbf{r}) f(\mathbf{r}). \quad (7.283)$$

In this case, the object is a function of a continuous variable \mathbf{r} , but the image is mixed, in the sense that it has both a continuous variable \mathbf{r}_d and a discrete index j .

A system that acquires multiple images of multiple object attributes is mixed in both object and image space. An appropriate linear description would be

$$g_j(\mathbf{r}_d) = \sum_k \int_{\infty} d^q r h_{jk}(\mathbf{r}_d, \mathbf{r}) f_k(\mathbf{r}). \quad (7.284)$$

In this case we have a matrix of CC operators.

Color imaging As a practical example of a mixed CC-CD system, consider a color imaging system that views an object $f(\mathbf{r}, \lambda)$, where \mathbf{r} is a 2D vector and λ is the wavelength, through three color filters. Three separate 2D images are produced, each related to the object by

$$g_m(\mathbf{r}_d) = \int_{\infty} d^2 r \int_0^{\infty} d\lambda f(\mathbf{r}, \lambda) h_m(\mathbf{r}_d, \mathbf{r}, \lambda), \quad (7.285)$$

where $m = 1$ indicates the red filter, $m = 2$ green and $m = 3$ blue. This operator, denoted as usual by \mathcal{H} , maps a function of three variables (x, y, λ) to three functions of two variables (x_d, y_d) each.

The adjoint operator \mathcal{H}^\dagger maps these data back to a function of \mathbf{r} and λ ; its form is

$$[\mathcal{H}^\dagger \mathbf{g}](\mathbf{r}, \lambda) = \sum_{m=1}^3 \int_{\infty} d^2 r_d g_m(\mathbf{r}_d) h_m^*(\mathbf{r}_d, \mathbf{r}, \lambda). \quad (7.286)$$

It follows that

$$[\mathcal{H}^\dagger \mathcal{H} \mathbf{f}](\mathbf{r}, \lambda) = \int_{\infty} d^2 r' \int_0^{\infty} d\lambda' k(\mathbf{r}, \mathbf{r}'; \lambda, \lambda') f(\mathbf{r}', \lambda'), \quad (7.287)$$

where

$$k(\mathbf{r}, \mathbf{r}'; \lambda, \lambda') = \sum_{m=1}^3 \int_{\infty} d^2 r_d h_m^*(\mathbf{r}_d, \mathbf{r}, \lambda) h_m(\mathbf{r}_d, \mathbf{r}', \lambda'). \quad (7.288)$$

This kernel is a combination of the corresponding CC and CD kernels, (7.116) and (7.239), respectively.

The operator $\mathcal{H}\mathcal{H}^\dagger$, which maps the mixed image space to itself, is given by

$$[\mathcal{H}\mathcal{H}^\dagger \mathbf{g}]_m(\mathbf{r}_d) = \sum_{k=1}^3 \int_{\infty} d^2 r_{d0} K_{mk}(\mathbf{r}_d, \mathbf{r}_{d0}) g_k(\mathbf{r}_{d0}), \quad (7.289)$$

where now the kernel is [cf. (7.124)]

$$K_{mk}(\mathbf{r}_d, \mathbf{r}_{d0}) = \int_{\mathbf{S}_f} d^2 r \int_0^{\infty} d\lambda h_m(\mathbf{r}_d, \mathbf{r}, \lambda) h_k^*(\mathbf{r}_{d0}, \mathbf{r}, \lambda). \quad (7.290)$$

As with the other system descriptions considered in this chapter, we can now, in principle, find the eigenvectors of $\mathcal{H}^\dagger \mathcal{H}$ and $\mathcal{H}\mathcal{H}^\dagger$ and use them to construct an SVD of the operator \mathcal{H} . The singular vectors in image space are functions of \mathbf{r}_d but also require an index m to specify the color band; we denote them by $v_n(\mathbf{r}_d, m)$. These functions must satisfy

$$[\mathcal{H}\mathcal{H}^\dagger \mathbf{v}_n](\mathbf{r}_d, m) = \mu_n v_n(\mathbf{r}_d, m). \quad (7.291)$$

The singular vectors in object space are functions of \mathbf{r} and λ , so we denote them by $u_n(\mathbf{r}, \lambda)$. For $n \leq R$ they can be found by operating on $v_n(\mathbf{r}_d, m)$ with \mathcal{H}^\dagger and renormalizing as in (7.253).

Special case: LSIV color imaging The expressions given above simplify considerably if we assume that the basic imaging system is LSIV and achromatic, so that

$$h_m(\mathbf{r}_d, \mathbf{r}, \lambda) = h(\mathbf{r}_d - \mathbf{r}) T_m(\lambda), \quad (7.292)$$

where $T_m(\lambda)$ is the transmission of the m^{th} filter. With this form, the kernel for $\mathcal{H}\mathcal{H}^\dagger$, (7.290), becomes

$$K_{mk}(\mathbf{r}_d - \mathbf{r}_{d0}) = \int_{-\infty}^{\infty} d^2r h_m(\mathbf{r}_d - \mathbf{r}) h_k^*(\mathbf{r}_{d0} - \mathbf{r}) \int_0^{\infty} d\lambda T_m(\lambda) T_k(\lambda). \quad (7.293)$$

The integral over \mathbf{r} is the complex autocorrelation of the PSF, and the integral over λ expresses the overlap of the filter functions.

Since this kernel is spatially (though not spectrally) shift-invariant, it suggests a spatial Fourier transform. If we denote the 2D Fourier transform of the image-space singular function by $V_{n,\rho}(\boldsymbol{\rho}_d, m)$ and the corresponding Hilbert-space vector as $\mathbf{V}_{n,\rho}$, then the eigenvalue equation, (7.291), becomes

$$[\mathcal{F}_2 \mathcal{H} \mathcal{H}^\dagger \mathcal{F}_2^{-1} \mathbf{V}_{n,\rho}] (\boldsymbol{\rho}_d, m) = \mu_n V_{n,\rho}(\boldsymbol{\rho}_d, m). \quad (7.294)$$

Arguments analogous to those leading to (7.169) reveal the structure of the operator $\mathcal{F}_2 \mathcal{H} \mathcal{H}^\dagger \mathcal{F}_2^{-1}$. It maps a function of $\boldsymbol{\rho}_d$ and index m to another function of the same form, and its kernel is

$$[\mathcal{F}_2 \mathcal{H} \mathcal{H}^\dagger \mathcal{F}_2^{-1}] (\boldsymbol{\rho}_d, \boldsymbol{\rho}_{d0}, m, k) = |H(\boldsymbol{\rho}_d)|^2 \delta(\boldsymbol{\rho}_d - \boldsymbol{\rho}_{d0}) A_{mk}, \quad (7.295)$$

where

$$A_{mk} = \int_0^{\infty} d\lambda T_m(\lambda) T_k(\lambda). \quad (7.296)$$

If we first solve

$$\sum_{k=1}^3 A_{mk} V_{nk} = \mu_n V_{nm}, \quad (7.297)$$

then $V_{n,\rho}(\boldsymbol{\rho}_d, m) = \delta(\boldsymbol{\rho}_d - \boldsymbol{\rho}) V_{nm}$. We have thus reduced the complicated mixed CD eigenvalue problem to a 3×3 matrix eigenvalue problem.

This reduction is reminiscent of the one that occurred in Sec. 7.2.10, where we considered axial systems that were LSIV in two of the three dimensions [see especially (7.222)]. In that case as well as the present problem, we were able to make good use of partial shift-invariance.

7.3.6 Discrete-to-continuous systems

Though Sec. 7.3 deals with CD mappings, it is an easy digression to touch on discrete-to-continuous (DC) mappings. As we shall see below, a DC mapping is the adjoint of a CD one.

The most common imaging application of DC mappings is *image display*. For example, if a set of coefficients stored in a computer is converted into a luminance pattern on a cathode-ray tube or other display device, the mapping is DC. Similarly, computer-generated holograms can be regarded as systems for converting discrete vectors into continuous optical fields. Again, the mapping is DC and the goal is display. Linear DC mappings are treated briefly here, and the effect of inevitable display nonlinearities is discussed in Sec. 7.5.

Form of the operator For definiteness, we shall discuss DC mappings specifically in terms of image display. A display system maps a stored set of numbers, described by a vector $\boldsymbol{\theta}$, to a luminance pattern $f_d(\mathbf{r})$, where the subscript stands for display. If the system is linear, the general form of the mapping is

$$f_d(\mathbf{r}) = \sum_{n=1}^N d_n(\mathbf{r}) \theta_n. \quad (7.298)$$

By comparison with (7.24), we see that this equation involves the adjoint of a CD operator with kernel $d_n(\mathbf{r})$. It can be written abstractly as

$$\mathbf{f}_d = \mathcal{D}_d^\dagger \boldsymbol{\theta}. \quad (7.299)$$

Uniformity A desirable feature of any image display is that it convert a uniform set of coefficients into a uniform displayed function. If all components of $\boldsymbol{\theta}$ are unity, the displayed function is

$$f_d^{(unif)}(\mathbf{r}) = \sum_{n=1}^N d_n(\mathbf{r}). \quad (7.300)$$

This expression is formally identical to that for the point sensitivity of a CD system, (7.232).

Magnification An image is rarely displayed at the same scale as the original object. For direct imaging, that means that the operator $\mathcal{D}_d^\dagger \mathcal{H}$ functions as a magnifier as discussed in Sec. 7.2.7. An easy way to incorporate an arbitrary magnification into \mathcal{D}^\dagger itself is to replace $d_n(\mathbf{r})$ with $d_n(\mathbf{r}/m)$ in (7.298).

7.4 LINEAR DISCRETE-TO-DISCRETE SYSTEMS

We have argued above that the correct mathematical description for a digital imaging system is a continuous-to-discrete mapping, but when we want to represent such a system in a computer, we must resort to discrete object representations. We learned in Sec. 7.1.3 how to construct such representations, and now we examine how they fit into the analysis of imaging systems.

7.4.1 System matrix

A linear object representation $f_a(\mathbf{r})$ is defined as a linear combination of more or less arbitrarily chosen expansion functions $\{\phi_n(\mathbf{r})\}$. The definition is given in (7.27), repeated here for reference:

$$f_a(\mathbf{r}) = \sum_{n=1}^N \theta_n \phi_n(\mathbf{r}), \quad (7.301)$$

where the subscript a stands for approximate. The expansion coefficients $\{\theta_n\}$ can be regarded as components of an $N \times 1$ vector $\boldsymbol{\theta}$ in the coefficient space introduced in Fig. 7.2.

Application of an imaging operator \mathcal{H} to this approximate object gives an approximate image vector \mathbf{g}_a , defined by

$$\mathbf{g}_a = \mathcal{H}\{f_a(\mathbf{r})\} = \sum_{n=1}^N \theta_n \mathcal{H}\{\phi_n(\mathbf{r})\}. \quad (7.302)$$

In the literature, the subscript is often omitted on \mathbf{g}_a and the vector $\boldsymbol{\theta}$ is often denoted \mathbf{f} , but both of those notations can be misleading. Omitting the subscript on \mathbf{g}_a risks confusing it with an actual, measured data vector, and the use of \mathbf{f} for a vector of expansion coefficients obscures the arbitrariness of the representation; there is no unique finite representation associated with a particular object $f(\mathbf{r})$. Moreover, with our convention of using \mathbf{f} for the infinite-dimensional object vector in Hilbert space, we need another symbol for a finite-dimensional approximation.

If we take \mathcal{H} as a general, linear CD mapping, then the m^{th} component of \mathbf{g}_a is given by

$$g_{am} = \sum_{n=1}^N \theta_n \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}) \phi_n(\mathbf{r}), \quad m = 1, \dots, M. \quad (7.303)$$

We can write this equation more compactly by defining an $M \times N$ matrix \mathbf{H} with elements H_{mn} given by

$$H_{mn} = \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}) \phi_n(\mathbf{r}), \quad (7.304)$$

so that

$$\mathbf{g}_a = \mathbf{H}\boldsymbol{\theta}. \quad (7.305)$$

The element H_{mn} is the response of the m^{th} detector in the actual CD system to an object consisting of a single expansion function with unit weight, *i.e.*, $f(\mathbf{r}) = \phi_n(\mathbf{r})$.

We shall refer to (7.305) as a discrete-to-discrete (or DD) model for an imaging system since both \mathbf{g}_a and $\boldsymbol{\theta}$ are specified by discrete indices, but it should be kept in mind that \mathbf{g}_a is also the result of a CD operator acting on an approximate (continuous but finite-dimensional) object representation, *i.e.*, $\mathbf{H}\boldsymbol{\theta} = \mathcal{H}\mathbf{f}_a$. There is a one-to-one mapping between a vector \mathbf{f}_a in representation space and a vector $\boldsymbol{\theta}$ in coefficient space, so either can be used to compute \mathbf{g}_a . As illustrated in Fig. 7.14, \mathbf{H} maps a vector $\boldsymbol{\theta}$ from coefficient space to a vector \mathbf{g}_a in image space, and \mathcal{H} maps the corresponding vector \mathbf{f}_a in representation space to the same vector in image space.

Relation to discretization operators The matrix \mathbf{H} can be expressed in terms of the discretization operators introduced in Sec. 7.1.3. From (7.37), we can write

$$\mathbf{g}_a = \mathcal{H}\mathcal{D}_\phi^\dagger \boldsymbol{\theta} = \mathcal{H}\mathcal{D}_\phi^\dagger \mathcal{D}_\chi \{f(\mathbf{r})\}, \quad (7.306)$$

where $\{\phi_n(\mathbf{r})\}$ is the set of expansion functions and $\{\chi_n(\mathbf{r})\}$ is the set of functions used to compute the coefficients in the expansion.

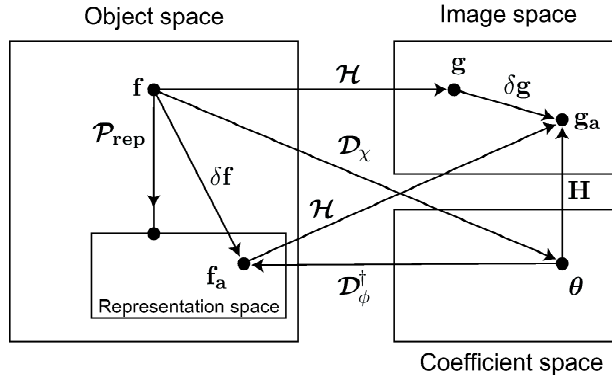

Fig. 7.14 Extension of Fig. 7.2 to include a CD imaging system. Shown are the effects of the actual CD operator \mathcal{H} on an object and its approximate representation as well as the effect of the matrix \mathbf{H} on the vector of coefficients associated with the object representation.

Comparison of (7.306) with (7.305) shows that

$$\mathbf{H} = \mathcal{H}\mathcal{D}_\phi^\dagger, \quad (7.307)$$

where, as in (7.35),

$$\boldsymbol{\theta} = \mathcal{D}_\chi\{f(\mathbf{r})\}. \quad (7.308)$$

These relations are illustrated in Fig. 7.14.

Measurement and computation of \mathbf{H} The definition of \mathbf{H} immediately suggests a way of measuring its elements if we have an actual digital imaging system in our laboratory. Suppose, for example, that the object is a 2D function and that we have chosen the expansion functions as pixels, so $\phi_n(\mathbf{r}) = \text{pix}_n(\mathbf{r})$ as defined in (7.29). Then we can construct a self-luminous or reflective test object in the form of a single pixel, place it at the n^{th} location in the object space, and record the response of all M detectors. This vector of responses is one column of \mathbf{H} , namely, the set of H_{mn} values for the chosen n and all m .

For some kinds of expansion functions, direct measurement of elements of \mathbf{H} is not possible. For example, with a truncated Fourier series, the expansion functions are complex and not realizable as physical objects. In these cases, or when the actual system is not available, we must resort to numerical computation. A straightforward approach is to sample the integrand in (7.304) finely and replace the integral by a sum.

A useful alternative, especially when the dimension q is large, is Monte Carlo integration. If $h_m(\mathbf{r})$ is nonnegative, as it must be in many kinds of imaging, then it can be normalized as a probability density on position \mathbf{r} :

$$p_m(\mathbf{r}) \equiv \frac{h_m(\mathbf{r})}{\int_{\mathbf{S}_f} d^q r h_m(\mathbf{r})}. \quad (7.309)$$

If sample points \mathbf{r}_j can be generated from this density, the elements of \mathbf{H} are given by

$$H_{mn} = \left[\int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}) \right] \cdot \lim_{J \rightarrow \infty} \frac{1}{J} \sum_{j=1}^J \phi_n(\mathbf{r}_j). \quad (7.310)$$

With a finite J , an estimate of H_{mn} is obtained, and it can be shown that this estimate is unbiased. See Gifford (1997) for details of the procedure and error analysis.

Flood uniformity and point sensitivity By analogy to (7.231) and (7.232), flood uniformity and point sensitivity for a DD system model can be defined, respectively, as

$$[\mathbf{g}_{fld}]_m = \sum_{n=1}^N H_{mn}; \quad (7.311)$$

$$[\mathbf{s}_{pt}]_n = \sum_{m=1}^M H_{mn}. \quad (7.312)$$

These two vectors are easily obtained from a calculated or measured system matrix.

We can relate these uniformity measures for the DD model back to the corresponding measures for an actual CD system. Inserting (7.304) into (7.311) yields

$$[\mathbf{g}_{fld}]_m = \sum_{n=1}^N \int_{\infty} d^q r h_m(\mathbf{r}) \phi_n(\mathbf{r}) = \int_{\infty} d^q r h_m(\mathbf{r}) \sum_{n=1}^N \phi_n(\mathbf{r}). \quad (7.313)$$

Comparison with (7.231) shows that the flood image determined from the \mathbf{H} matrix is proportional to the flood image for a CD system provided the sum of expansion functions is a constant independent of \mathbf{r} . This condition implies that the expansion functions are adequate to represent a flood object exactly. For example, it is satisfied by pixel functions if they fit together without gaps or overlap. [See the discussion around (7.72).]

The point sensitivity for the DD model is given explicitly by

$$[\mathbf{s}_{pt}]_n = \int_{\infty} d^q r \phi_n(\mathbf{r}) \sum_{m=1}^M h_m(\mathbf{r}) = \int_{\infty} d^q r \phi_n(\mathbf{r}) s_{pt}(\mathbf{r}), \quad (7.314)$$

where $s_{pt}(\mathbf{r})$ is the CD point sensitivity from (7.232). We see that the DD point sensitivity \mathbf{s}_{pt} is a sampled version of $s_{pt}(\mathbf{r})$ if the latter varies sufficiently slowly that $\phi_n(\mathbf{r})$ can be approximated by $const \cdot \delta(\mathbf{r} - \mathbf{r}_n)$.

7.4.2 Adjoint operator and singular-value decomposition

Unless the number of measurements M is equal to the number of expansion coefficients N , \mathbf{H} is not a square matrix and eigenanalysis of \mathbf{H} is not possible, but SVD will prove to be a useful tool here as in earlier sections of this chapter. After introducing the adjoint of the operator \mathbf{H} , we shall discuss the SVD of a DD imaging operator and relate it to the SVD of the CD operator it is intended to model.

Adjoint operator We know from Sec. 1.3.5 that the adjoint of an $M \times N$ matrix is an $N \times M$ matrix obtained by transposing the original matrix (interchanging rows and columns) and taking the complex conjugate of each element. For real matrices, the adjoint is just the transpose. In the context of DD models for imaging systems, the operator \mathbf{H}^\dagger maps a vector in the M -dimensional image space to a vector in the N -dimensional coefficient space, which is isomorphic to representation space.

From (7.307) and a basic property of adjoints (see Sec. 1.3.5), the adjoint of a system matrix \mathbf{H} can be written formally as

$$\mathbf{H}^\dagger = \mathcal{D}_\phi \mathcal{H}^\dagger. \quad (7.315)$$

This operator can be applied to any vector in data space. If it is applied to an actual data vector $\mathbf{g} = \mathcal{H}\mathbf{f}$, where \mathcal{H} is a CD operator, the result is

$$\mathbf{H}^\dagger \mathbf{g} = \mathcal{D}_\phi \mathcal{H}^\dagger \mathcal{H} \mathbf{f}. \quad (7.316)$$

The right-hand side is the same as we would have obtained by backprojecting \mathbf{g} through the actual CD system and then discretizing the result with the functions $\{\phi_n(\mathbf{r})\}$.

On the other hand, if \mathbf{H}^\dagger is applied to an approximate data vector \mathbf{g}_a as given by (7.306), the result is

$$\mathbf{H}^\dagger \mathbf{g}_a = \mathcal{D}_\phi \mathcal{H}^\dagger \mathcal{H} \mathcal{D}_\phi^\dagger \mathcal{D}_\chi \mathbf{f}. \quad (7.317)$$

We can simplify this expression if we assume that $\{\chi_n(\mathbf{r})\}$ has been chosen for optimal representational accuracy. From Sec. 7.1.4 we recall that the norm of the object error is minimized if $\mathcal{D}_\phi^\dagger \mathcal{D}_\chi = \mathcal{P}_{rep}$, the projector onto representation space. A simple way to achieve this condition is to take $\{\phi_n(\mathbf{r})\}$ and $\{\chi_n(\mathbf{r})\}$ as identical orthonormal sets. With this assumption, (7.317) becomes

$$\mathbf{H}^\dagger \mathbf{g}_a = \mathcal{D}_\phi \mathcal{H}^\dagger \mathcal{H} \mathcal{D}_\phi^\dagger \mathcal{D}_\phi \mathbf{f} = \mathcal{D}_\phi \mathcal{H}^\dagger \mathcal{H} \mathcal{P}_{rep} \mathbf{f}. \quad (7.318)$$

The effect of the operator $\mathcal{H}^\dagger \mathcal{H} \mathcal{P}_{rep}$ is to eliminate components of \mathbf{f} that do not lie in representation space, then project and backproject what is left through the system (thereby eliminating null functions and weighting measurement functions by eigenvalues of $\mathcal{H}^\dagger \mathcal{H}$). The result is a vector (function) in measurement space; a subsequent discretization of this function yields $\mathbf{H}^\dagger \mathbf{g}_a$.

Singular-value decomposition As with the other operators discussed in this chapter, we shall construct the SVD of \mathbf{H} by first considering the eigenvalue problems for two Hermitian operators, $\mathbf{H}^\dagger \mathbf{H}$ and $\mathbf{H} \mathbf{H}^\dagger$.

Since \mathbf{H} is an $M \times N$ matrix, $\mathbf{H}^\dagger \mathbf{H}$ is an $N \times N$ matrix mapping one $N \times 1$ vector in coefficient space to another. Its eigenfunctions are $N \times 1$ vectors denoted $\mathbf{u}_n^{(d)}$, where the superscript d , standing for discrete, serves to distinguish these eigenvectors from the Hilbert-space eigenvectors of $\mathcal{H}^\dagger \mathcal{H}$, which we have denoted by \mathbf{u}_n . The eigenvalue equation for $\mathbf{H}^\dagger \mathbf{H}$ is thus

$$\mathbf{H}^\dagger \mathbf{H} \mathbf{u}_n^{(d)} = \mu_n^{(d)} \mathbf{u}_n^{(d)}. \quad (7.319)$$

There is no reason to expect the eigenvalues of $\mathbf{H}^\dagger \mathbf{H}$, here denoted $\mu_n^{(d)}$, to equal those for $\mathcal{H}^\dagger \mathcal{H}$, even if \mathbf{H} is intended to model \mathcal{H} , so again we use the superscript.

The set $\{\mathbf{u}_n^{(d)}, n = 1, \dots, N\}$ is orthonormal and complete in coefficient space, so any coefficient vector $\boldsymbol{\theta}$ can be expanded as

$$\boldsymbol{\theta} = \sum_{k=1}^N a_k \mathbf{u}_k^{(d)}, \quad a_k = [\mathbf{u}_k^{(d)}]^\dagger \boldsymbol{\theta}, \quad (7.320)$$

and an individual coefficient θ_n is given by

$$\theta_n = \sum_{k=1}^N a_k u_{kn}^{(d)}, \quad (7.321)$$

where $u_{kn}^{(d)}$ is the n^{th} component of the vector $\mathbf{u}_k^{(d)}$. The set $\{a_k\}$ constitutes a vector \mathbf{a} , which is simply the vector $\boldsymbol{\theta}$ in a different basis in coefficient space. Since we always choose $\{\mathbf{u}_n^{(d)}\}$ to be an orthonormal set, \mathbf{a} and $\boldsymbol{\theta}$ differ by a unitary transformation.

The operator $\mathbf{H}\mathbf{H}^\dagger$ is an $M \times M$ matrix mapping image space to itself, and its eigenvalue equation is

$$\mathbf{H}\mathbf{H}^\dagger \mathbf{v}_m^{(d)} = \mu_m^{(d)} \mathbf{v}_m^{(d)}. \quad (7.322)$$

The set $\{\mathbf{v}_m^{(d)}, m = 1, \dots, M\}$ is orthonormal and complete in image space, so any image vector (approximate or real) can be expanded in terms of them. In particular, the approximate image vector \mathbf{g}_a can be written as

$$\mathbf{g}_a = \sum_{m=1}^M b_m \mathbf{v}_m^{(d)}, \quad b_m = [\mathbf{v}_m^{(d)}]^\dagger \mathbf{g}_a. \quad (7.323)$$

With these preliminaries, we can now express the SVD of \mathbf{H} as

$$\mathbf{H} = \sum_{n=1}^R \sqrt{\mu_n^{(d)}} \mathbf{v}_n^{(d)} \mathbf{u}_n^{(d)\dagger}, \quad (7.324)$$

where, as discussed in Sec. 1.2.3, the rank R must satisfy the constraint $R \leq \min(M, N)$.

If $R = N$, then \mathbf{H} does not have a null space, but this statement must be interpreted carefully. Since \mathbf{H} operates on coefficient vectors, the lack of a null space means simply that there is no vector $\boldsymbol{\theta}_{null}$ in coefficient space such that $\mathbf{H}\boldsymbol{\theta}_{null} = 0$. It does not imply that the actual CD operator \mathcal{H} , which \mathbf{H} is supposed to represent, has no null space; all CD operators have null spaces, even when their approximate matrix representations do not.

Discrete imaging equation in SVD form We saw in (7.129) and (7.258) that SVD reduces an actual imaging equation to a simple multiplication. The same holds true for an approximate imaging equation; (7.305) is equivalent to

$$b_n = \sqrt{\mu_n^{(d)}} a_n, \quad (7.325)$$

where a_n and b_n are expansion coefficients for $\boldsymbol{\theta}$ and \mathbf{g}_a , respectively, as defined by (7.320) and (7.323).

Relation between discrete and continuous singular vectors Since the matrix \mathbf{H} is intended to be a finite approximation to the CD operator \mathcal{H} , we hope that there is some simple relation between the finite-dimensional singular vectors $\{\mathbf{u}_n^{(d)}\}$ appropriate to \mathbf{H} and the infinite-dimensional ones $\{\mathbf{u}_n\}$ appropriate to \mathcal{H} . Since $\mathbf{u}_n^{(d)}$ is a discrete vector, the only way it can be related to a function of a continuous variable, such as \mathbf{u}_n , is through some discretization operator, and the natural one

to consider is the one we have been using all along, \mathcal{D}_ϕ . We inquire, therefore, whether $\mathcal{D}_\phi \mathbf{u}_n$ might be an eigenvector of the matrix $\mathbf{H}^\dagger \mathbf{H}$.

From (7.307) and (7.315), we can write

$$\mathbf{H}^\dagger \mathbf{H} \mathcal{D}_\phi \mathbf{u}_n = \mathcal{D}_\phi \mathcal{H}^\dagger \mathcal{H} \mathcal{D}_\phi^\dagger \mathcal{D}_\phi \mathbf{u}_n. \quad (7.326)$$

If $\{\phi_n\}$ is an orthonormal set, we know from (7.40) that $\mathcal{D}_\phi^\dagger \mathcal{D}_\phi = \mathcal{P}_{rep}$, the projector onto representation space. If \mathbf{u}_n lies in representation space, so that

$$\mathcal{P}_{rep} \mathbf{u}_n = \mathbf{u}_n, \quad (7.327)$$

then we have at once that

$$\mathbf{H}^\dagger \mathbf{H} \mathcal{D}_\phi \mathbf{u}_n = \mu_n \mathcal{D}_\phi \mathbf{u}_n. \quad (7.328)$$

This equation shows that $\mathcal{D}_\phi \mathbf{u}_n$ is indeed an eigenvector of $\mathbf{H}^\dagger \mathbf{H}$ and that the eigenvalue $\mu_n^{(d)}$ is identical to μ_n , but keep in mind that we have used the assumptions that $\{\phi_n\}$ is an orthonormal set and that \mathbf{u}_n lies in representation space. The latter condition is equivalent to saying that \mathbf{u}_n can be written exactly as a linear superposition of the expansion functions $\{\phi_n\}$.

If pixels are used for the expansion functions, then (7.327) is approximately satisfied for eigenfunctions \mathbf{u}_n that vary slowly on the scale of the pixel. In practice, this often means for large values of μ_n since systems usually image fine details more poorly than coarse ones; thus eigenfunctions that contain fine detail correspond to small eigenvalues.

In Sec. 7.4.3, we shall show how to choose the functions $\{\phi_n\}$ so that representation space is identical to measurement space; in this case all of the eigenvectors of $\mathbf{H}^\dagger \mathbf{H}$ corresponding to nonzero eigenvalues (*i.e.*, the entire measurement space of \mathbf{H}) can be found simply by discretizing the measurement-space eigenvectors of $\mathcal{H}^\dagger \mathcal{H}$.

7.4.3 Image errors

In Sec. 7.1.4 we discussed several error norms that could be used to evaluate the degree of agreement between an actual object \mathbf{f} and an approximate representation \mathbf{f}_a . These norms were defined in object space, but we can also use an image-space error norm $\|\mathcal{H} \delta \mathbf{f}\|$ as a way of specifying the accuracy of the data produced through an actual CD system by an approximate object representation. Because of the dual interpretation of \mathbf{g}_a as either $\mathcal{H} \mathbf{f}_a$ or $\mathbf{H} \boldsymbol{\theta}$ [see (7.302) and (7.305)], this same norm is also a measure of how accurately the CD system is modeled by a discrete matrix \mathbf{H} .

The definition of the image error norm is

$$\|\mathcal{H} \delta \mathbf{f}\| = \|\mathcal{H}(\mathbf{f} - \mathbf{f}_a)\| = \|\mathbf{g} - \mathbf{g}_a\|. \quad (7.329)$$

But we know from (7.306)–(7.308) how \mathbf{g}_a is related to \mathbf{f} , so we can write

$$\|\mathcal{H} \delta \mathbf{f}\| = \|\mathcal{H} \mathbf{f} - \mathbf{H} \boldsymbol{\theta}\| = \|\mathcal{H}(\mathcal{I} - \mathcal{D}_\phi^\dagger \mathcal{D}_\chi) \mathbf{f}\|, \quad (7.330)$$

where \mathcal{I} is the identity operator in object space. One immediate conclusion from (7.330) is that only the components of $\delta \mathbf{f}$ within the measurement space of \mathcal{H} contribute to $\|\mathcal{H} \delta \mathbf{f}\|$.

The image error is zero if and only if

$$\mathcal{D}_\phi^\dagger \mathcal{D}_\chi \mathbf{f} = \mathbf{f}_{meas} + \mathbf{f}_0, \quad (7.331)$$

where \mathbf{f}_0 is any null vector of \mathcal{H} (not necessarily the null component of \mathbf{f}). One way to satisfy this condition is to require that

$$\mathcal{D}_\phi^\dagger \mathcal{D}_\chi = \mathcal{P}_{meas}, \quad (7.332)$$

but we could also add any operator whose range lies entirely in the null space of \mathcal{H} .

Truncated SVD expansions One way to make $\|\mathcal{H} \delta \mathbf{f}\|$ vanish is to use the singular vectors of \mathcal{H} as the expansion functions, so that

$$\mathbf{f}_a = \sum_{n=1}^N \theta_n \mathbf{u}_n. \quad (7.333)$$

If we choose $N \geq R$, then $\|\mathcal{H} \delta \mathbf{f}\|$ is identically zero. The first R terms of the SVD expansion are an exact object representation in the sense that the representation produces exactly the same data set as the true object itself. The remaining $N - R$ terms constitute a vector that lies entirely in the null space of \mathcal{H} .

If we choose $\phi_n = \mathbf{u}_n$ and $N = R$, then representation space and measurement space are identical and (7.332) holds. Under these same assumptions, the measurement-space eigenvector $\mathbf{u}_n^{(d)}$ of $\mathbf{H}^\dagger \mathbf{H}$ is given by $\mathcal{D}_\phi \mathbf{u}_n$, where \mathbf{u}_n is an eigenvector of $\mathcal{H}^\dagger \mathcal{H}$ with $n \leq R$.

Natural pixels Another way to implement (7.332) is to use the point response functions as the expansion functions. Because we wish to allow the generality of complex kernels, we take the expansion functions as $\{\phi_m(\mathbf{r}), m = 1, \dots, M\} = \{h_m^*(\mathbf{r}), m = 1, \dots, M\}$, where M is the number of measurements acquired by the CD system we are trying to represent. Buonocore *et al.* (1981) refer to these expansion functions as *natural pixels*.

With natural pixels, the approximate object representation has the functional form,

$$f_a(\mathbf{r}) = \sum_{m=1}^M \theta_m h_m^*(\mathbf{r}). \quad (7.334)$$

By comparison with (7.237), we see that this function corresponds to a vector \mathbf{f}_a in object space given by

$$\mathbf{f}_a = \mathcal{H}^\dagger \boldsymbol{\theta}. \quad (7.335)$$

Since we have chosen the number of coefficients, previously denoted by N , to be equal to the number of measurements M , coefficient space and image space are now identical and $\mathcal{D}_\phi^\dagger = \mathcal{H}^\dagger$.

The natural pixels are not orthonormal, but they span measurement space. Any \mathbf{f}_a of the form (7.335) is necessarily in measurement space since

$$\mathcal{P}_{meas} \mathbf{f}_a = \mathcal{H}^+ \mathcal{H} \mathbf{f}_a = \mathcal{H}^+ \mathcal{H} \mathcal{H}^\dagger \boldsymbol{\theta} = \mathcal{H}^\dagger \boldsymbol{\theta} = \mathbf{f}_a, \quad (7.336)$$

where we have used the pseudoinverse identity (1.153). Moreover, it is always possible to choose the coefficient vector $\boldsymbol{\theta}$ so that \mathbf{f}_a equals \mathbf{f}_{meas} . The proper choice is

$$\boldsymbol{\theta} = [\mathcal{H}^\dagger]^\dagger \mathbf{f}_a, \quad (7.337)$$

for then, by use of (1.151) and (1.149),

$$\mathbf{f}_a = \mathcal{H}^\dagger [\mathcal{H}^\dagger]^\dagger \mathbf{f} = \mathcal{H}^\dagger \mathcal{H} \mathbf{f} = \mathbf{f}_{meas}. \quad (7.338)$$

With coefficients chosen by (7.337), therefore, (7.332) is satisfied and $\|\mathcal{H} \delta \mathbf{f}\| = 0$.

When \mathbf{f}_a is given by (7.338), we have

$$\mathbf{g} = \mathcal{H} \mathbf{f} = \mathcal{H} \mathbf{f}_a = \mathcal{H} \mathcal{H}^\dagger [\mathcal{H}^\dagger]^\dagger \mathbf{f} = \mathcal{H} \mathcal{H}^\dagger \boldsymbol{\theta}. \quad (7.339)$$

The system matrix \mathbf{H} is thus $\mathcal{H} \mathcal{H}^\dagger$ in this case, and its elements are given by the overlap between point response functions (Buonocore *et al.*, 1981):

$$H_{mn} = [\mathcal{H} \mathcal{H}^\dagger]_{mn} = \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}) h_n^*(\mathbf{r}). \quad (7.340)$$

We shall return to natural pixels in Chap. 15 when we discuss inverse problems.

7.4.4 Discrete representations of shift-invariant systems

As discussed in detail in Sec. 7.2.3, a linear shift-invariant CC system is described by a convolution integral. The corresponding DD description models the integral by a matrix-vector multiplication. If we take the expansion functions as uniform translates of a single function and also sample the image on a regular grid, then the matrix has a certain regular structure, which is the topic of this section. We discuss that structure first for 1D imaging and then in an arbitrary number of dimensions.

Matrix description of a 1D LSIV system A 1D linear shift-invariant CC system has a kernel of the form $h(x_d - x)$. As in Sec. 7.3.4, we assume that the image is sampled with detector elements spaced by ϵ . The resulting CD kernel $h_m(x)$ has the form [cf. (7.272)],

$$h_m(x) = p(m\epsilon - x). \quad (7.341)$$

To get a DD model, we also assume that the object is expanded in uniform translates as

$$f(x) = \sum_n \theta_n \phi(x - n\epsilon), \quad (7.342)$$

where the spacing is the same as in the image.

With these assumptions, the DD system matrix has elements given, from (7.304), by

$$H_{mn} = \int_{-\infty}^{\infty} dx p(m\epsilon - x) \phi(x - n\epsilon) = \int_{-\infty}^{\infty} dx' p(x') \phi[(m - n)\epsilon - x'], \quad (7.343)$$

where the second integral follows from the change of variables $x' = m\epsilon - x$. By inspection of that integral, we see that the value of each element of \mathbf{H} is a function of only the difference in its indices, so we can write

$$H_{mn} = h_{m-n}. \quad (7.344)$$

As illustrated on the left in Fig. 7.15, each column is identical to the one adjacent to it but shifted by one element. Matrices of this form, called *Toeplitz*, were introduced in App. A and discussed earlier in this chapter in Sec. 7.1.5.

$$\left[\begin{array}{ccccccccc} c & b & a & 0 & 0 & 0 & 0 & 0 & 0 \\ d & c & b & a & 0 & 0 & 0 & 0 & 0 \\ e & d & c & b & a & 0 & 0 & 0 & 0 \\ 0 & e & d & c & b & a & 0 & 0 & 0 \\ 0 & 0 & e & d & c & b & a & 0 & 0 \\ 0 & 0 & 0 & e & d & c & b & a & 0 \\ 0 & 0 & 0 & 0 & e & d & c & b & a \\ 0 & 0 & 0 & 0 & 0 & e & d & c & b \\ 0 & 0 & 0 & 0 & 0 & 0 & e & d & c \end{array} \right] \quad \left[\begin{array}{ccccccccc} c & b & a & 0 & 0 & 0 & 0 & e & d \\ d & c & b & a & 0 & 0 & 0 & 0 & e \\ e & d & c & b & a & 0 & 0 & 0 & 0 \\ 0 & e & d & c & b & a & 0 & 0 & 0 \\ 0 & 0 & e & d & c & b & a & 0 & 0 \\ 0 & 0 & 0 & e & d & c & b & a & 0 \\ 0 & 0 & 0 & 0 & e & d & c & b & a \\ a & 0 & 0 & 0 & 0 & e & d & c & b \\ b & a & 0 & 0 & 0 & 0 & e & d & c \end{array} \right]$$

Fig. 7.15 Matrix representations of a 1D LSIV system in which the PSF has the form $(\dots 0 0 a b c d e 0 0 \dots)$. The object and image vectors are both 9×1 . *Left:* Toeplitz matrix; *Right:* Circulant approximation to the Toeplitz matrix.

It is convenient to take the indices m and n to range from 0 to $N-1$. The DD imaging equation (7.305) for a 1D LSIV system represented by a Toeplitz matrix then becomes

$$g_{am} = \sum_{n=0}^{N-1} h_{m-n} \theta_n. \quad (7.345)$$

One column of \mathbf{H} can be interpreted as a discrete PSF. A discrete point object is a vector $\boldsymbol{\theta}$ where all elements but one are zero and that one is unity. If the nonzero element is the k^{th} , so that $\theta_n = \delta_{nk}$, then the image elements g_{am} are h_{m-k} . Thus the k^{th} column of \mathbf{H} is the shift-invariant discrete PSF shifted to pixel k .

Truncation issues Even with very fine sampling, (7.345) is a poor representation of an LSIV system in one respect: a convolution integral has infinite limits but the indices m and n have a finite range. If there is no restriction on the form of h_{m-n} , the system is not really shift-invariant; as the PSF is shifted, part of it falls off one end of the column. What we are really modeling is not a true LSIV system but one with a finite field of view and detector size (see Sec. 7.2.8). The DD system of (7.345) corresponds to a CC system with the kernel given in (7.189).

Fortunately, in many imaging applications both the object and the PSF have finite spatial support, so infinite fields of view are not really needed. In particular, for direct imaging the width of the PSF is almost always much less than the size of the object field, so most of the elements in one column of \mathbf{H} are zero. Moreover, for any given object, we can always define the spatial support to extend well beyond the region where the object is nonzero, so the vector $\boldsymbol{\theta}$ will have strings of zeros on both ends. If we choose N and the sample spacing to allow coverage of this extended field, then there is no truncation of nonzero portions of the image by the finite limits in (7.345).

Discrete convolutions and circulant matrices The right-hand side of (7.345) is almost—but not quite—a discrete convolution. When we defined discrete convolutions in (3.329), it was asserted that all indices would be interpreted modulo N . If we apply this convention to the Toeplitz matrix \mathbf{H} , then when the PSF is shifted so that part of it falls off the bottom of the matrix, that same part magically reappears on the top as illustrated in the matrix on the right in Fig. 7.15. The matrix

elements then satisfy

$$H_{mn} = h_{[m-n]}, \quad (7.346)$$

where the square brackets denote modulo- N arithmetic. That is, whenever $m - n$ falls outside the range $[0, N - 1]$, an appropriate integer multiple of N is added to bring it back to that range. Matrices with this structure are called *circulant* (Davis, 1979).

The cyclic behavior of circulant matrices has almost no counterpart in real imaging systems,¹¹ but it is very convenient mathematically. Moreover, if the PSF and the object have finite support and N is chosen large enough, there is no error at all from replacing a Toeplitz matrix by a circulant one. If there is no restriction on the width of the PSF or the size of the field of view, however, the circulant matrix is only an approximation to the Toeplitz one, and significant errors might occur, especially at the edges of an image.

Diagonalization of circulant matrices In Sec. 7.2.4 we showed the key role played by the Fourier transform in the analysis of LSIV systems. A similar role is played by the discrete Fourier transform (DFT) in analyzing discrete models of LSIV systems, but only when the circulant form of the system matrix is used.

To develop this point, we express both \mathbf{g}_a and $\boldsymbol{\theta}$ in terms of their DFTs [*cf.* (3.313)]:

$$\theta_n = \frac{1}{N} \sum_{k=0}^{N-1} A_k \exp(2\pi ink/N); \quad (7.347)$$

$$g_{am} = \frac{1}{N} \sum_{j=0}^{N-1} G_{aj} \exp(2\pi imj/N). \quad (7.348)$$

The circulant version of the DD imaging equation now becomes

$$\frac{1}{N} \sum_{j=0}^{N-1} G_{aj} \exp(2\pi imj/N) = \frac{1}{N} \sum_{n=0}^{N-1} \sum_{k=0}^{N-1} A_k h_{[m-n]} \exp(2\pi ink/N). \quad (7.349)$$

Following a line parallel to (7.166) - (7.169), we next multiply both sides of (7.349) by $\exp(-2\pi imp/N)$ and sum over m from 0 to $N - 1$. Because of the discrete orthogonality of the complex exponentials, (3.12), this step yields

$$G_{ap} = \frac{1}{N} \sum_{k=0}^{N-1} A_k \sum_{n=0}^{N-1} \sum_{m=0}^{N-1} h_{[m-n]} \exp[2\pi i(nk - mp)/N]. \quad (7.350)$$

Now we can make a change of variables, $\ell = m - n$. It is at this point that the cyclic nature of the kernel comes into play: since both $h_{[m-n]}$ and the exponential factor are cyclic functions, there is no need to change the limits of integration, and we can write

$$G_{ap} = \frac{1}{N} \sum_{k=0}^{N-1} A_k \sum_{n=0}^{N-1} \exp[2\pi in(k - p)/N] \sum_{\ell=0}^{N-1} h_{\ell} \exp(-2\pi i\ell p/N). \quad (7.351)$$

¹¹For amusement, the reader may try to devise an imaging system in which the cyclic behavior actually occurs. Hint: It is all done with mirrors.

The sum over ℓ is now recognized as the DFT of one column of \mathbf{H} , which we shall denote as H_p . The sum over n gives $N\delta_{nk}$, and the Kronecker delta allows us to perform the sum over k , so we find

$$G_{ap} = A_p H_p. \quad (7.352)$$

Thus discrete Fourier transformation has reduced multiplication by a circulant matrix to a simple product. The discrete transfer function is, not surprisingly, the DFT of the discrete PSF.

We can also view this result in terms of matrix diagonalization. By analogy to (7.167), we can express (7.350) as

$$\mathbf{G}_a = \mathbf{W}_N \mathbf{H} \mathbf{W}_N^{-1} \mathbf{A}, \quad (7.353)$$

where \mathbf{W}_N is the matrix operator that performs the DFT [see (3.315)]; the elements of \mathbf{W}_N are $[\mathbf{W}_N]_{kn} = \exp(2\pi i kn/N)$. Comparison of (7.353) and (7.352) reveals that

$$[\mathbf{W}_N \mathbf{H} \mathbf{W}_N^{-1}]_{kp} = H_p \delta_{kp}, \quad (7.354)$$

which is the discrete counterpart of (7.169). Thus a circulant matrix is diagonalized by the DFT, and the diagonal elements are given by the DFT of one column of the original matrix.

Multidimensional systems The concepts of Toeplitz and circulant matrices can be extended to multidimensional systems by use of multi-indices. Suppose we want to devise a matrix representation for a CC system that maps a q D object to a q D image. If we approximate the object as a weighted sum of uniform translates of a single expansion function as in (7.64), then each term is specified by a multi-index \mathbf{n} . Similarly, if we presume that the digital image is obtained by regular sampling of the image $g(\mathbf{r}_d)$, then elements of the discrete image vector can be specified by a multi-index \mathbf{m} . An element of the system matrix can then be written as $H_{\mathbf{m}\mathbf{n}}$.

In a matrix with scalar indices, the elements H_{mn} for all values of m and one particular n constitute one column of the matrix. With multi-indices, we can still think of the index \mathbf{n} as specifying a column, which is now the collection of all elements with different m_1, \dots, m_q for fixed values of n_1, \dots, n_q .

If the CC system to be represented is LSIV, the matrix \mathbf{H} has a multidimensional Toeplitz structure,

$$H_{\mathbf{m}\mathbf{n}} = h_{\mathbf{m}-\mathbf{n}} = \text{function of } (m_1 - n_1, \dots, m_q - n_q). \quad (7.355)$$

Like its 1D counterpart, this form shows that each column is identical to the one adjacent to it but shifted by one element.

As in the 1D case, we assume that each component of each multi-index runs from 0 to $N_0 - 1$, so the DD imaging equation (7.305) becomes

$$g_{\mathbf{a}\mathbf{m}} = \sum_{\mathbf{n}=0}^{N_0-1} h_{\mathbf{m}-\mathbf{n}} \theta_{\mathbf{n}}. \quad (7.356)$$

As in Sec. 7.1.2, summation over a multi-index is equivalent to summing over all q of its components, so here each n_j ($j = 1, \dots, q$) runs from 0 to $N_0 - 1$. The total number of elements in both \mathbf{g}_a and $\boldsymbol{\theta}$ is thus $M = N = N_0^q$.

Multidimensional circulant matrices and DFTs With the same arguments as in the 1D case, the multidimensional Toeplitz matrix can be replaced by a multidimensional circulant one simply by replacing $h_{\mathbf{m}-\mathbf{n}}$ with $h_{[\mathbf{m}-\mathbf{n}]}$, where now the square brackets imply modulo- N arithmetic in each of the elements of the multi-index. Again, this substitution entails no approximation if the object and the PSF have finite support in all dimensions and N_0 is large enough to avoid truncation of the image. If this condition is not satisfied, some error will arise at the edge of the image.

The derivations of (7.352) and (7.354) still hold if all indices are rewritten in boldface type. A q D DFT diagonalizes a q D circulant matrix and hence reduces a discrete q D convolution to simple multiplication.

Display of multidimensional Toeplitz and circulant matrices Though it simplifies the notation, the use of multi-indices makes it tricky to display the matrix \mathbf{H} on a printed page. Another approach is to use lexicographic ordering and specify the matrix by scalar indices. If each component of a multi-index takes on N_0 values, the scalar lexicographic index takes on N_0^q values, so a very large number of elements may have to be displayed, but at least four-dimensional paper is not required. We shall illustrate the procedure for $q = 2$.

A matrix describing a 2D imaging system has two multi-indices and a total of four component indices. To convert such a matrix to one specified by only two indices, let $\mathbf{n} = (n_x, n_y)$ and define the scalar index n by

$$n = n_x + n_y N_0, \quad n = 0, \dots, N - 1, \quad N = N_0^2, \quad (7.357)$$

and similarly for \mathbf{m} . Next we define a new matrix of size $N_0^2 \times N_0^2$ with elements equal to $H_{\mathbf{mn}}$ after the conversion (7.357). This new matrix, referred to as the lexicographic matrix, can be displayed as a function of n and m as usual.

For a 2D LSIV system, the lexicographic matrix consists of a set of blocks, each of which is a Toeplitz matrix. Moreover, the blocks themselves have a Toeplitz structure; shifting horizontally by N_0 is equivalent to shifting vertically by N_0 . We say that the matrix is *block-Toeplitz with Toeplitz blocks*. Similar terminology applies to lexicographic circulant matrices.

More details on lexicographic matrices can be found in Andrews and Hunt (1977) and Pratt (1991), but we shall generally avoid lexicographic ordering and work mainly with vector indices in this book.

7.5 NONLINEAR SYSTEMS

So far we have discussed only linear imaging systems, but sometimes nonlinear mathematics is either mandated by the physics of the system or convenient for analysis. In this section we survey some of the main nonlinear descriptions that have found use in image science.

7.5.1 Point nonlinearities

One way to classify nonlinear responses is to distinguish *point nonlinearities* from *nonlocal nonlinearities*. Photographic film provides a good way of making this distinction.

Film is a highly nonlinear detector. The output variable (transmission of the developed film or optical density) is a complicated nonlinear function of the input (irradiance or exposure), but it may be a good approximation to say that the output at point \mathbf{r}_d is determined fully by the input at that same point. Under this assumption, we can write the input–output relation of film as

$$g_{out}(\mathbf{r}_d) = \Phi\{g_{in}(\mathbf{r}_d)\}, \quad (7.358)$$

where $\Phi\{\cdot\}$ is an ordinary scalar-valued nonlinear function of a scalar argument.

When an equation of this form is valid, we say that the system exhibits a point nonlinearity. On the other hand, if it is necessary to know $g_{in}(\mathbf{r}_d)$ at more than one point in order to compute $g_{out}(\mathbf{r}_d)$ at one point, then the system is said to be nonlocal, and if it is also nonlinear, it is said to exhibit a nonlocal nonlinearity.

In reality, film is indeed nonlocal. Light entering the emulsion diffuses and affects the optical density over a region with a width which we can call the resolution width of the film. If this resolution width is small compared to the width of the PSF associated with the remainder of the system (*e.g.*, the imaging lens), then it may be a useful approximation to treat the film as a point nonlinearity. Alternatively, we can describe the light diffusion as a nonlocal but linear blurring process and then regard the nonlinear step as just the conversion of light to developed photographic grains. In that case (7.358) can be used, with a reinterpreted $g_{in}(\mathbf{r}_d)$, even though blur within the film is not negligible.

Another example of a point nonlinearity occurs in coherent optical imaging. As discussed in Chap. 18, such systems are linear in a complex amplitude $u(\mathbf{r})$ related to the electric field. Thus all of the formalism for linear CC systems developed in Sec. 7.2 is applicable—right up to the detector. Optical detectors, however, do not respond to complex amplitude but rather to the irradiance, which is proportional to the squared modulus of the amplitude, $|u(\mathbf{r}_d)|^2$. Since the irradiance at point \mathbf{r}_d is a nonlinear function of the amplitude at that point and is independent of the amplitude at any other point, the conversion from amplitude to irradiance is a point nonlinearity.

Point nonlinearities in CD systems The concept of point nonlinearities applies to discrete images also. If we think of the CD system as a CC operator \mathcal{H}_{CC} followed by a discretization operator \mathcal{D} as in (7.227), there are two places where the nonlinearity can occur—before or after discretization. In a digital camera with a nonlinear detector array, for example, the output voltage of the m^{th} detector can be written as

$$V_m = \Phi_{det}\{g_m\} = \Phi_{det}\{[\mathcal{D}\mathcal{H}_{CC}\mathbf{f}]_m\}, \quad (7.359)$$

where $\Phi_{det}(\cdot)$ is a function describing detector saturation and nonlinearities in the subsequent electronics. In this equation, the image is first integrated over the detector area and then subjected to the nonlinearity. It is a point nonlinearity in a discrete sense because V_m is determined solely by $[\mathcal{D}\mathcal{H}_{CC}\mathbf{f}]_m$ for that same m .

For coherent imaging, on the other hand, it is the irradiance rather than the amplitude that is integrated, so the proper description is

$$g_m = [\mathcal{D}\{\Phi_{sq}[\mathcal{H}_{CC}\mathbf{f}]\}]_m, \quad (7.360)$$

where $\Phi_{sq}(u) = |u|^2$. In this case we encounter a point nonlinearity in the continuous sense, before discretization.

Both kinds of nonlinearity may be present simultaneously. If the detector in a coherent imaging system responds nonlinearly, its output voltage is expressed by

$$V_m = \Phi_{det} \{ [\mathcal{D}[\Phi_{sq}(\mathcal{H}_{CC}\mathbf{f})]]_m \}. \quad (7.361)$$

This form now involves two nested nonlinearities; both of them are point nonlinearities, but in different senses.

X-ray computed tomography involves a form similar to (7.361). This kind of imaging involves an exponential decay of radiation, and the exponent is a linear CC mapping of the object of interest; the output of this step is then integrated over a detector. As a preprocessing step, the logarithm of the measured data is computed, but this step does not cancel the exponential because of the intervening discretization operator. Instead, the result has the form

$$V_m = \ln \{ [\mathcal{D}[\exp(\mathcal{H}_{CC}\mathbf{f})]]_m \}. \quad (7.362)$$

Invertible vs. noninvertible point nonlinearities Often the nonlinear function $\Phi(\cdot)$ will be a monotonic function of its argument, at least over some range of values. In such cases, we can define an inverse function $\Phi^{-1}(\cdot)$ and use it to undo the effects of the nonlinearity. In (7.359), for example, all we require is that an increase in irradiance on the detector always produces an increase in the output voltage, and we can then recover g_m by

$$g_m = \Phi_{det}^{-1}\{V_m\} = [\mathcal{D}\mathcal{H}_{CC}\mathbf{f}]_m. \quad (7.363)$$

In other words, an invertible point nonlinearity does not interfere at all with the nice linear models we have emphasized in this chapter, provided we know the nonlinear response and correct the measured data accordingly.

Conversion of complex amplitude to irradiance is an example of a noninvertible point nonlinearity. We cannot determine the amplitude and phase of a complex number from its squared modulus.

Linearization If the function $\Phi(\cdot)$ is differentiable, it may be possible to approximate a nonlinear system by a linear one for small excursions from some nominal operating point. Consider a nonlinear detector that always receives an input g_m near some mean value \bar{g}_m . The output can be written as a Taylor expansion of (7.359):

$$V_m = \Phi_{det}\{\bar{g}_m\} + [(\mathcal{D}\mathcal{H}_{CC}\mathbf{f})_m - \bar{g}_m] \Phi'_{det}\{\bar{g}_m\} + \dots, \quad (7.364)$$

where $\Phi'_{det}\{\bar{g}_m\}$ is the derivative of $\Phi_{det}\{\cdot\}$ evaluated at the nominal operating point. If higher terms can be neglected and $\Phi_{det}\{\bar{g}_m\}$ and $\Phi'_{det}\{\bar{g}_m\}$ are known, we can solve (7.364) for $(\mathcal{D}\mathcal{H}_{CC}\mathbf{f})_m$, again salvaging all of our efforts to understand linear systems.

7.5.2 Nonlocal nonlinearities

A general expression covering a wide variety of nonlinear responses is the *Volterra series* (Schetzen, 1980), given by

$$\begin{aligned}
g(\mathbf{r}_d) &= \int_{\mathbf{S}_f} d^q r f(\mathbf{r}) h_1(\mathbf{r}_d; \mathbf{r}) + \int_{\mathbf{S}_f} d^q r \int_{\mathbf{S}_f} d^q r' f(\mathbf{r}) f(\mathbf{r}') h_2(\mathbf{r}_d; \mathbf{r}, \mathbf{r}') \\
&+ \int_{\mathbf{S}_f} d^q r \int_{\mathbf{S}_f} d^q r' \int_{\mathbf{S}_f} d^q r'' f(\mathbf{r}) f(\mathbf{r}') f(\mathbf{r}'') h_3(\mathbf{r}_d; \mathbf{r}, \mathbf{r}', \mathbf{r}'') + \dots \quad (7.365)
\end{aligned}$$

If $f(\mathbf{r})$ is complex, additional terms with various combinations of f and f^* are needed for full generality.

Bilinear transforms When only the second term in the Volterra series is present, as in partially coherent imaging (see Chap. 9), we refer to the system as *bilinear*. In this case it is convenient to include a complex conjugate in the definition and write

$$g(\mathbf{r}_d) = \int_{\infty} d^q r \int_{\infty} d^q r' f^*(\mathbf{r}) f(\mathbf{r}') h(\mathbf{r}_d; \mathbf{r}, \mathbf{r}'). \quad (7.366)$$

A more general bilinear transform would be obtained by using two different functions $f_1(\mathbf{r})$ and $f_2(\mathbf{r})$, but this degree of generality is not needed for imaging if we map a single object $f(\mathbf{r})$ to an image.

Other bilinear transforms, such as the Wigner distribution function and the Woodward ambiguity function, were introduced in Chap. 5. Note, however, that both the Wigner and Woodward functions involve single integrals, so the kernel in (7.366) must be a delta function to reproduce those special cases.

A bilinear system in q dimensions can be reformulated as a linear system in $2q$ dimensions (Saleh, 1978; Saleh and Freeman, 1987). Let \mathbf{R} be the $2q$ -dimensional vector obtained by concatenating \mathbf{r} and \mathbf{r}' , and define an auxiliary function $F(\mathbf{R})$ by

$$F(\mathbf{R}) \equiv f^*(\mathbf{r}) f(\mathbf{r}'). \quad (7.367)$$

Then (7.366) becomes

$$g(\mathbf{r}_d) = \int_{\infty} d^{2q} R F(\mathbf{R}) h(\mathbf{r}_d; \mathbf{R}), \quad (7.368)$$

where $h(\mathbf{r}_d; \mathbf{R}) \equiv h(\mathbf{r}_d; \mathbf{r}, \mathbf{r}')$. We see that (7.368) has the general form of a linear CC mapping, but now the mapping is from a $2q$ D function to an s D one rather than from q D to s D as in (7.101).

7.5.3 Object-dependent system operators

In some imaging systems it is difficult to distinguish the object from the imaging operator. Consider, for example, an optical microscope viewing a thick biological specimen. The light reaching the lens from one layer in the specimen is altered as it passes through other layers (Andrews and Hunt, 1977). If the specimen is transparent, the alteration is in the phase of the light, so the effect is similar to that produced by lens aberrations, which also alter the phase. The medium is both message and messenger.

A general mathematical description for a CC system with an object dependent system operator is

$$g(\mathbf{r}_d) = \int_{\mathbf{S}_f} d^q r h(\mathbf{r}_d, \mathbf{r}; \mathbf{f}) f(\mathbf{r}). \quad (7.369)$$

Since the kernel $h(\mathbf{r}_d, \mathbf{r}; \mathbf{f})$ can depend on $f(\mathbf{r})$ at more than one point \mathbf{r} , this equation expresses a nonlocal nonlinearity in \mathbf{f} .

The Volterra structure emerges if we assume that the kernel depends only weakly on \mathbf{f} . To see this, we first decompose the kernel into object-independent and object-dependent parts:

$$h(\mathbf{r}_d, \mathbf{r}; \mathbf{f}) = h_1(\mathbf{r}_d, \mathbf{r}) + \delta h_1(\mathbf{r}_d, \mathbf{r}; \mathbf{f}), \quad (7.370)$$

where $h_1(\mathbf{r}_d, \mathbf{r})$ might be computed by ignoring the effect of the object on the system, and $\delta h_1(\mathbf{r}_d, \mathbf{r}; \mathbf{f})$ is whatever is left over. If we can approximate $\delta h_1(\mathbf{r}_d, \mathbf{r}; \mathbf{f})$ as a linear functional in \mathbf{f} , then we can write

$$\delta h_1(\mathbf{r}_d, \mathbf{r}; \mathbf{f}) \simeq \int_{\mathbf{S}_f} d^q r' h_2(\mathbf{r}_d; \mathbf{r}, \mathbf{r}') f(\mathbf{r}'). \quad (7.371)$$

Substituting (7.370) and (7.371) into (7.369) yields the first two terms in the Volterra expansion, (7.365).

If the approximation of (7.370) is not adequate, h_2 must also depend on \mathbf{f} . Then we can write h_2 as a term independent of \mathbf{f} plus a correction term δh_2 which we can approximate as a linear functional in \mathbf{f} . This step yields the next term in the Volterra expansion, and repeating the process indefinitely gives the entire series.

Multicomponent objects As noted in Sec. 7.1.1, it is often necessary to consider multiple attributes of an object. If J attributes are needed for a full object description, then the object function $\mathbf{f}(\mathbf{r})$ is a vector field with J components. The object in fluorescence microscopy, for example, is characterized by its emission density $f_1(\mathbf{r})$, but also by a spatially varying absorption coefficient $f_2(\mathbf{r})$ and refractive index $f_3(\mathbf{r})$, so in this case $J = 3$.

These components do not necessarily enter into the imaging equation in the same way. A fluorescent microscope, for example, may respond linearly to the emission density but with a kernel that depends on the absorption coefficient and refractive index. Thus we can write¹²

$$g(\mathbf{r}_d) = \int_{\mathbf{S}_f} d^q r h(\mathbf{r}_d, \mathbf{r}; \mathbf{f}_2, \mathbf{f}_3) f_1(\mathbf{r}). \quad (7.372)$$

We see that \mathbf{g} is linear in \mathbf{f}_1 for fixed \mathbf{f}_2 and \mathbf{f}_3 , but it is nonlinear in the latter two quantities.

We can convert (7.372) to a CD description by integrating $g(\mathbf{r}_d)$ over a detector, as in (7.229), so that

$$g_m = \int_{\mathbf{S}_g} d^s r_d w_m(\mathbf{r}_d) g(\mathbf{r}_d) = \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}; \mathbf{f}_2, \mathbf{f}_3) f_1(\mathbf{r}). \quad (7.373)$$

Nonlinear imaging with known sources In many imaging systems, the radiation source is controllable and known, and the detector may respond linearly to the

¹²The notation here is potentially confusing. We use $f_j(\mathbf{r})$ for one component of the 3D vector field $\mathbf{f}(\mathbf{r})$, but we also use \mathbf{f}_j for $f_j(\mathbf{r})$ when we wish to regard it as a vector in Hilbert space. The kernel in (7.372) is written as $h(\mathbf{r}_d, \mathbf{r}; \mathbf{f}_2, \mathbf{f}_3)$ since it depends on $f_2(\mathbf{r})$ and $f_3(\mathbf{r})$ at all \mathbf{r} , not just at a single point.

radiation, but the radiation reaching the detector may be a complicated nonlinear function of the object. An example occurs in optical imaging through a turbid medium, where the light is strongly scattered *en route* from source to detector. The goal of the imaging is to map the distribution of the scatterers. As we shall see in detail in Chap. 10, the propagation of light in a strongly scattering medium can often be described by a diffusion equation of the form,

$$\nabla \cdot [f(\mathbf{r}) \nabla u(\mathbf{r})] = s(\mathbf{r}), \quad (7.374)$$

where $u(\mathbf{r})$ is the photon density in the medium, $s(\mathbf{r})$ is the source distribution and $f(\mathbf{r})$ is the diffusion coefficient, which we denote by $f(\mathbf{r})$ here to emphasize that it is the object we seek to image. A detector placed on the periphery of the medium responds linearly to the photon density, which in turn is a linear functional of the source distribution, but the kernel of that linear mapping depends nonlinearly on $f(\mathbf{r})$. Since many different detectors and source configurations can be used, we write the response of the m^{th} detector to the n^{th} source as

$$g_{mn} = \int_{\infty} d^q r h_m(\mathbf{r}; \mathbf{f}) s_n(\mathbf{r}). \quad (7.375)$$

This form is analogous to (7.373) except there is only one object component (the diffusion coefficient) and the source is not considered an attribute of the object.

Parametric models In Sec. 7.1.6, we surveyed a variety of parametric object descriptions. In every case, the end result was an expression for an object function $f(\mathbf{r})$, which could be the input to an imaging system. Even if the system output is a linear functional of $f(\mathbf{r})$, however, it may be nonlinear in the parameters. For the forward problem, this nonlinearity poses no great difficulty. Given a set of parameters describing an object, the image can be computed in two stages: a nonlinear mapping from parameters to \mathbf{f} , then a linear mapping from \mathbf{f} to \mathbf{g} . The inverse problem, estimating the parameters from \mathbf{g} , is more complicated and will be discussed in Chap. 15.

Sometimes a mixed linear/nonlinear parametric representation is useful. An example occurs in magnetoencephalography (MEG), which is the imaging of magnetic sources in the brain. A popular model in that field is that the object consists of a discrete set of magnetic dipoles, each characterized by a dipole moment $\boldsymbol{\mu}_k$ and location \mathbf{r}_k ($k = 1, \dots, K$) (Leahy *et al.*, 1998). The detectors used in MEG respond linearly (though nonlocally) to the dipole strengths, but that response is a complicated nonlinear function of the dipole positions.

To get a mathematical description of an MEG system, we define two new vectors. Since each dipole moment is a 3D vector, we can define a $3K \times 1$ vector \mathbf{d} that contains the information about the strength of each component of each dipole. Similarly, a $3K \times 1$ vector \mathbf{R} contains the information about the location of the dipoles. If M measurements are collected, the imaging equation takes the form

$$\mathbf{g} = [\mathbf{H}(\mathbf{R})]\mathbf{d}, \quad (7.376)$$

where $\mathbf{H}(\mathbf{R})$ is an $M \times 3K$ matrix, the elements of which depend nonlinearly on \mathbf{R} .

Adaptive imaging systems An *adaptive* system is one where system parameters are modified in response to its input. The prime example in imaging is adaptive optics,

where controllable mirrors are often used to compensate for image blurring resulting from atmospheric turbulence.

We can describe adaptive systems as linear CC or CD mappings, where the kernel has one or more controllable parameters. To be specific, we take the CD form and assume that there are J controllable parameters, which we can arrange as a $J \times 1$ vector Θ . The imaging equation is then

$$g_m = \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}; \Theta) f(\mathbf{r}). \quad (7.377)$$

For the system to be adaptive, each parameter Θ_j must be determined in some way by the object, but we have access only to the image values. We therefore assume that each Θ_j is a functional of \mathbf{g} . In adaptive optics, for example, we might derive some measure of image sharpness and use it in a feedback system to control mirror positions.

If the parameters are controlled linearly, we can write

$$\Theta_j = \Theta_{j0} + \sum_{m=1}^M T_{jm} g_m, \quad (7.378)$$

where Θ_{j0} is some nominal or preset value that Θ_j assumes when no object is present and \mathbf{T} is a $J \times M$ matrix.

The two simultaneous sets of equations, (7.377) and (7.378), then constitute a nonlinear system, even though each individual equation is linear in \mathbf{f} if other parameters are held fixed.

7.5.4 Postdetection nonlinear operations

So far in this section we have discussed nonlinear imaging systems, where \mathbf{g} is a nonlinear function of \mathbf{f} , but often nonlinear operations are performed on an image \mathbf{g} after detection. These operations may have many purposes, including data compression and storage, image reconstruction, image enhancement, and various forms of image analysis, including pattern recognition and estimation of numerical parameters. In this section we take a brief look at some of these topics with the aim of showing how they can be incorporated into the mathematical description of the overall system. Nonlinear estimation and image-reconstruction algorithms are discussed in further detail in Chap. 15.

Digitization and bit planes The output of a detector is often digitized by an analog-to-digital (A/D) converter in order to store it in computer memory. A convenient mathematical description of A/D converters (especially for programmers) is

$$\Phi_{AD}(g_m) = \text{int}(C_1 g_m + C_2), \quad (7.379)$$

where C_1 and C_2 are constants, and $\text{int}(\cdot)$ returns the integer part of its argument [e.g., $\text{int}(2.57) = 2$].

In the language of Sec. 7.5.1, $\Phi_{AD}(\cdot)$ is a noninvertible point nonlinearity. The nonlinear function in this case has a staircase response with a discrete set of possible output values. It is not invertible since it is not a one-to-one mapping; all inputs in some finite range yield the same output.

If we assume that the output of an A/D converter is always $\leq 2^K - 1$, we can write it as

$$\Phi_{AD}(g_m) = \sum_{k=0}^{K-1} g_{mk} 2^k, \quad g_{mk} = 0 \text{ or } 1. \quad (7.380)$$

The set of all g_{mk} for a chosen level k and all m can be displayed as a binary image, taking on only the values 0 and 1 or black and white. This image is referred to as the k^{th} *bitplane map*.

The conversion of the A/D outputs to a set of bitplane maps is another nonlinear operation. Since any integer $\leq 2^K - 1$, can be expressed as a binary number with K bits, $\Phi_{AD}(g_m)$ can be reconstructed from the full set of K bitplane maps, so the nonlinearity is invertible. On the other hand, conversion from $\Phi_{AD}(g_m)$ to a single bitplane map is noninvertible.

Image compression A simple way of storing an image is to assign one location in computer memory to each value of $\Phi_{AD}(g_m)$. For example, if K in (7.380) is 8, we can use one byte for each m and store values of $\Phi_{AD}(g_m)$ in the range 0 to 255. If more precision is needed, we can use 2 bytes for each m , which makes $K = 16$ and allows storage of values from 0 to 65,535.

In many applications, however, computer storage or data-transmission capability is at a premium, and it is highly desirable to use more efficient digital representations. The generic term for methods that start with one set of digital data and return another set occupying less space is *data compression*. When applied specifically to images, data compression is often called *image compression*.

An image-compression algorithm can be thought of as an imaging system where the input is one digital image and the output is another. In this sense a compression algorithm is a discrete-to-discrete or DD mapping. Since compression is almost always nonlinear, it cannot be described by a matrix as linear DD mappings can.

As with point nonlinearities, it is necessary to distinguish reversible from irreversible compression. A simple example of reversible compression is run-length coding. If an image (or any other digital data set) contains a sequence of N entries all of which have the same value, then it is more efficient to store the value once along with the number of entries N rather than to store the same value N times. It is straightforward to undo this mapping.

Reversible compression is in the realm of computer science rather than image science; the techniques could as well be applied to any digital data. The fact that the data constitute an image is of little import, except perhaps in determining the degree of compression attainable. Irreversible image compression, on the other hand, results in an image that is not mathematically equivalent to its input, so in some sense it is degraded. The methods of image-quality assessment developed later in this book can be used to quantify the degree of degradation for specific tasks and observers.

Specific techniques for image compression are well beyond the scope of this book. For a succinct review, see Dorf (2000), and for many details see Rabbani and Jones (1991).

Nonlinear displays Linear image displays were discussed in Sec. 7.3.6. Real displays, however, exhibit nonlinearities, and their output can be written generally as

$$f_{disp}(\mathbf{r}) = \Phi_{disp} \{f_d(\mathbf{r})\}, \quad (7.381)$$

where $f_d(\mathbf{r})$ is given by (7.298). The display function $\Phi(\cdot)$ is often a monotonic but nonlinear curve. A common form is

$$\Phi_{disp}\{x\} = Ax^\gamma, \quad \gamma > 0, \quad (7.382)$$

where γ is called (not surprisingly) the *gamma* of the display. Higher gammas correspond to more contrast in the displayed image.

In addition to this inherent display nonlinearity, various other point nonlinearities are often applied in software before display in order to manipulate the contrast of an image. When the useful information in an image occupies a limited range of gray levels, for example, we can set upper and lower thresholds and not display values outside this range at all. Values within the range can then be multiplied by a constant to fill up the available range of the display, or more complicated nonlinear mappings such as histogram equalization can be performed. These mappings go under the general term *gray-level transformations*.

Since gray-level transformations are applied to individual image values before display as a function of a continuous variable, the general form of the mapping is obtained by combining (7.298) with a point nonlinearity acting on each θ_n and then inserting the result into (7.381); the result is

$$f_{disp}(\mathbf{r}) = \Phi_{disp} \left\{ \sum_{n=1}^N d_n(\mathbf{r}) \Phi_{gl}\{\theta_n\} \right\}, \quad (7.383)$$

where $\Phi_{gl}\{\cdot\}$ is the gray-level mapping.

8

Stochastic Descriptions of Objects and Images

There are many random, unpredictable physical effects that influence the structure of images. The inherent randomness that occurs in photoelectric detection and the noise limits imposed by basic thermodynamics inevitably make images *noisy* or *stochastic* (Greek *stochos*, aim, guess, chance). Additional randomness can arise from a variety of mechanisms in real image detectors. A full description of imaging systems requires analysis of all of these processes. Moreover, any imaging system will be used for a variety of objects, and the randomness of the objects themselves must be taken into account for many purposes.

The natural stochastic description for a digital image is as a finite-dimensional random vector, where each component corresponds to the gray value of a single pixel or to an individual measurement. Objects, on the other hand, are more accurately described as functions of continuous spatial or temporal variables (hence as vectors in an infinite-dimensional vector space); when these functions are stochastic in nature, they are called random processes. In either case, a *stochastic model* is at least a partial description of the statistics of the random vector or process.

Stochastic models have many uses in image science. They are needed for computing simple statistical descriptors such as moments and autocorrelation functions; they allow realistic computer simulation of typical images, and they provide the framework for pattern recognition, image analysis and data compression. In image reconstruction, it is useful to incorporate prior information about the object, and this information is often statistical in nature. Furthermore, as we shall see in detail in Chap. 14, objective assessment of image quality necessarily requires knowledge of the statistical properties of images, and these in turn are sensitive to the statistical properties of the objects being imaged.

It is our objective in this chapter to lay the groundwork for discussing all of these manifestations of randomness. As a starting point, we assume that the reader has a good grasp of the basic concepts of probability and random variables as surveyed in App. C. In Sec. 8.1 we discuss multivariate probability and vector random variables in general terms, though without reference to specific probability

laws. Random processes are treated in similar generality in Sec. 8.2. In Sec. 8.3 we discuss an important class of specific probability laws, the Gaussian or normal distributions, as applied to random vectors and random processes. In Sec. 8.4, we introduce a few of the many stochastic models that have been used for random objects, and in Sec. 8.5 we extend the discussion to images (as opposed to objects).

A notable omission in this chapter is any discussion of the Poisson distribution, which plays a crucial role in stochastic modeling of many imaging systems; that omission will be remedied in Chap. 11.

The assistance of Robert F. Wagner in formulating and writing this chapter is gratefully acknowledged.

8.1 RANDOM VECTORS

In Sec. C.2.1 of App. C, a random variable was defined as a function that maps the sample space S of some experiment onto the set of real numbers. That is, each experimental outcome ζ in S is associated with a real scalar $g(\zeta)$. To generalize this idea to a random vector, we need only consider a vector-valued function $\mathbf{g}(\zeta)$.

For example, suppose we want to measure the irradiance of a light beam at some location. We can insert an appropriate photodetector at that location, and the detector output is a scalar random variable. If the beam consists of white light, however, we might want to know the irradiance in each of three color bands. In that case we can use three photodetectors and an arrangement of beamsplitters and filters so that each measurement yields three scalars, which we can regard as components of a three-dimensional (3D) random vector.

Repeated scalar measurements can also be arranged as a vector. If we measure the irradiance at some location K times with a single photodetector, it is often useful to think of the result as a K -dimensional (KD) random vector. Alternatively, we might be interested in the spatial distribution of light in some image plane. We can use an array of M photodetectors and measure the irradiance at M different locations simultaneously, regarding the result as an MD random vector.

Finally, complex scalar random variables can be regarded as 2D vectors. If we measure the amplitude A and phase ϕ of an electromagnetic wave received on an antenna, these quantities can be regarded as two components of a vector. We can also use A and ϕ to compute the real and imaginary parts of a complex number $g = g' + ig''$, and the components g' and g'' are naturally depicted as Cartesian coordinates of a random vector in the complex plane. Equivalently, we can think of g as a complex random scalar if that is convenient. If we measure M complex numbers, we can display the results as either a vector with M complex components or one with $2M$ real components.

It is the goal of this section to establish notation and procedures for dealing with all of these manifestations of random vectors.

8.1.1 Basic concepts

A real MD random vector, denoted \mathbf{g} , can be formed from any collection of M real scalar random variables $\{g_m, m = 1, \dots, M\}$. For definiteness, the elements will be arranged as a column, so \mathbf{g} is a column vector or $M \times 1$ matrix.

An MD complex random vector \mathbf{g} has components $g_m = g'_m + ig''_m$. It can be represented by the $M \times 1$ column vector of complex random values $(g_1, g_2, \dots, g_M)^T$, or as the $2M \times 1$ column vector $(g'_1, g'_2, \dots, g'_M, g''_1, g''_2, \dots, g''_M)^T$. Hence it is equivalent to think of an MD vector of complex numbers as residing in either \mathbb{C}^M or \mathbb{R}^{2M} . Therefore, the treatment in this chapter is often given in terms of real random vectors, with the understanding that the complex case can be obtained by doubling the number of components in the random vector to include both real and imaginary parts as separate elements.

The probability law for a random vector is nothing more than the multivariate probability law for all of its components. Like any other random variable, each component of a random vector is either discrete-valued or continuous-valued. If each component can take on only a finite set of values, or at most a countably infinite set, then we refer to the random vector as discrete-valued. The probability law of a discrete-valued random variable specifies the probability associated with all possible combinations of values for all components. If all of the components of an MD random vector \mathbf{g} are continuous-valued random variables, the full probability law is a multivariate probability density function (PDF) $\text{pr}(g_1, g_2, \dots, g_M)$.

The cumulative distribution function for a random vector is defined analogously to that of a scalar random variable [*cf.* (C.26)]:

$$F(\mathbf{c}) \equiv \Pr(g_1 \leq c_1, g_2 \leq c_2, \dots, g_M \leq c_M), \quad (8.1)$$

where \mathbf{c} is a vector with components $\{c_i\}$.

If \mathbf{g} is a continuous-valued random vector, $F(\mathbf{c})$ is a continuous function of each c_i . Then, in a generalization of (C.29), the PDF on \mathbf{g} can be defined in terms of partial derivatives of $F(\mathbf{g})$:

$$\text{pr}(\mathbf{g}) \equiv \frac{\partial^M F(\mathbf{g})}{\partial g_1 \partial g_2 \cdots \partial g_M}. \quad (8.2)$$

If we integrate (8.2) we retrieve the cumulative distribution function:

$$F(\mathbf{g}) = \int_{-\infty}^{g_1} dg'_1 \int_{-\infty}^{g_2} dg'_2 \cdots \int_{-\infty}^{g_M} dg'_M \text{pr}(\mathbf{g}'). \quad (8.3)$$

A more compact vector notation for (8.3) is

$$F(\mathbf{g}) = \int_{-\infty}^{\mathbf{g}} d^M g' \text{pr}(\mathbf{g}'). \quad (8.4)$$

The corresponding expression for a discrete-valued random vector would involve multiple sums in place of the continuous integrals in (8.4), one for each of the components of \mathbf{g} .

Marginal probability densities We are often interested in the statistical behavior of a subset of the components of a random vector regardless of the behavior of the others. The statistical description of a single component g_m of the random vector \mathbf{g} is called the marginal probability density function on g_m . To determine the marginal probability density of g_m , we integrate the joint density of \mathbf{g} over all other components:

$$\text{pr}(g_m) = \int_{-\infty}^{\infty} dg_1 \cdots \int_{-\infty}^{\infty} dg_{m-1} \int_{-\infty}^{\infty} dg_{m+1} \cdots \int_{-\infty}^{\infty} dg_M \text{pr}(\mathbf{g}). \quad (8.5)$$

We can also determine the marginal density of the $(M - 1)$ -dimensional subvector $\mathbf{g}' = (g_1, g_2, \dots, g_{M-1})^t$, which is given by

$$\text{pr}(\mathbf{g}') = \int_{-\infty}^{\infty} dg_M \text{pr}(\mathbf{g}). \quad (8.6)$$

Equation (8.5) gives the marginal density of one component of the random vector \mathbf{g} ; (8.6) gives the marginal density of the random vector \mathbf{g}' formed from all but one component of the random vector \mathbf{g} . The marginal density of any other subset of the components of \mathbf{g} is similarly obtained by integrating over all variables not included in the subset.

A simple geometric construction can be used to visualize computation of a marginal. If we compute $\text{pr}(x_0)$ by integrating $\text{pr}(x_0, y)$ over y , we can write that integral as

$$\text{pr}(x_0) = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy \text{pr}(x, y) \delta(x - x_0). \quad (8.7)$$

The delta function is nonzero on a line parallel to the y -axis, and only values of $\text{pr}(x, y)$ along that line contribute to the integral. The PDF of x_0 is essentially a 1D projection of the 2D joint PDF on (x, y) .

Conditional probability densities All of the relations given in Sec. C.4 for joint and conditional probabilities and densities hold for random vectors with minor notational changes. For example, given two random vectors \mathbf{f} and \mathbf{g} , Bayes' rule [cf. (C.17)] becomes

$$\text{pr}(\mathbf{g}|\mathbf{f}) = \frac{\text{pr}(\mathbf{f}|\mathbf{g}) \text{pr}(\mathbf{g})}{\text{pr}(\mathbf{f})}. \quad (8.8)$$

Two random vectors \mathbf{f} and \mathbf{g} are *statistically independent* if the value of one of them has no influence on the other, that is, $\text{pr}(\mathbf{f}|\mathbf{g}) = \text{pr}(\mathbf{f})$. When two random vectors are independent, their joint PDF factors:

$$\text{pr}(\mathbf{f}, \mathbf{g}) = \text{pr}(\mathbf{g}) \text{pr}(\mathbf{f}). \quad (8.9)$$

It can be shown that the cumulative distribution function of two independent random vectors also factors.

8.1.2 Expectations

Discrete-valued random vectors Expectation values of discrete-valued random vectors are defined by summing over the possible combinations of the components weighted by the corresponding probabilities. Consider, for example, the MD vector \mathbf{g} , where each component g_m can take on any of J values x_j , $j = 1, \dots, J$. By extension of the discussion in Sec. C.4, the expectation of an arbitrary function of the components is given by

$$\begin{aligned} & \langle h(g_1, g_2, \dots, g_M) \rangle \\ &= \sum_{j_1=1}^J \sum_{j_2=1}^J \cdots \sum_{j_M=1}^J h(x_{j_1}, x_{j_2}, \dots, x_{j_M}) \text{Pr}(g_1 = x_{j_1}, g_2 = x_{j_2}, \dots, g_M = x_{j_M}). \end{aligned} \quad (8.10)$$

This notation is cumbersome, but we can shorten it to

$$\langle h(\mathbf{g}) \rangle = \sum_{g_1} \sum_{g_2} \cdots \sum_{g_M} h(\mathbf{g}) \Pr(\mathbf{g}), \quad (8.11)$$

where it is understood that each sum runs over the possible values of the component. An even more compact notation with the same meaning is

$$\langle h(\mathbf{g}) \rangle = \sum_{\mathbf{g}} h(\mathbf{g}) \Pr(\mathbf{g}), \quad (8.12)$$

where the sum over a vector index signifies a multiple sum over all components running over all possible values.

As in App. C, we shall use the notations $\langle h(\mathbf{g}) \rangle$ and $E\{h(\mathbf{g})\}$ interchangeably, and we shall also use an overbar to denote expectation. Thus, $\bar{\mathbf{g}} = \langle \mathbf{g} \rangle = E\{\mathbf{g}\}$.

Continuous-valued random vectors Given a continuous-valued random vector \mathbf{g} , the expectation of an arbitrary function $h(\mathbf{g})$ is written as

$$\langle h(g_1, g_2, \dots, g_M) \rangle = \int_{-\infty}^{\infty} dg_1 \int_{-\infty}^{\infty} dg_2 \cdots \int_{-\infty}^{\infty} dg_M h(g_1, g_2, \dots, g_M) \Pr(g_1, g_2, \dots, g_M). \quad (8.13)$$

There is no loss of generality in the infinite limits since the density might be zero except on a finite support. In more compact notation, (8.13) becomes

$$\langle h(\mathbf{g}) \rangle = \int_{\infty} d^M g h(\mathbf{g}) \Pr(\mathbf{g}), \quad (8.14)$$

where the subscript ∞ on the integral sign indicates that it runs over an infinite range for each of the M variables of integration.

We have not specified the nature of the function $h(\mathbf{g})$. It could be a scalar-valued or a vector-valued function of the random vector \mathbf{g} . It could even be \mathbf{g} itself, in which case $\langle \mathbf{g} \rangle$ is the *mean vector* $\bar{\mathbf{g}}$. The components of this vector are given by

$$\bar{g}_m = \langle g_m \rangle. \quad (8.15)$$

For complex vectors, the mean is defined separately for real and imaginary parts. Thus $\mathbf{g} = \mathbf{g}' + i\mathbf{g}''$ implies $g_m = g'_m + ig''_m$ and $\bar{\mathbf{g}} = \bar{\mathbf{g}}' + i\bar{\mathbf{g}}''$, which means that $\bar{g}_m = \bar{g}'_m + i\bar{g}''_m$ for all m .

8.1.3 Covariance and correlation matrices

It is often of interest to know whether two different components of a random vector *covary*, that is, whether fluctuations in one are statistically related to fluctuations in the other. To quantify this concept, we define the *covariance matrix* \mathbf{K} . For an M D random vector \mathbf{g} , \mathbf{K} is an $M \times M$ matrix with elements given by

$$K_{ij} = \langle (g_i - \bar{g}_i)(g_j - \bar{g}_j)^* \rangle, \quad (8.16)$$

where the asterisk indicates complex conjugate, allowing for the possibility that

components of \mathbf{g} might be complex. It is easy to see from this definition that \mathbf{K} is Hermitian, *i.e.*, $K_{ij} = K_{ji}^*$.

For the special case where g_i and g_j are statistically independent, we can write

$$K_{ij} = \langle (g_i - \bar{g}_i) \rangle \langle (g_j - \bar{g}_j)^* \rangle = 0, \quad i \neq j. \quad (8.17)$$

Any random variable covaries with itself. The diagonal elements of the covariance matrix are the variances of the components:

$$K_{jj} = \text{Var}\{g_j\}. \quad (8.18)$$

Another way of expressing the covariance matrix is as an *outer product*, as discussed in Sec. 1.3.7. With the notation of (1.53), (8.16) is equivalent to

$$\mathbf{K} = \langle (\mathbf{g} - \bar{\mathbf{g}})(\mathbf{g} - \bar{\mathbf{g}})^\dagger \rangle = \langle \Delta \mathbf{g} \Delta \mathbf{g}^\dagger \rangle, \quad (8.19)$$

where $\Delta \mathbf{g} \equiv \mathbf{g} - \bar{\mathbf{g}}$.

A related matrix is the *correlation matrix* \mathbf{R} , defined as

$$\mathbf{R} = \langle \mathbf{g} \mathbf{g}^\dagger \rangle. \quad (8.20)$$

By unscrambling the outer-product notation, we see that $R_{ij} = \langle g_i g_j^* \rangle$, so \mathbf{R} is the matrix organization of the second moments of the random vector. As a generalization of a well-known relation for two random variables, (C.85), we have

$$\mathbf{K} = \mathbf{R} - \bar{\mathbf{g}} \bar{\mathbf{g}}^\dagger. \quad (8.21)$$

For zero-mean random vectors, therefore, \mathbf{R} and \mathbf{K} are identical.

When two or more random vectors are involved in the same problem, we shall add appropriate subscripts to \mathbf{K} and \mathbf{R} . Thus $\mathbf{R}_{\mathbf{g}} = \langle \mathbf{g} \mathbf{g}^\dagger \rangle$ and $\mathbf{R}_{\mathbf{f}} = \langle \mathbf{f} \mathbf{f}^\dagger \rangle$.

Positive-definiteness Every covariance matrix \mathbf{K} is positive-semidefinite, as defined in Sec. A.8. To demonstrate this point, consider an arbitrary quadratic form as in (A.115):

$$\begin{aligned} Q_{\mathbf{K}}(\mathbf{x}) &= \mathbf{x}^\dagger \mathbf{K} \mathbf{x} = \mathbf{x}^\dagger \langle \Delta \mathbf{g} \Delta \mathbf{g}^\dagger \rangle \mathbf{x} = \langle \mathbf{x}^\dagger \Delta \mathbf{g} \Delta \mathbf{g}^\dagger \mathbf{x} \rangle \\ &= \langle |\mathbf{x}^\dagger \Delta \mathbf{g}|^2 \rangle, \end{aligned} \quad (8.22)$$

where \mathbf{x} is a nonrandom vector and we have used elementary properties of scalar products and norms from Chap. 1. Since $|\mathbf{x}^\dagger \Delta \mathbf{g}|^2$ is never negative, its expectation is never negative, so the quadratic form $Q_{\mathbf{K}}(\mathbf{x})$ is never negative and \mathbf{K} is positive-semidefinite (nonnegative-definite) by definition.

Moreover, it is rare that covariance matrices are not strictly positive-definite. From Sec. A.8 we know that an $M \times M$ positive-semidefinite matrix is positive-definite if its rank R equals its dimension M , and from Sec. A.3 we know that the rank is the number of linearly independent rows or columns. Thus the only way we can have $R < M$ is if at least one of the columns of \mathbf{K} can be written as a linear combination of the other columns. One way in which this can happen is if not all components of \mathbf{g} are measured independently, but instead one component is computed as a weighted sum of the others. Barring such unusual circumstances, however, it is reasonable to assume that $R = M$.

Cross-covariance and cross-correlation The cross-covariance matrix and the cross-correlation matrix for two random vectors \mathbf{g} and \mathbf{f} are defined analogously to (8.19) and (8.20), respectively. They are related by an expression analogous to (8.21):

$$\mathbf{R}_{\mathbf{g}\mathbf{f}} = \langle \mathbf{g} \mathbf{f}^\dagger \rangle = \mathbf{K}_{\mathbf{g}\mathbf{f}} + \bar{\mathbf{g}} \bar{\mathbf{f}}^\dagger. \quad (8.23)$$

The random vectors \mathbf{g} and \mathbf{f} are said to be *uncorrelated* if their cross-correlation matrix factors as

$$\mathbf{R}_{\mathbf{g}\mathbf{f}} = \langle \mathbf{g} \rangle \langle \mathbf{f}^\dagger \rangle = \bar{\mathbf{g}} \bar{\mathbf{f}}^\dagger, \quad (8.24)$$

or, equivalently, if their cross-covariance matrix is identically zero.

Since the PDF of two independent random vectors separates into the product of their individual PDFs, we have the immediate result that independent random vectors are uncorrelated. No general statement can be made to the converse, but we shall see later in this chapter that uncorrelated normally distributed random vectors are statistically independent.

Two random vectors are said to be *orthogonal* if

$$\mathbf{R}_{\mathbf{g}\mathbf{f}} = \langle \mathbf{g} \mathbf{f}^\dagger \rangle = 0. \quad (8.25)$$

Note that this stochastic definition involves the outer product whereas the deterministic definition of orthogonality of two vectors involves the inner product. From (8.23) we see that if the mean of either \mathbf{g} or \mathbf{f} is zero, the cross-correlation and the cross-covariance matrices are equal; in that case orthogonal random vectors are also uncorrelated.

8.1.4 Characteristic functions

The characteristic function $\psi_{\mathbf{g}}(\boldsymbol{\xi})$ of a random vector can be defined as the natural generalization of the characteristic function of a scalar random variable (see Sec. C.3.3). For a real $M \times 1$ random vector \mathbf{g} (column vector), the characteristic function is defined as

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \langle \exp(-2\pi i \boldsymbol{\xi}^t \mathbf{g}) \rangle, \quad (8.26)$$

where $\boldsymbol{\xi}^t$ is a real $1 \times M$ vector¹ (row vector) and hence $\boldsymbol{\xi}^t \mathbf{g}$ is the scalar product of \mathbf{g} and $\boldsymbol{\xi}$.

For the case of a continuous-valued random vector, $\psi_{\mathbf{g}}(\boldsymbol{\xi})$ can be written as

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \int_{-\infty}^{\infty} d^M g \, \text{pr}(\mathbf{g}) \exp(-2\pi i \boldsymbol{\xi}^t \mathbf{g}). \quad (8.27)$$

This integral is the MD Fourier transform of the PDF, so the properties of Fourier transforms from Chap. 3 can be used in its manipulation. In particular, since any PDF is nonnegative and normalized to unity, it is in \mathbb{L}_1 ; thus $\psi_{\mathbf{g}}(\boldsymbol{\xi})$ is finite for all $\boldsymbol{\xi}$, is continuous everywhere, and vanishes at infinity [see (3.65) and (3.66)]. The PDF on \mathbf{g} is given by the inverse Fourier transform of $\psi_{\mathbf{g}}(\boldsymbol{\xi})$:

$$\text{pr}(\mathbf{g}) = \int_{-\infty}^{\infty} d^M \boldsymbol{\xi} \, \psi_{\mathbf{g}}(\boldsymbol{\xi}) \exp(2\pi i \boldsymbol{\xi}^t \mathbf{g}). \quad (8.28)$$

¹One should not confuse $\boldsymbol{\xi}$ with the x component of spatial frequency, denoted ξ in other chapters. The vector $\boldsymbol{\xi}$ used here is a frequency in the sense that it is a variable in a Fourier transform, but it is not a spatial frequency.

The characteristic function of a random vector is unique, in that two random vectors have the same characteristic function if and only if they have the same probability distribution. And, as in the univariate case, two random vectors are independent if and only if their joint characteristic function can be written as the product of their marginal characteristic functions.

Moments The characteristic function has great utility not only for deriving PDFs but also as a shortcut to obtaining the moments of a random vector. This property follows from the definition (8.26) by expanding the exponential in a power series before taking the expectation value. This leads to a series of terms involving increasingly higher moments of the random variable \mathbf{g} . These moments can be isolated by differentiation of the series and then setting $\boldsymbol{\xi} = \mathbf{0}$, where $\mathbf{0}$ is the vector with all elements equal to zero. Alternatively, one can simply differentiate the characteristic function directly. For example, if we take the gradient we obtain (in the notation of Sec. A.9.2)

$$\frac{\partial \psi_{\mathbf{g}}(\boldsymbol{\xi})}{\partial \boldsymbol{\xi}} = \langle (-2\pi i \mathbf{g}) \exp(-2\pi i \boldsymbol{\xi}^t \mathbf{g}) \rangle. \tag{8.29}$$

On setting $\boldsymbol{\xi} = \mathbf{0}$, this yields

$$\langle \mathbf{g} \rangle = (-2\pi i)^{-1} \left[\frac{\partial \psi_{\mathbf{g}}(\boldsymbol{\xi})}{\partial \boldsymbol{\xi}} \right]_{\boldsymbol{\xi}=\mathbf{0}}. \tag{8.30}$$

Differentiating twice yields the second moment:

$$\mathbf{R} = \langle \mathbf{g} \mathbf{g}^t \rangle = (-2\pi i)^{-2} \left[\frac{\partial^2 \psi_{\mathbf{g}}(\boldsymbol{\xi})}{\partial \boldsymbol{\xi} \partial \boldsymbol{\xi}^t} \right]_{\boldsymbol{\xi}=\mathbf{0}}. \tag{8.31}$$

Higher-order moments can be determined using the following general expression:

$$\mathbb{E}\{g_1^{k_1} g_2^{k_2} \dots g_M^{k_M}\} = (-2\pi i)^{k_1+k_2+\dots+k_M} \left[\frac{\partial^{k_1+k_2+\dots+k_M} \psi_{\mathbf{g}}(\boldsymbol{\xi})}{\partial \xi_1^{k_1} \partial \xi_2^{k_2} \dots \partial \xi_M^{k_M}} \right]_{\boldsymbol{\xi}=\mathbf{0}}. \tag{8.32}$$

Complex random vectors The characteristic function of a complex random vector \mathbf{g} can be written

$$\begin{aligned} \psi_{\mathbf{g}}(\boldsymbol{\xi}) &= \langle \exp[-2\pi i \operatorname{Re}(\boldsymbol{\xi}^\dagger \mathbf{g})] \rangle = \langle \exp[-\pi i (\boldsymbol{\xi}^\dagger \mathbf{g} + \mathbf{g}^\dagger \boldsymbol{\xi})] \rangle \\ &= \langle \exp[-2\pi i (\xi'_1 g'_1 + \xi''_1 g''_1 + \dots + \xi'_M g'_M + \xi''_M g''_M)] \rangle, \end{aligned} \tag{8.33}$$

where now $\boldsymbol{\xi}$ is an MD complex vector $\boldsymbol{\xi} = \boldsymbol{\xi}' + i\boldsymbol{\xi}''$.

We see that the scalar product in the exponent of (8.33) is the sum of $2M$ real terms, rather than the M terms of (8.26). Another avenue for obtaining this expression is to make use of the fact that complex vectors can be considered to lie in either \mathbb{C}^M or \mathbb{R}^{2M} . Thus we could have chosen to represent the MD complex random vector \mathbf{g} by the $2MD$ vector of real components $(g'_1, g'_2, \dots, g'_M, g''_1, g''_2, \dots, g''_M)^t$ and similarly represent $\boldsymbol{\xi}$ by the vector of real components $(\xi'_1, \xi'_2, \dots, \xi'_M, \xi''_1, \xi''_2, \dots, \xi''_M)^t$. The use of (8.26) with these real vectors would give an expression for the characteristic function identical to (8.33).

The moments of \mathbf{g} can be determined by differentiation of $\psi(\mathbf{g})$ if we mind the rules for differentiation with respect to complex vectors given in Sec. A.9.5. The

mean of the random vector \mathbf{g} is found by taking the derivative of $\psi_{\mathbf{g}}(\boldsymbol{\xi})$ with respect to the complex vector $\boldsymbol{\xi}$:

$$\nabla\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \left[\frac{\partial}{\partial \boldsymbol{\xi}'} + i \frac{\partial}{\partial \boldsymbol{\xi}''} \right] \psi_{\mathbf{g}}(\boldsymbol{\xi}) = \left\langle (-2\pi i \mathbf{g}) \exp[-\pi i(\boldsymbol{\xi}^\dagger \mathbf{g} + \mathbf{g}^\dagger \boldsymbol{\xi})] \right\rangle, \quad (8.34)$$

where we have made use of (A.159) and (A.160). When we set $\boldsymbol{\xi}$ to zero we find

$$\langle \mathbf{g} \rangle = (-2\pi i)^{-1} [\nabla\psi_{\mathbf{g}}(\boldsymbol{\xi})]_{\boldsymbol{\xi}=\mathbf{0}}. \quad (8.35)$$

The second moment is found from the generalized Hessian (A.165):

$$\mathbf{R} = \langle \mathbf{g} \mathbf{g}^\dagger \rangle = (-2\pi i)^{-2} [\nabla \nabla^\dagger \psi_{\mathbf{g}}(\boldsymbol{\xi})]_{\boldsymbol{\xi}=\mathbf{0}}. \quad (8.36)$$

Higher-order moments can be derived using successive differentiation, similar to the case of real \mathbf{g} .

8.1.5 Transformations of random vectors

Section C.3.1 gives rules for transforming PDFs of scalar random variables. A bivariate extension of these rules is presented in Sec. C.4.5. In this section we extend these rules further so that they apply to random vectors of general dimension. Our treatment is limited to real vectors; the extension to complex vectors can be done by converting the complex vectors to real vectors with double the dimension as described above.

Suppose the random vector \mathbf{g} is related to the random vector \mathbf{f} through the general nonlinear relationship $\mathbf{g} = \mathcal{O}\mathbf{f}$. The mapping from \mathbf{f} to \mathbf{g} is discrete-to-discrete even though the components of the vectors are continuous valued. If we assume that this mapping is differentiable (with respect to the component values) and also one-to-one and onto, then the inverse mapping $\mathbf{f} = \mathcal{O}^{-1}(\mathbf{g})$ exists. The PDF of \mathbf{g} is then obtained from the known PDF of \mathbf{f} by recognizing the equivalence of the probability spaces used to describe random events in terms of either \mathbf{f} or \mathbf{g} :

$$\text{pr}_{\mathbf{g}}(\mathbf{g}) d^N \mathbf{g} = \text{pr}_{\mathbf{f}}(\mathbf{f}) d^N \mathbf{f}. \quad (8.37)$$

The random vector \mathbf{g} must have the same dimensionality as \mathbf{f} if the mapping from \mathbf{f} to \mathbf{g} is invertible. From (8.37) we obtain

$$\text{pr}_{\mathbf{g}}(\mathbf{g}) = \text{pr}_{\mathbf{f}}(\mathcal{O}^{-1}\mathbf{g}) |\det \mathbf{J}|, \quad (8.38)$$

where \mathbf{J} is the Jacobian matrix of partial derivatives relating the components of \mathbf{f} and \mathbf{g} [cf. (C.102)]:

$$J_{ij} = \frac{\partial f_i}{\partial g_j}, \quad (8.39)$$

and $|\det \mathbf{J}|$ is the absolute value of its determinant.

Linear transformations If the random vector \mathbf{g} is generated as the output of a linear filter acting on the random vector \mathbf{f} , we can characterize the linear transformation by an $M \times N$ matrix \mathbf{H} . Then we can write the $M \times 1$ output vector \mathbf{g} in terms of the $N \times 1$ input vector \mathbf{f} as

$$\mathbf{g} = \mathbf{H}\mathbf{f}. \quad (8.40)$$

If $M = N$ and \mathbf{H}^{-1} exists, the PDF of \mathbf{g} can be written in terms of the PDF of \mathbf{f} as a special case of (8.38):

$$\text{pr}_{\mathbf{g}}(\mathbf{g}) = \text{pr}_{\mathbf{f}}(\mathbf{H}^{-1}\mathbf{g}) |\det \mathbf{H}^{-1}|. \quad (8.41)$$

Characteristic function of the transformed vector If \mathbf{H} is not invertible, we cannot use (8.41) to relate the PDF for \mathbf{g} to the PDF for \mathbf{f} , but we can relate the corresponding characteristic functions. With (8.40), (8.26) becomes

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \langle \exp(-2\pi i \boldsymbol{\xi}^t \mathbf{H} \mathbf{f}) \rangle = \langle \exp[-2\pi i (\mathbf{H}^t \boldsymbol{\xi})^t \mathbf{f}] \rangle, \quad (8.42)$$

where the last step has used the definition of the adjoint, (1.39). (Since we are considering real matrices here, adjoint is the same as transpose.) Comparison of the last expectation in (8.42) with (8.26) shows that

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \psi_{\mathbf{f}}(\mathbf{H}^t \boldsymbol{\xi}), \quad (8.43)$$

so knowledge of $\psi_{\mathbf{f}}$ and \mathbf{H} immediately gives $\psi_{\mathbf{g}}$. As an exercise, the reader can show that (8.43) and (8.38) are equivalent if \mathbf{H}^{-1} exists.

The PDF on \mathbf{g} can in principle be found by taking an inverse MD Fourier transform of (8.43). Formally, we can write

$$\text{pr}(\mathbf{g}) = \int_{\infty} d^M \xi \psi_{\mathbf{f}}(\mathbf{H}^t \boldsymbol{\xi}) \exp(2\pi i \boldsymbol{\xi}^t \mathbf{g}), \quad (8.44)$$

but in practice the integral might not be easy. The problem is that we are integrating a function of an ND vector over an MD space.

Alternative approach Another way to derive an expression for the PDF of \mathbf{g} , when $\mathbf{g} = \mathbf{H}\mathbf{f}$, is to use the multivariate counterpart of (C.77) to write

$$\text{pr}(\mathbf{g}) = \int_{\infty} d^N f \text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}). \quad (8.45)$$

Here the notation $\text{pr}(\mathbf{g}|\mathbf{f})$ is a bit tricky: \mathbf{g} is *defined* as $\mathbf{H}\mathbf{f}$ (not $\mathbf{H}\mathbf{f} + \mathbf{n}$ here), so once \mathbf{f} is given, \mathbf{g} is no longer random; it is just $\mathbf{H}\mathbf{f}$. Nevertheless, we can still use (8.45) if we let $\text{pr}(\mathbf{g}|\mathbf{f})$ be the MD delta function, $\delta(\mathbf{g} - \mathbf{H}\mathbf{f})$. Then we have

$$\text{pr}(\mathbf{g}) = \int_{\infty} d^N f \delta(\mathbf{g} - \mathbf{H}\mathbf{f}) \text{pr}(\mathbf{f}). \quad (8.46)$$

This form is, in fact, equivalent to (8.42). If we take the MD Fourier transform of both sides of (8.46), we find

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \mathcal{F}_M\{\text{pr}(\mathbf{g})\} = \int_{\infty} d^M g \int_{\infty} d^N f \delta(\mathbf{g} - \mathbf{H}\mathbf{f}) \text{pr}(\mathbf{f}) \exp(-2\pi i \boldsymbol{\xi}^t \mathbf{g}). \quad (8.47)$$

The delta function allows us to perform the integral over \mathbf{g} , and we obtain

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \int_{\infty} d^N f \text{pr}(\mathbf{f}) \exp(-2\pi i \boldsymbol{\xi}^t \mathbf{H}\mathbf{f}) = \langle \exp(-2\pi i \boldsymbol{\xi}^t \mathbf{H}\mathbf{f}) \rangle. \quad (8.48)$$

This equation is the same as (8.42), and (8.43) follows as before.

Although (8.43) and (8.46) are equivalent, the latter may be easier to interpret geometrically. Suppose $M < N$. Then the integral is over an ND space but the delta function is nonzero only on an MD hyperplane defined by $\mathbf{g} = \mathbf{H}\mathbf{f}$. Only vectors \mathbf{f} that lie on this hyperplane make any contribution to the integral for a particular \mathbf{g} . This is similar to the geometric construction we presented for the computation of a marginal in (8.7).

Transformation of the mean and covariance When $\mathbf{g} = \mathbf{H}\mathbf{f}$, all moments of \mathbf{g} can be derived by differentiating (8.43), but often we are interested in just the mean or covariance matrix. From the linearity of the expectation operator, we have immediately for the mean of \mathbf{g} ,

$$\bar{\mathbf{g}} = \langle \mathbf{g} \rangle = \langle \mathbf{H}\mathbf{f} \rangle = \mathbf{H} \langle \mathbf{f} \rangle = \mathbf{H}\bar{\mathbf{f}}. \quad (8.49)$$

The covariance matrix of \mathbf{g} is found as

$$\mathbf{K}_{\mathbf{g}} = \langle \Delta \mathbf{g} \Delta \mathbf{g}^\dagger \rangle = \langle (\mathbf{H}\mathbf{f} - \mathbf{H}\bar{\mathbf{f}})(\mathbf{H}\mathbf{f} - \mathbf{H}\bar{\mathbf{f}})^\dagger \rangle = \mathbf{H} \langle \Delta \mathbf{f} \Delta \mathbf{f}^\dagger \rangle \mathbf{H}^\dagger = \mathbf{H}\mathbf{K}_{\mathbf{f}}\mathbf{H}^\dagger, \quad (8.50)$$

where $\Delta \mathbf{f} \equiv \mathbf{f} - \bar{\mathbf{f}}$. The same results can, of course, also be found from (8.43).

These rules for transforming means and covariance matrices will recur often in this book.

8.1.6 Eigenanalysis of covariance matrices

A covariance matrix is Hermitian, and we saw in Sec. 1.4.4 that eigenvectors and eigenvalues of Hermitian matrices have many nice properties. The eigenvalues are real, and the eigenvectors can be chosen to form a complete, orthonormal set in the domain of the matrix. Expansion of a random vector in eigenvectors of its covariance matrix is a valuable tool in statistical analysis.

Let $\mathbf{K}_{\mathbf{g}}$ be the $M \times M$ covariance matrix for a random vector \mathbf{g} . The eigenvalue equation for this matrix is

$$\mathbf{K}_{\mathbf{g}}\phi_m = \mu_m\phi_m, \quad m = 1, \dots, M, \quad (8.51)$$

where ϕ_m is an $M \times 1$ eigenvector and μ_m is the corresponding eigenvalue. (Note that the subscript on ϕ_m denotes a particular eigenvector, not a component.) Since $\mathbf{K}_{\mathbf{g}}$ is Hermitian, μ_m is real even if $\mathbf{K}_{\mathbf{g}}$ is complex.

We showed above that $\mathbf{K}_{\mathbf{g}}$ is at least positive-semidefinite, so $\mu_m \geq 0$ for all m . For convenience we assume that the eigenvalues are labeled by decreasing value:

$$\mu_1 \geq \mu_2 \geq \dots \geq \mu_R > 0, \quad (8.52)$$

where R is the rank. We know from Sec. 1.4.3 that the rank is also the number of nonzero eigenvalues, so μ_R is the smallest nonzero eigenvalue. We also argued above that the rank of $\mathbf{K}_{\mathbf{g}}$ is likely to be the dimension M , in which case there are no nonzero eigenvalues. Then $\mathbf{K}_{\mathbf{g}}$ is positive-definite and hence nonsingular (see Sec. 1.4.3).

We know from Sec. 1.4.4 that the eigenvectors of $\mathbf{K}_{\mathbf{g}}$ can always be chosen as a complete, orthonormal set. The orthonormality can be expressed in inner-product notation as

$$\phi_m^\dagger \phi_n = \delta_{mn}, \quad (8.53)$$

where ϕ_m^\dagger is the row vector obtained by transposing the column vector ϕ_m and taking an element-by-element complex conjugate. The completeness of the eigenvectors is expressed by the closure relation,

$$\sum_{m=1}^M \phi_m \phi_m^\dagger = \mathbf{I}, \quad (8.54)$$

where $\phi_m \phi_m^\dagger$ is an outer product (see Sec. 1.3.7) and \mathbf{I} is the $M \times M$ unit matrix.

From the discussion in Sec. 1.4.5, we know that the eigenvalue problem (8.51) can also be expressed as

$$\mathbf{K}_g \Phi = \Phi \mathbf{M}, \quad (8.55)$$

where Φ is a matrix formed by arraying the column vectors ϕ_m side by side and \mathbf{M} is a diagonal matrix with the m^{th} diagonal element equal to μ_m . (Note that \mathbf{M} is capital μ .) From (8.53) and (8.54), it follows that Φ is a unitary matrix, *i.e.*, $\Phi^{-1} = \Phi^\dagger$. From this property, we immediately find a useful representation of the covariance matrix [*cf.* (1.85)]:

$$\mathbf{K}_g = \Phi \mathbf{M} \Phi^\dagger. \quad (8.56)$$

This representation can also be expressed in terms of outer products [*cf.* (1.86)] as

$$\mathbf{K}_g = \sum_{m=1}^M \mu_m \phi_m \phi_m^\dagger. \quad (8.57)$$

This expression is the *spectral decomposition* of the covariance matrix.

Discrete Karhunen-Loève expansion Since the eigenvectors of a Hermitian operator form a complete, orthonormal set in the relevant space, any $M \times 1$ vector \mathbf{g} can be expressed as

$$\mathbf{g} = \sum_{m=1}^M \beta_m \phi_m, \quad (8.58)$$

where the coefficients are given by

$$\beta_m = \phi_m^\dagger \mathbf{g}. \quad (8.59)$$

We can express these relations in matrix-vector form by defining an $M \times 1$ vector β with components $\{\beta_m\}$. Then

$$\mathbf{g} = \Phi \beta, \quad \beta = \Phi^\dagger \mathbf{g}. \quad (8.60)$$

These equations are quite general, holding for any \mathbf{g} and any orthonormal basis vectors. If, however, \mathbf{g} is a random vector and the vectors $\{\phi_m\}$ are eigenvectors of its covariance matrix, then the coefficients $\{\beta_m\}$ are uncorrelated random variables. It is easy to demonstrate this point. In component form, the covariance matrix for β is given by

$$\begin{aligned} \langle \Delta \beta_n \Delta \beta_m^* \rangle &= \left\langle \left[\phi_n^\dagger \Delta \mathbf{g} \right] \left[\phi_m^\dagger \Delta \mathbf{g} \right]^* \right\rangle = \left\langle \phi_n^\dagger \Delta \mathbf{g} \Delta \mathbf{g}^\dagger \phi_m \right\rangle \\ &= \phi_n^\dagger \langle \Delta \mathbf{g} \Delta \mathbf{g}^\dagger \rangle \phi_m = \phi_n^\dagger \mathbf{K}_g \phi_m = \mu_m \phi_n^\dagger \phi_m = \mu_m \delta_{nm}, \end{aligned} \quad (8.61)$$

where $\Delta\beta_m \equiv \beta_m - \langle\beta_m\rangle$ and we have used the eigenvalue equation (8.51) and the orthonormality of the eigenvectors (8.53). In matrix form, (8.61) reads

$$\mathbf{K}_\beta = \Phi^\dagger \mathbf{K}_g \Phi = \Phi^\dagger \Phi \mathbf{M} \Phi^\dagger \Phi = \mathbf{M}, \quad (8.62)$$

where we have used (8.56), (8.60) and the unitarity of Φ .

Expansion of a random vector in eigenvectors of its covariance matrix is known as *Karhunen-Loève* or KL expansion. The key feature of a KL expansion is that the coefficients are uncorrelated (since \mathbf{K}_β is diagonal). A similar expansion for random processes will be presented in Sec. 8.2.7.

The KL expansion enables us immediately to find a useful representation of the inverse of a covariance matrix. Since Φ is a unitary matrix, *i.e.*, $\Phi^{-1} = \Phi^\dagger$, we can use (8.62) to write the covariance matrix \mathbf{K}_g as

$$\mathbf{K}_g = \Phi \mathbf{M} \Phi^\dagger. \quad (8.63)$$

The inverse of \mathbf{K}_g is then given by

$$\mathbf{K}_g^{-1} = \Phi \mathbf{M}^{-1} \Phi^\dagger, \quad (8.64)$$

where \mathbf{M}^{-1} is also diagonal, with the m^{th} diagonal element given by $1/\mu_m$. Thus the same matrix that diagonalizes \mathbf{K}_g also diagonalizes \mathbf{K}_g^{-1} .

Whitening As we have just seen, the KL expansion results in a vector β with uncorrelated components. It is often useful to go further and force the components all to have the same variance. The concept of a square-root matrix, discussed in Sec. A.8.3, provides us with the tool to accomplish this goal.

By analogy to (A.118), we can define the square root of the covariance matrix of \mathbf{g} by

$$\mathbf{K}_g^{\frac{1}{2}} = \sum_{m=1}^M \sqrt{\mu_m} \phi_m \phi_m^\dagger. \quad (8.65)$$

If \mathbf{K}_g is nonsingular, as it usually is, we can write the inverse of the square-root matrix as

$$\mathbf{K}_g^{-\frac{1}{2}} = \sum_{m=1}^M \frac{1}{\sqrt{\mu_m}} \phi_m \phi_m^\dagger. \quad (8.66)$$

To verify that this is the correct form for the inverse, one can multiply (8.65) by (8.66) and use the orthonormality relation (8.53) to obtain (8.54).

We now define the vector \mathbf{y} by

$$\mathbf{y} = \mathbf{K}_g^{-\frac{1}{2}} (\mathbf{g} - \bar{\mathbf{g}}). \quad (8.67)$$

With this construction $\bar{\mathbf{y}} = \mathbf{0}$, and its covariance matrix is given by

$$\mathbf{K}_y = \langle \mathbf{y} \mathbf{y}^\dagger \rangle = \mathbf{K}_g^{-\frac{1}{2}} \mathbf{K}_g \mathbf{K}_g^{-\frac{1}{2}} = \mathbf{I}, \quad (8.68)$$

where we have used the definition of the square-root matrix from (A.117) and the fact that covariance matrices are Hermitian, so that $\mathbf{K}_g^{-\frac{1}{2}}$ is its own adjoint.

Thus the transformation (8.67) always results in a random vector \mathbf{y} such that

$$\langle y_n y_m \rangle = \delta_{nm}. \quad (8.69)$$

By analogy to white noise (a topic discussed further in Sec. 8.2.6), this transformation is referred to as *whitening*; it is also called *prewhitening* when it precedes other signal processing. As we shall see in Chap. 13, prewhitening plays a key role in signal-detection theory.

Simultaneous diagonalization We have shown that a Hermitian matrix can always be diagonalized by a unitary transformation. It can be shown that two different Hermitian matrices can be diagonalized by the *same* unitary transformation if and only if they commute. If the different Hermitian matrices do not commute, they can be simultaneously diagonalized by a linear transformation, but the transformation matrix will not be unitary (Fukunaga, 1990). Details of the procedure were given in Sec. 1.4.6.

8.2 RANDOM PROCESSES

8.2.1 Definitions and basic concepts

We now generalize the concept of a random variable further by assigning to every experimental outcome ζ a spatial or temporal function, real or complex, according to some rule (Wentzell, 1981). In the spatial case the function will be denoted $f(\mathbf{r}, \zeta)$, where \mathbf{r} is a position vector, and in the temporal case it will be denoted by $f(t, \zeta)$, where t is the time. We now have a family of functions referred to as a stochastic or random process. The words stochastic and random will be used interchangeably here. If the spatial (or temporal) variable \mathbf{r} (or t) is a continuous one, the family is referred to as a continuous stochastic process; if the variables are taken as discrete, for example by sampling in space or time, the family is referred to as a discrete stochastic process, or a random sequence. A random process or sequence is said to be continuous-valued or discrete-valued according to whether the underlying random variables are continuous- or discrete-valued.

A spatial random process is a function of two variables, \mathbf{r} and ζ . Depending on the context, $f(\mathbf{r}, \zeta)$ can refer to (Papoulis, 1965; Middleton, 1960):

1. The family of spatial functions, referred to as the ensemble; in this case, \mathbf{r} and ζ are variables.
2. A single realization or sample of the spatial functions; in this case, \mathbf{r} is variable and ζ is fixed.
3. The random variable at a single point; in this case, \mathbf{r} is fixed and ζ is variable.
4. A single number; in this case, \mathbf{r} is fixed and ζ is fixed.

The intended interpretation will usually be clear from the context.

Some notational issues require attention here. First, it is frequently cumbersome to carry along the index ζ , so we shall usually refer to the random process simply as $f(\mathbf{r})$. Second, we usually make no notational distinction between the random process *per se*, understood as the ensemble of all possible functions $f(\mathbf{r})$ (interpretation 1), and a specific realization or sample (interpretation 2). This practice is in accord with our conventions on random variables as set out in Sec. C.2.1 of App. C. Occasionally a specific realization will have to be designated, and in those

cases we shall either reinstate ζ or use primes, subscripts or other typographical devices. Finally, the variable \mathbf{r} will be understood to be a general q -dimensional position vector unless otherwise stated.

Square-integrable random processes We shall say that a random process lies in some Hilbert space if all sample functions [*i.e.*, $f(\mathbf{r}, \zeta)$ as a function of \mathbf{r} for all ζ] lie in that space. In particular, we shall often be concerned with random processes in $\mathbb{L}_2(\mathbb{R}^q)$ where each sample function is square-integrable.

In many physical problems, $|f(\mathbf{r})|^2$ can be interpreted as an energy density (energy per unit area or volume). For example, that interpretation works when $f(\mathbf{r})$ is an electric field or the amplitude of an acoustic wave. In those cases, the integral of $|f(\mathbf{r})|^2$ is the total energy, and a square-integrable function is one with finite energy. This terminology is used more broadly, and any square-integrable function can be called a finite-energy function without regard to interpretation as a physical energy.

Finite-power random processes For temporal random processes, however, the assumption of finite energy is frequently not warranted. Consider, for example, the thermal noise produced by a resistor. The duration of this noise is completely indefinite. So long as the resistor exists, there will be a fluctuating voltage across it. In this example, ζ designates a particular resistor and $f(t, \zeta)$ is the noise voltage, and there is no reason to assume that the integral of $|f(t, \zeta)|^2$ over $-\infty < t < \infty$ is finite. We could get around this problem by imposing some artificial boundary conditions, *e.g.*, the resistor is manufactured at $t = -T$ and destroyed at $t = T$, but we are not really interested in when the resistor was manufactured.

A more natural approach is just to give up on the restriction to finite energy. The noise voltage across a resistor has finite *power* (energy per unit time). Mathematically, we can state this condition for the random process $f(t, \zeta)$ as

$$0 < \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T dt |f(t, \zeta)|^2 < \infty \quad \text{for all } \zeta. \quad (8.70)$$

A random process for which this condition is satisfied will be called a *finite-power random process*. Note that a finite-energy (or \mathbb{L}_2) random process cannot simultaneously be a finite-power one because of the left-hand inequality. If the function is in \mathbb{L}_2 , then the integral is finite as $T \rightarrow \infty$, but the factor of $1/2T$ drives the product to zero. It is only when the integral is asymptotically linear in T that (8.70) is satisfied. As we shall see, finite-energy and finite-power random processes require rather different mathematical treatments.

Generalized random processes We shall also have occasion to use random processes constructed with delta functions or other generalized functions. Such constructs are mathematically very convenient, even though no physical process is exactly described by them. We shall refer to random processes where the sample functions are generalized functions as (not surprisingly) *generalized random processes* (Kanwal, 1983). These processes are not in \mathbb{L}_2 but instead define a space of tempered distributions (see Chap. 2). If the generalized function in question is a delta function, the generalized random process has neither finite energy nor finite power.

8.2.2 Averages of random processes

We consider here a scalar random process $f(\mathbf{r})$ that is a function of position vector \mathbf{r} . The generalization to a vector random process is straightforward using multivariate PDFs. The random process may in principle be either continuous- or discrete-valued, but we shall illustrate the concepts with continuous-valued random processes. The discrete-valued case proceeds via a parallel approach but with sums over discrete values replacing integrals over continuous values.

For fixed \mathbf{r} , $f(\mathbf{r})$ is simply a random variable (interpretation 3), and its expectation is defined just as for any other random variable. As before, we use the notations $E\{\cdot\}$, $\langle \cdot \rangle$ and overbar interchangeably to indicate an expectation, and we can write

$$E\{f(\mathbf{r})\} = \langle f(\mathbf{r}) \rangle = \bar{f}(\mathbf{r}) = \int_{-\infty}^{\infty} df(\mathbf{r}) f(\mathbf{r}) \text{pr}[f(\mathbf{r})]. \quad (8.71)$$

Computation of this expectation requires only the univariate PDF $\text{pr}[f(\mathbf{r})]$. Note carefully that the integral is over $f(\mathbf{r})$, not \mathbf{r} , so $E\{f(\mathbf{r})\}$ can be (and usually will be) a function of \mathbf{r} .

Moments and variance Moments of $f(\mathbf{r})$ are defined easily. For example, the j^{th} moment is given by [cf. (C.38)]

$$\langle [f(\mathbf{r})]^j \rangle = \int_{-\infty}^{\infty} df(\mathbf{r}) [f(\mathbf{r})]^j \text{pr}[f(\mathbf{r})]. \quad (8.72)$$

The resultant, $\langle [f(\mathbf{r})]^j \rangle$, can still be a function of \mathbf{r} ; again, the integral is over $f(\mathbf{r})$, not over \mathbf{r} .

Having defined moments, we can also define the variance of a random process. In the general complex case, the variance is given by

$$\begin{aligned} \text{Var}\{f(\mathbf{r})\} &= E\{|f(\mathbf{r})| - |E\{f(\mathbf{r})\}|^2\} = E\{|f(\mathbf{r})|^2\} - |E\{f(\mathbf{r})\}|^2 \\ &= \int_{-\infty}^{\infty} df(\mathbf{r}) |f(\mathbf{r})|^2 \text{pr}[f(\mathbf{r})] - \left| \int_{-\infty}^{\infty} df(\mathbf{r}) f(\mathbf{r}) \text{pr}[f(\mathbf{r})] \right|^2. \end{aligned} \quad (8.73)$$

Note that this definition works equally for finite-energy and finite-power processes. It is possible for a random process to have a finite variance at all points, yet not be square-integrable.

Multiple-point expectations We are often interested in *two-point expectations* or joint second moments of the form $E\{f(\mathbf{r}_1)f(\mathbf{r}_2)\}$. The usual definitions for joint expectations stand us in good stead here, and we can write

$$E\{f(\mathbf{r}_1)f(\mathbf{r}_2)\} = \int_{-\infty}^{\infty} df(\mathbf{r}_1) \int_{-\infty}^{\infty} df(\mathbf{r}_2) f(\mathbf{r}_1) f(\mathbf{r}_2) \text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]. \quad (8.74)$$

Here, $f(\mathbf{r}_1)$ and $f(\mathbf{r}_2)$ must be regarded as two *distinct* random variables and $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]$ is their joint density. Only in very special circumstances will it be possible to write $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]$ as $\text{pr}[f(\mathbf{r}_1)]\text{pr}[f(\mathbf{r}_2)]$.

A general two-point moment is defined by

$$E\{[f(\mathbf{r}_1)]^m [f(\mathbf{r}_2)]^n\} = \int_{-\infty}^{\infty} df(\mathbf{r}_1) \int_{-\infty}^{\infty} df(\mathbf{r}_2) [f(\mathbf{r}_1)]^m [f(\mathbf{r}_2)]^n \text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]. \quad (8.75)$$

Moments involving more points are defined similarly. Any moment involving the K points $\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_K$ can be computed if $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2), \dots, f(\mathbf{r}_K)]$ is known. If this K -fold joint density is known for all values of each of the \mathbf{r}_k , the process is said to be *fully characterized* to order K (Snyder and Miller, 1991).

Density of the process Expressing N -fold joint densities using notation of the form $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2), \dots, f(\mathbf{r}_N)]$ is cumbersome at best and quite inadequate when we want to define expectations of general functionals $\Phi\{f(\mathbf{r})\}$, which can depend on $f(\mathbf{r})$ at all points \mathbf{r} . We now introduce an alternative approach, which works at least for finite-energy random processes (or vectors in \mathbb{L}_2). Our objective is to give meaning to an expression like $\text{pr}(\mathbf{f})$, where \mathbf{f} is the Hilbert-space vector corresponding to $f(\mathbf{r})$. We saw in Chap. 1 that \mathbb{L}_2 is a *separable* Hilbert space, which means simply that it is spanned by a denumerably infinite set of basis functions. Each sample function of a random process in $\mathbb{L}_2(\mathbb{R}^q)$ can be written as

$$f(\mathbf{r}, \zeta) = \sum_{j=1}^{\infty} \alpha_j(\zeta) \psi_j(\mathbf{r}), \quad (8.76)$$

where the set $\{\psi_j(\mathbf{r})\}$ is any orthonormal basis for the space. We can also express this same concept as

$$f(\mathbf{r}) = \lim_{J \rightarrow \infty} \sum_{j=1}^J \alpha_j \psi_j(\mathbf{r}). \quad (8.77)$$

We have dropped the index ζ with the understanding that the equation holds for any $f(\mathbf{r}, \zeta)$ so long as the corresponding expansion coefficients $\alpha_j(\zeta)$ are used on the right. The convergence of (8.77) is in the sense of $\mathbb{L}_2(\mathbb{R}^q)$ (see Sec. 3.2.2); if we use the truncated series in place of the original function $f(\mathbf{r})$, the \mathbb{L}_2 norm of the error converges to zero as $J \rightarrow \infty$. The expansion of the sample function $f(\mathbf{r})$ given in (8.77) is exactly the same form that was used in (7.8) to represent a deterministic object.

Expansion (8.77) provides a convenient way of defining averages involving random processes. Each coefficient α_j is a random variable, and the set of them $\{\alpha_j, j = 1, \dots, J\}$ can be regarded as a random vector $\boldsymbol{\alpha}_J$ with J components. In the limit $J \rightarrow \infty$, the vector $\boldsymbol{\alpha}_J$ completely defines $f(\mathbf{r})$, and averaging over $f(\mathbf{r})$ is equivalent to averaging over all components of $\boldsymbol{\alpha}$. For finite J , the requisite density can be written as $\text{pr}(\boldsymbol{\alpha}_J)$ or $\text{pr}(\alpha_1, \alpha_2, \dots, \alpha_J)$. In the limit,

$$\text{pr}(\boldsymbol{\alpha}) = \lim_{J \rightarrow \infty} \text{pr}(\boldsymbol{\alpha}_J), \quad (8.78)$$

and this density is operationally equivalent to $\text{pr}(\mathbf{f})$.

When $f(\mathbf{r})$ is approximated by the truncated series, any functional $\Phi\{f(\mathbf{r})\}$ is also a function of $\boldsymbol{\alpha}_J$; call it $\Phi_J(\boldsymbol{\alpha}_J)$. If the functional is continuous, in the sense defined in Sec. 1.3.2, then the limit of the functional is the functional of the limit, and we have

$$\Phi\{f(\mathbf{r})\} = \lim_{J \rightarrow \infty} \Phi_J(\boldsymbol{\alpha}_J). \quad (8.79)$$

Moreover, expectation is also a continuous functional, so we can write

$$\text{E}\{\Phi[f(\mathbf{r})]\} = \lim_{J \rightarrow \infty} \text{E}\{\Phi_J(\boldsymbol{\alpha}_J)\} = \lim_{J \rightarrow \infty} \int_{\infty} d^J \alpha \Phi_J(\boldsymbol{\alpha}_J) \text{pr}(\boldsymbol{\alpha}_J). \quad (8.80)$$

For notational convenience, we write this expectation as

$$\mathbb{E}\{\Phi[f(\mathbf{r})]\} = \int_{\mathbb{L}_2} d\mathbf{f} \Phi[f(\mathbf{r})] \text{pr}(\mathbf{f}). \quad (8.81)$$

Here \mathbf{f} is $f(\mathbf{r})$ regarded as a vector in the Hilbert space, and the integral is really a denumerably infinite multiple integral² over all basis functions in the space; in other words, (8.81) must be realized operationally by (8.80).

Example: Linear functionals To clarify how (8.81) works in practice, consider a linear functional that depends on $f(\mathbf{r})$ at K points:

$$\Phi\{f(\mathbf{r}_1), \dots, f(\mathbf{r}_K)\} \equiv \sum_{k=1}^K \beta_k f(\mathbf{r}_k) = \lim_{J \rightarrow \infty} \sum_{k=1}^K \beta_k \sum_{j=1}^J \alpha_j \psi_j(\mathbf{r}_k). \quad (8.82)$$

The random variables here are the coefficients $\{\alpha_j\}$. Using (8.80) and invoking the linearity of the expectation operator, we find

$$\mathbb{E}\{\Phi[f(\mathbf{r}_1), \dots, f(\mathbf{r}_K)]\} = \lim_{J \rightarrow \infty} \sum_{k=1}^K \beta_k \sum_{j=1}^J \psi_j(\mathbf{r}_k) \int_{-\infty}^{\infty} d^J \alpha \alpha_j \text{pr}(\alpha_j). \quad (8.83)$$

In the J -fold multiple integral, we can immediately integrate out all of the variables except α_j . By (C.75), the result is the marginal density on α_j , so

$$\begin{aligned} \mathbb{E}\{\Phi[f(\mathbf{r}_1), \dots, f(\mathbf{r}_K)]\} &= \lim_{J \rightarrow \infty} \sum_{k=1}^K \beta_k \sum_{j=1}^J \psi_j(\mathbf{r}_k) \int_{-\infty}^{\infty} d\alpha_j \alpha_j \text{pr}(\alpha_j) \\ &= \lim_{J \rightarrow \infty} \sum_{k=1}^K \beta_k \sum_{j=1}^J \psi_j(\mathbf{r}_k) \mathbb{E}\{\alpha_j\}. \end{aligned} \quad (8.84)$$

Thus, for a linear functional of the form (8.82), and by extension any linear functional,

$$\langle \Phi\{\mathbf{f}\} \rangle = \Phi\{\langle \mathbf{f} \rangle\}. \quad (8.85)$$

Integrals of random processes An integral of a random process $f(x)$, sometimes called a *stochastic integral*, is another random process, the realizations of which are obtained by integrating corresponding realizations of $f(x)$. For example, the statement

$$g(x) = \int_{-\infty}^{\infty} dx' f(x') h(x, x') \quad (8.86)$$

means that

$$g(x, \zeta) = \int_{-\infty}^{\infty} dx' f(x', \zeta) h(x, x') \quad (8.87)$$

²We have customarily denoted volume elements by italics rather than boldface, *e.g.*, d^3r rather than $d\mathbf{r}$, on the theory that volume elements are scalars. To preserve a distinction between integrals over Euclidean spaces and ones over Hilbert spaces, however, we use $d\mathbf{f}$ (along with the subscript \mathbb{L}_2) to indicate a multiple integral with an infinite number of dimensions.

for all ζ and some fixed kernel $h(x, x')$. A similar definition holds for derivatives of a random process.

Since $g(x)$ is a functional of $f(x')$, its average at any fixed x can be computed by (8.81) as

$$\langle g(x) \rangle = \int_{\mathbb{L}_2} d\mathbf{f} g(x) \text{pr}(\mathbf{f}) = \int_{\mathbb{L}_2} d\mathbf{f} \int_{-\infty}^{\infty} dx' f(x') h(x, x') \text{pr}(\mathbf{f}). \quad (8.88)$$

It is often useful to interchange the order of these two integrals, but most books gloss over issues of the validity of this step. Middleton (1960) puts it thus: “The condition on the interchangeability of integration and expectation is, *of course*, the existence of the resulting integral” (emphasis added).

When the interchange can be justified, (8.88) becomes

$$\langle g(x) \rangle = \int_{-\infty}^{\infty} dx' h(x, x') \int_{\mathbb{L}_2} d\mathbf{f} f(x') \text{pr}(\mathbf{f}) = \int_{-\infty}^{\infty} dx' h(x, x') \langle f(x') \rangle. \quad (8.89)$$

In other words, the average of a linear integral transform of a random process is the same linear transform of the average of the random process (but only under conditions that we haven't yet stated clearly).

When is the interchange legal? The classical theorem that states when interchange of the order of two integrals is allowed is Fubini's theorem (Lang, 1993). In essence, this theorem tells us that

$$\int_{-\infty}^{\infty} du \int_{-\infty}^{\infty} dv k(u, v) = \int_{-\infty}^{\infty} du \left[\int_{-\infty}^{\infty} dv k(u, v) \right] = \int_{-\infty}^{\infty} dv \left[\int_{-\infty}^{\infty} du k(u, v) \right] \quad (8.90)$$

provided $|k(u, v)|$ is integrable over the product space, here the u - v plane.

There are two difficulties in directly applying Fubini to (8.88). First, we often want to assume that the integrand is in \mathbb{L}_2 rather than in \mathbb{L}_1 , and we know from Sec. 3.3.2 that a function in \mathbb{L}_2 need not be in \mathbb{L}_1 (the prime example being $\text{sinc } x$). One way around this problem is to consider only random processes where all sample functions are absolutely integrable as well as square-integrable. Another way is to consider a finite interval, say $-\frac{1}{2}X < x \leq \frac{1}{2}X$. This allows use of Fubini with \mathbb{L}_2 functions since $\mathbb{L}_2(-\frac{1}{2}X, \frac{1}{2}X)$ is a subspace of $\mathbb{L}_1(-\frac{1}{2}X, \frac{1}{2}X)$.

The second difficulty is that Fubini's theorem can be extended to higher-dimensional multiple integrals, but (8.88) in its most general form requires an infinite nested set of integrals. Fubini's theorem can still be used in this case, but it must be justified with advanced measure-theoretic arguments (Lipster and Shiryayev, 1977). A more elementary argument can be given by using the theory of distributions.

Retreat to distributions Much of the discussion above has hinged on the assumption that the random process lies in a separable Hilbert space. For finite-power processes, we do not have this luxury, and even with \mathbb{L}_2 processes, we ran into some problems justifying the interchange of integration and expectation. The solution to these difficulties is the theory of distributions³ as outlined in Chap. 2. The thing we have

³At least three distinctly different meanings attach to the word *distribution* in connection with random processes. A *probability distribution* is, loosely speaking, any probability law, such as the

going for us is that sample functions of a random process may be badly behaved but kernel functions in integral transforms like (8.86) are usually good functions.

Let $t(x)$ denote a good function and $f(x, \zeta)$ be a sample function of a random process. This random process defines a distribution,

$$\Phi_f \{t(x)\} = \int_{-\infty}^{\infty} dx t(x) f(x, \zeta) \equiv \phi(\zeta). \quad (8.91)$$

Note that $\phi(\zeta)$ is a random variable. It is proved by Kanwal (1983) that this random variable has finite variance if $f(x, \zeta)$ is continuous (in the sense that $f(x + \epsilon, \zeta) \rightarrow f(x, \zeta)$ in the limit that $\epsilon \rightarrow 0$) and has finite variance at all x . With these mild restrictions, any random process defines a distribution mapping good functions to finite-variance random variables.

By the Schwarz inequality, the finite variance of $\phi(\zeta)$ implies that $\phi(\zeta)$ has finite mean. The expectation $E\{\phi(\zeta)\}$ is defined conventionally by

$$E\{\phi(\zeta)\} = E\{\Phi_f[t(x)]\} = \int_{-\infty}^{\infty} d\phi \phi \text{pr}(\phi). \quad (8.92)$$

But this is just a linear combination of distributions, which by (2.15) is another distribution. Thus

$$E\{\Phi_f[t(x)]\} = \Phi_{E_f}\{t(x)\} = \int_{-\infty}^{\infty} dx t(x) E\{f(x, \zeta)\}, \quad (8.93)$$

where $\Phi_{E_f}\{t(x)\}$ is a distribution defined by using $E\{f(x, \zeta)\}$ as the generalized function. Equation (8.93) is just what one would obtain by interchanging the expectation operation and the integration over x .

Thus the issue of interchangeability is resolved once we have established that the random process defines a distribution (in the Schwartz sense), and Kanwal did this for us with mild restrictions.

8.2.3 Characteristic functionals

Characteristic functions for scalar random variables were introduced in App. C and extended to random vectors in Sec. 8.1.4. Now we shall extend the concept further to random processes. In a formal sense, the extension is straightforward; all we have to do is to pay attention to the dimensionality of the vectors involved.

As defined in (8.26), the characteristic function of an MD random vector is a function of an MD frequency vector $\boldsymbol{\xi}$. In the case of a random process, each sample function corresponds to a vector \mathbf{f} in an infinite-dimensional Hilbert space, so the frequency vector $\boldsymbol{\xi}$ in (8.26) must be replaced by an infinite-dimensional vector \mathbf{s} in the same Hilbert space as \mathbf{f} . That means that \mathbf{s} describes a function $s(\mathbf{r})$, so the characteristic function becomes a characteristic *functional* $\Psi_{\mathbf{f}}\{s(\mathbf{r})\}$ or $\Psi_{\mathbf{f}}(\mathbf{s})$ for short. It is defined by

$$\Psi_{\mathbf{f}}(\mathbf{s}) = \langle \exp[-2\pi i(\mathbf{s}, \mathbf{f})] \rangle, \quad (8.94)$$

Poisson distribution. The *distribution function* refers specifically to the cumulative probability distribution function defined in Sec. C.2.3. In the present context the word is used in the Schwartz sense defined in Chap. 2.

where (\mathbf{s}, \mathbf{f}) is the usual \mathbb{L}_2 scalar product. Note that we use $\Psi(\cdot)$ for characteristic functional and $\psi(\cdot)$ for characteristic function.

The characteristic functional of a random process can be related to the characteristic *function* of any random vector derived from the random process by a linear operator; the calculation is a simple generalization of one performed in Sec. 8.1.5. For example, if $\mathbf{g} = \mathcal{H}\mathbf{f}$, where \mathcal{H} is a continuous-to-discrete (CD) operator as discussed in Secs. 1.2.4 and 7.3, then (8.26) becomes

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \langle \exp[-2\pi i(\boldsymbol{\xi}, \mathcal{H}\mathbf{f})] \rangle = \langle \exp[-2\pi i(\mathcal{H}^\dagger \boldsymbol{\xi}, \mathbf{f})] \rangle, \quad (8.95)$$

where the second step follows from the definition of the adjoint, (1.39). Comparison of (8.94) and (8.95) shows that

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \Psi_{\mathbf{f}}(\mathcal{H}^\dagger \boldsymbol{\xi}), \quad (8.96)$$

which is the generalization of (8.43) to random processes.

Thus, if we know the characteristic functional for \mathbf{f} , we immediately have the characteristic function for $\mathcal{H}\mathbf{f}$. We shall exploit this relation in Sec. 8.3.5 when we discuss normal random processes.

8.2.4 Correlation analysis

The autocorrelation function $R(\mathbf{r}_1, \mathbf{r}_2)$ of a random process $f(\mathbf{r})$ is defined by

$$R(\mathbf{r}_1, \mathbf{r}_2) = \langle f(\mathbf{r}_1) f^*(\mathbf{r}_2) \rangle, \quad (8.97)$$

which is the two-point expectation defined in (8.74), with the minor modification of the complex conjugate on the second factor [irrelevant if $f(\mathbf{r})$ is real].

The autocovariance function $K(\mathbf{r}_1, \mathbf{r}_2)$ is defined by

$$\begin{aligned} K(\mathbf{r}_1, \mathbf{r}_2) &= \langle [f(\mathbf{r}_1) - \langle f(\mathbf{r}_1) \rangle] [f^*(\mathbf{r}_2) - \langle f^*(\mathbf{r}_2) \rangle] \rangle \\ &= R(\mathbf{r}_1, \mathbf{r}_2) - \bar{f}(\mathbf{r}_1) \bar{f}^*(\mathbf{r}_2). \end{aligned} \quad (8.98)$$

The autocovariance function is thus the two-point moment that is the generalization of the variance; it reduces to the variance when $\mathbf{r}_2 = \mathbf{r}_1 = \mathbf{r}$, *i.e.*,

$$K(\mathbf{r}, \mathbf{r}) = R(\mathbf{r}, \mathbf{r}) - |\bar{f}(\mathbf{r})|^2 = \text{Var}\{f(\mathbf{r})\} \quad (8.99)$$

from (8.73).

When two or more random processes occur in the same problem, their autocorrelation and autocovariance functions will be distinguished with subscripts, *e.g.*, $R_f(\mathbf{r}_1, \mathbf{r}_2)$. It is frequently convenient to define zero-mean random processes such as

$$\Delta f(\mathbf{r}) \equiv f(\mathbf{r}) - \bar{f}(\mathbf{r}). \quad (8.100)$$

With this definition, $\langle \Delta f(\mathbf{r}) \rangle = 0$ and

$$R_{\Delta f}(\mathbf{r}_1, \mathbf{r}_2) = K_f(\mathbf{r}_1, \mathbf{r}_2). \quad (8.101)$$

The autocorrelation and autocovariance functions play a fundamental role in the theory of random processes since they specify how far apart two points must be for their fluctuations to be uncorrelated. If $K_f(\mathbf{r}_1, \mathbf{r}_2)$ is zero, the random variables

$f(\mathbf{r}_1)$ and $f(\mathbf{r}_2)$ do not covary; colloquially, they are said to be uncorrelated, though in fact the autocorrelation function $R_f(\mathbf{r}_1, \mathbf{r}_2)$ may be nonzero because of the mean values.

Cross-correlation and cross-covariance functions can also be defined. Consider two functions $f(\mathbf{r})$ and $g(\mathbf{r}')$, where \mathbf{r} and \mathbf{r}' are not necessarily in the same space. The cross-correlation or mutual correlation function is defined by

$$R_{fg}(\mathbf{r}, \mathbf{r}') = \langle f(\mathbf{r}) g^*(\mathbf{r}') \rangle. \quad (8.102)$$

Similarly, the cross-covariance function is

$$K_{fg}(\mathbf{r}, \mathbf{r}') = \langle [f(\mathbf{r}) - \langle f(\mathbf{r}) \rangle] [g^*(\mathbf{r}') - \langle g^*(\mathbf{r}') \rangle] \rangle = R_{fg}(\mathbf{r}, \mathbf{r}') - \bar{f}(\mathbf{r}) \bar{g}^*(\mathbf{r}'). \quad (8.103)$$

Two random processes $f(\mathbf{r})$ and $g(\mathbf{r}')$ are said to be uncorrelated if $R_{fg}(\mathbf{r}, \mathbf{r}') = \bar{f}(\mathbf{r}) \bar{g}^*(\mathbf{r}')$ for all \mathbf{r} and \mathbf{r}' . They are orthogonal if, for all \mathbf{r} and \mathbf{r}' , $R_{fg}(\mathbf{r}, \mathbf{r}') = 0$.

Properties of the autocorrelation function From the definition (8.98), we obtain the symmetry property

$$R(\mathbf{r}_1, \mathbf{r}_2) = R^*(\mathbf{r}_2, \mathbf{r}_1). \quad (8.104)$$

In particular, for $\mathbf{r}_1 = \mathbf{r}_2 = \mathbf{r}$, (8.104) shows that $R(\mathbf{r}, \mathbf{r})$ or $\text{Var}\{f(\mathbf{r})\}$ is real.

It follows from the Schwarz inequality that

$$|R(\mathbf{r}_1, \mathbf{r}_2)|^2 \leq R(\mathbf{r}_1, \mathbf{r}_1) R(\mathbf{r}_2, \mathbf{r}_2). \quad (8.105)$$

It can also be shown (Mandel and Wolf, 1995) that $R(\mathbf{r}_1, \mathbf{r}_2)$ is positive-semidefinite, meaning that [cf. (8.22)]

$$\int_{-\infty}^{\infty} d^q r_1 w^*(\mathbf{r}_1) \int_{-\infty}^{\infty} d^q r_2 R(\mathbf{r}_1, \mathbf{r}_2) w(\mathbf{r}_2) \geq 0, \quad (8.106)$$

for all functions $w(\mathbf{r})$. We shall exploit this property in Sec. 8.2.7 when we discuss the Karhunen-Loève expansion of random processes.

Another way to think about $R(\mathbf{r}_1, \mathbf{r}_2)$ is that it is the kernel of an integral operator \mathcal{R} . With this view, the inner integral of (8.106) is recognized as the function $[\mathcal{R}\mathbf{w}](\mathbf{r}_1)$, and the double integral is the scalar $\mathbf{w}^\dagger \mathcal{R}\mathbf{w}$. An autocovariance operator \mathcal{K} can be defined similarly, with the autocovariance function as the kernel.

Temporal stationarity Temporal random processes often have a statistical character that is independent of time, even though any individual realization is a randomly fluctuating function of time. An example is a steady beam of white light, where the electric field fluctuates rapidly, yet there is no preferred origin in time as far as the statistics are concerned. Such processes are said to be *stationary*. Glauber (1965) has phrased it this way: “The term ‘stationary’ does not mean that nothing is happening. On the contrary, the field is ordinarily oscillating quite rapidly. It means that our knowledge of the field does not change in time.”

A temporal random process $f(t)$ is said to be stationary in the strict sense if, for any K , its K -point PDF $\text{pr}[f(t_1), \dots, f(t_K)]$ is such that

$$\text{pr}[f(t_1), \dots, f(t_K)] = \text{pr}[f(t_1 + \tau), \dots, f(t_K + \tau)] \quad (8.107)$$

for any τ . In particular, this requires that the single-point density function be independent of time,

$$\text{pr}[f(t)] = \text{pr}[f(t + \tau)], \quad (8.108)$$

and therefore the mean of the random process is also independent of time,

$$\langle f(t) \rangle = \langle f(t + \tau) \rangle . \quad (8.109)$$

Similarly, the two-point density function must be independent of time,

$$\text{pr}[f(t_1), f(t_2)] = \text{pr}[f(t_1 + \tau), f(t_2 + \tau)] , \quad (8.110)$$

and so the autocorrelation function $R(t_1, t_2)$, is also independent of time,

$$R(t_1, t_2) = \langle f(t_1) f^*(t_2) \rangle = \langle f(t_1 + \tau) f^*(t_2 + \tau) \rangle . \quad (8.111)$$

The only way (8.111) can be satisfied for all t_1 and t_2 is if $R(t_1, t_2)$ is really a function of only $t_1 - t_2$. We shall denote this function by $R(t_1 - t_2)$, but the reader is cautioned that $R(t_1 - t_2)$ is not the same function as $R(t_1, t_2)$; it could not be since the latter has two arguments and the former has only one. With this notation, we have (for a stationary random process),

$$R(t_1, t_2) = R(t_1 - t_2) = R(\Delta t) , \quad (8.112)$$

where $\Delta t \equiv t_1 - t_2$. The shift Δt is frequently called the *lag* of the autocorrelation function.

Continuing on in this way, we see that strict stationarity requires that all K -point moments of the process be independent of absolute time. A process is said to be stationary to order M if (8.107) is true only for $K \leq M$.

A process is said to be weakly stationary, or stationary in the wide sense, if its expected value does not depend on absolute time t and its autocorrelation depends only on Δt :

$$\langle f(t) \rangle = \text{const} , \quad \langle f(t + \Delta t) f^*(t) \rangle = R(\Delta t) . \quad (8.113)$$

If a process is stationary to second order, then it is wide-sense stationary; however, a wide-sense stationary process is not necessarily stationary to second order because the former involves only the first two moments while the latter involves the entire PDF. One case where we can make a more definitive statement is with normal or Gaussian random processes, to be discussed in Sec. 8.3.5. If a process is normal and stationary in the wide sense, then it is also stationary in the strict sense since the statistical description of a normal process is completely specified once its mean and autocorrelation are specified.

Stationarity is closely connected to the concept of a finite-power random process, introduced in Sec. 8.2.1, but the distinctions should not be overlooked. The finite-power designation applies to individual sample functions of the random process, while stationarity applies to averages. A stationary random process might not have finite power, since it is conceivable (though pathological) that an individual realization could diverge but the average not. Of more practical importance, a process can have finite power yet not be stationary; examples of this situation are discussed below. On the other hand, a nontrivial stationary temporal random process certainly cannot have finite energy.

Properties of the stationary autocorrelation function The general properties of autocorrelations given above specialize in the stationary case as follows: The symmetry property of (8.104) becomes

$$R(\Delta t) = R^*(-\Delta t) . \quad (8.114)$$

In particular, for $\Delta t = 0$, (8.114) shows that $R(0)$ is real.

The Schwarz inequality shows that

$$|R(\Delta t)| \leq R(0). \quad (8.115)$$

The condition that $R(\Delta t)$ is positive-semidefinite now means that

$$\int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} dt' w^*(t) R(t-t') w(t') \geq 0, \quad (8.116)$$

for all functions $w(t)$.

Spatial stationarity The spatial counterpart of the wide-sense stationarity condition (8.112) is

$$R(\mathbf{r}_1, \mathbf{r}_2) = R(\mathbf{r}_1 - \mathbf{r}_2) = R(\Delta \mathbf{r}), \quad (8.117)$$

where $\Delta \mathbf{r} \equiv \mathbf{r}_1 - \mathbf{r}_2$.

This condition cannot be exactly satisfied⁴ by spatial processes representing real objects or images since they have finite support, but it might be a useful mathematical description within a certain boundary. That is, we might be able to assume that $R(\mathbf{r}_1, \mathbf{r}_2) = R(\Delta \mathbf{r})$ provided \mathbf{r}_1 and \mathbf{r}_2 lie inside the borders of an image. An example would be a piece of x-ray film with a uniform exposure, where the only deviation from stationarity comes from the finite size of the film.

If $f(\mathbf{r})$ vanishes outside the boundary, this kind of stationarity is expressed mathematically by

$$R(\mathbf{r}_1, \mathbf{r}_2) = R(\Delta \mathbf{r}) W(\mathbf{r}_1) W(\mathbf{r}_2), \quad (8.118)$$

where $W(\mathbf{r})$ is a window function that is unity for \mathbf{r} inside the boundary, zero outside.

Quasistationarity In optics and imaging we often encounter spatial random processes whose autocorrelation function can be approximated as a product of two factors—a slowly varying contribution due to slow variations in overall intensity and a short-range function describing correlation between neighboring points. As a simple example, consider a ground glass illuminated nonuniformly with a laser beam. If the statistical character of the ground glass is the same at all points, then we can describe the complex amplitude (see Chap. 9) of the wave emerging from the ground glass by a spatial autocorrelation function of the form,

$$R(\mathbf{r}_1, \mathbf{r}_2) = a(\Delta \mathbf{r}) b(\mathbf{r}_0), \quad (8.119)$$

where

$$\mathbf{r}_0 = \frac{1}{2}(\mathbf{r}_1 + \mathbf{r}_2), \quad \Delta \mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2. \quad (8.120)$$

We shall refer to \mathbf{r}_0 as the *center coordinate* (analogous to center of mass) and $\Delta \mathbf{r}$ as the *relative coordinate* or *difference coordinate*. Since the transformation from $(\mathbf{r}_1, \mathbf{r}_2)$ to $(\mathbf{r}_0, \Delta \mathbf{r})$ is unique and invertible (with Jacobian = unity), we always have a choice of which coordinate system to use for any function of two variables, but we

⁴The stationarity condition cannot be exactly satisfied by real temporal processes either. The difference is that we usually do not observe the beginning and end of a temporal process; we almost always observe the boundaries of an object or image.

won't always find that the function can be factored as in (8.119). The factorization is particularly useful if $b(\mathbf{r}_0)$ is slowly varying, in which case the random process is said to be *quasistationary*. If $b(\mathbf{r}_0)$ is a constant and the mean is also constant, the process is wide-sense stationary.

The short-range contribution, $a(\Delta\mathbf{r})$, is usually normalized to be unity at zero shift or lag ($\Delta\mathbf{r} = 0$).

Time averages and ergodicity We have seen that statistical descriptors of a random process, like the mean and autocorrelation function, are determined by averaging over the ensemble of realizations. Knowledge of the ensemble is equivalent to knowledge of the full PDF that describes the random process. However, suppose we are presented with data derived from a single realization of a temporal random process. It is natural to ask how this single data realization might be related to the statistical descriptors of the random process from which it was drawn. The answer to this question rests in the theory of *ergodicity*, a subject that traces its origins to classical statistical mechanics and the works of such luminaries as Maxwell, Boltzmann, Clausius and Gibbs (Ter Haar, 1955).

A random process is said to be *ergodic* if each realization of the process carries the same statistical information as every other realization. The practical ramification of this feature is that when a process is ergodic it becomes possible to derive statistical information about the entire ensemble based on knowledge of a single realization.

In order for a random process to be ergodic, it must first be stationary. The degree of stationarity of the process influences the degree to which the process is ergodic. For example, only wide-sense stationarity is necessary (though not sufficient) for a process to be ergodic in its mean and autocorrelation.

We now present criteria for a random process to be ergodic with respect to its mean and autocorrelation. A more complete development can be found in Papoulis (1965). Let $f(t, \zeta_0)$ denote a particular realization of a random process. Its finite-time average is then given by

$$\langle f(t, \zeta_0) \rangle_T = \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt f(t, \zeta_0), \quad (8.121)$$

where $\langle \rangle_T$ denotes a finite-time average over period T . In general this finite-time average is itself a random variable that depends on the particular realization under consideration as well as the interval T .

The time average of the sample function $f(t, \zeta_0)$ is found by taking the limit of (8.121) as $T \rightarrow \infty$:

$$\langle f(t, \zeta_0) \rangle_\infty = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt f(t, \zeta_0). \quad (8.122)$$

The result in (8.122) is independent of time but depends in general on the realization ζ_0 . Thus the notational distinction that this average refers to realization ζ_0 must be maintained.

A process is said to be *ergodic in the mean* if the time average of a single realization equals the ensemble average $\langle f(t) \rangle$. We already know that a stationary process has a mean that is independent of time. It can be shown (Papoulis, 1965)

that $\langle f(t, \zeta_0) \rangle_T$ approaches this same constant as $T \rightarrow \infty$ if and only if

$$\lim_{T \rightarrow \infty} \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} d\Delta t R(\Delta t) = \langle f(t) \rangle^2, \quad (8.123)$$

where $R(\Delta t)$ is the ensemble autocorrelation function of the stationary random process [cf. (8.112)]. In words, (8.123) states that ergodicity in the mean requires the time average of the autocorrelation function of $f(t)$ to be equal to the square of the ensemble mean. When this is true, the variance of the random variable that is the outcome of (8.121) approaches zero as the period T goes to infinity.

As Khinchin (1949) and others have noted, ergodicity in the mean is equivalent to the law of large numbers. In his discussion of ergodicity in statistical mechanics, Khinchin defines an ergodic process as: "On average, a system, whose evolution in time is governed by the equations of motion, remains in different parts of a given manifold of constant energy for fractions of the total time interval which are proportional to the volumes of these parts. Therefore, if we observe any physical quantity associated with a given system over a definite time interval, the arithmetic average of the results of a sufficiently large number of measurements will, as a rule, be close to the (theoretical) statistical average." He goes on to say that it is "hard to prove ergodicity in classical systems and impossible in principle to do so in quantum mechanics."

Multiple-point expectations of one realization of a temporal random process (see Sec. 8.2.2) can also be considered. For example, the finite-time autocorrelation function of one realization with itself is given by

$$R_T(\Delta t, \zeta_0) = \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt f(t + \Delta t, \zeta_0) f^*(t, \zeta_0). \quad (8.124)$$

A random process is said to be *ergodic in autocorrelation* if $R_T(\Delta t, \zeta_0)$ approaches the ensemble quantity $R(\Delta t)$ as $T \rightarrow \infty$. We can see that the ensemble average of the sample quantity $R_T(\Delta t, \zeta_0)$ is equal to the ensemble autocorrelation function:

$$E\{R_T(\Delta t, \zeta_0)\} = \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt E\{f(t + \Delta t, \zeta_0) f^*(t, \zeta_0)\} = R(\Delta t), \quad (8.125)$$

where the last step follows since $R(\Delta t)$ is independent of the integration time T . It is more difficult to demonstrate that the temporal average of $R_T(\Delta t, \zeta_0)$ approaches $R(\Delta t)$ in the limit as T becomes infinite. While a test for ergodicity of the mean requires knowledge of the ensemble mean and autocorrelation function, Papoulis demonstrates that knowledge of fourth-order moments is required to test for ergodicity of the autocorrelation function.

In general, demonstration of higher levels of ergodicity requires increasing knowledge of the density function that describes the random process. One exception, however, is the special case of the Gaussian random process. We shall see in Sec. 8.3.5 that in that case a straightforward criterion for complete ergodicity can be stated.

Ergodicity comes into play in optics when we consider the output of a detector sensing a rapidly fluctuating optical field. The period of integration in the finite-time average (8.121) is directly analogous to the detector response time. If the field

fluctuates rapidly enough that fluctuations in the random process are not evident in the detector output, the random process can be said to be ergodic, and the detector can be assumed to sense an ensemble average.

We have deliberately discussed ergodicity in terms of temporal rather than spatial random processes. Remember that the first condition for ergodicity is that the random process be stationary, but as we stated earlier in this section, the physical boundaries of objects and images make spatial stationarity rarely a plausible assumption. Nevertheless, ergodicity is often assumed in the image-processing community to determine, for example, noise statistics at a single location in an image (an ensemble quantity) based on the characteristics of the fluctuations in a spatial region of that single image.

8.2.5 Spectral analysis

The Fourier transform is an important tool in the analysis of signals in general, and random signals are no exception. The Fourier transform of one sample function of a random process is defined just as for any other function, and all of the properties given in Chap. 3 are applicable. In some cases, particularly finite-power random processes, it may be necessary to consider the sample function as a generalized function and compute its Fourier transform by use of the theory of tempered distributions, but this presents no essential difficulty. With the background on generalized functions presented in Chaps. 2 and 3, we should have no qualms about issues of existence of the transform.

On the other hand, the Fourier transform of a random process is another random process, and we are usually more interested in averages than in properties of individual samples. In particular, with finite-power processes, we often want to know how the average power is distributed as a function of frequency. The branch of stochastic theory that addresses this question is called *spectral analysis*, and a frequency-domain description of the average power is known as a *spectrum*, *power spectrum* or *power spectral density*.

We shall give a brief overview of the historical development of spectral analysis and then give two equivalent definitions of power spectral density. Initially the discussion will consider stationary processes in the time domain, but then we make the transition to the space domain as we see how the theory can be applied to processes that are not exactly stationary.

A brief history of spectra The early history of spectral analysis was motivated by a desire to understand white light (Gouy, 1886; Rayleigh, 1903; Schuster, 1894, 1904, 1906). Gouy's work was based on the Fourier series, while Lord Rayleigh used the newly developed Plancherel (\mathbb{L}_2) interpretation of the Fourier transform. Wiener (1930) marvels (though not without a touch of irony) at these forays: "In both cases one is astonished by the skill with which the authors use clumsy and unsuitable tools to obtain the right results, and one is led to admire the unflinching heuristic insight of the true physicist."

Wiener's own pioneering treatise, *Generalized Harmonic Analysis* (Wiener, 1930), was built on the work of Sir Arthur Schuster. Schuster used a windowed or truncated function defined by

$$f_T(t) = f(t) \operatorname{rect}(t/T), \quad (8.126)$$

with a Fourier transform defined by

$$F_T(\nu) = \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt f(t) \exp(-2\pi i \nu t). \quad (8.127)$$

Schuster proposed specifying the spectrum of $f(t)$ by the *periodogram*, defined by

$$S_p(\nu) = \lim_{T \rightarrow \infty} \frac{1}{T} |F_T(\nu)|^2. \quad (8.128)$$

By (3.135), $|F_T(\nu)|^2$ is the Fourier transform of the deterministic autocorrelation *integral* (not to be confused with the statistical autocorrelation function) of $f_T(t)$. Thus (8.128) is equivalent to

$$S_p(\nu) = \lim_{T \rightarrow \infty} \frac{1}{T} \mathcal{F}\{[f_T \star f_T^*](x)\}, \quad (8.129)$$

where \mathcal{F} is the Fourier operator and, by (3.115),

$$[f_T \star f_T^*](t) = \int_{-\infty}^{\infty} dt' f_T(t+t') f_T^*(t'). \quad (8.130)$$

Wiener's approach was slightly different. He defined

$$R_{W,T}(t) = \frac{1}{T} \int_{-\frac{1}{2}T}^{\frac{1}{2}T} dt' f(t+t') f^*(t'), \quad (8.131)$$

which differs from (8.130) mainly in the fact that the truncation is on the limits rather than on both functions separately; there is also a factor of $1/T$ built into the definition.

The only requirement placed on the function $f(t)$ is that $R_{W,T}(t) < \infty$ for all t , but this turns out to be a very useful mathematical condition (Champney, 1987). The special case $t = 0$ shows that these functions must be finite-power functions as defined in (8.70). For such functions, Wiener defined a spectrum by

$$S_W(\nu) = \lim_{T \rightarrow \infty} \mathcal{F}\{R_{W,T}(t)\}. \quad (8.132)$$

Note that neither S_p nor S_W involves any statistical average; both Wiener and Schuster took a functional or deterministic viewpoint and did not invoke ensembles of any kind. Thus their spectra apply to a single realization of the random process, albeit one of infinite length. For any function for which S_W is finite, S_W and S_p are identical (Champney, 1987).

Convergence issues In practice, one might think that a reasonable approximation of S_p or S_W could be obtained by using a single periodogram of finite length and just omitting the limit $T \rightarrow \infty$ in (8.128) or (8.132). It might also be expected that this approximation would get better as T gets larger. In fact, however, the Fourier transform of a single sample function of a random process is a very poor spectral measure.

Fig. 8.1 Three sample functions of a random process (top) and their periodograms (bottom). The random process was created by calling a uniform random-number generator independently at each of 1024 sample points, then performing a discrete convolution with a Gaussian to produce a random process with a Gaussian power spectrum. The sample functions were windowed as shown, and the periodograms were computed by discrete Fourier transforms.

This point is illustrated in Fig. 8.1, which shows three sample functions of different length of a stationary random process, along with the corresponding finite-length periodograms. Note that the periodograms do not smoothly approach a limit as $T \rightarrow \infty$ but instead oscillate ever more rapidly.

One way to deal with the rapid oscillation is to average the periodogram by convolution with some smooth function. In fact, this average can be built in by windowing the samples with the Fourier transform of the smoothing function. This approach smooths out any fine details that might be present in the spectrum but provides better convergence as T gets large. Some additional approaches to this problem will be discussed briefly in Sec. 8.4.4.

Power spectra as statistical averages Another way to fix the convergence problems associated with S_p and S_W is to use not one but many independent realizations of the random process and to average the resulting periodograms. In the limit of an infinite number of realizations, this approach, pioneered by Khinchin, amounts to incorporating a statistical average in the definition of the spectrum. Khinchin's definition was

$$S_{ac}(\nu) = \mathcal{F}\{R(\Delta t)\} = \int_{-\infty}^{\infty} d\Delta t \langle f(t + \Delta t) f^*(t) \rangle \exp(-2\pi i\nu\Delta t), \quad (8.133)$$

where the subscript *ac* indicates that this version of the spectrum is derived from the autocorrelation function $R(\Delta t)$ of a stationary random process. The spectrum defined this way is well behaved mathematically and universally used. Equation (8.133) is often referred to as the *Wiener-Khinchin theorem*, though it is really a definition rather than a theorem.

Expected periodogram Another way to incorporate an ensemble average into the definition of the spectrum is to take the expectation of the periodogram,

$$S_{ep}(\nu) = \lim_{T \rightarrow \infty} \frac{1}{T} \langle |F_T(\nu)|^2 \rangle. \quad (8.134)$$

Unlike $S_{ac}(\nu)$, $S_{ep}(\nu)$ is defined for nonstationary as well as stationary random processes, though they have to be finite-power processes for S_{ep} to be nonzero. For stationary processes, however, $S_{ep}(\nu)$ is equivalent to $S_{ac}(\nu)$, as we shall now show.

From the definition of $F_T(\nu)$, we can write

$$S_{ep}(\nu) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} dt' \langle f(t) f^*(t') \rangle \text{rect} \left(\frac{t}{T} \right) \text{rect} \left(\frac{t'}{T} \right) \exp[2\pi i(t' - t)\nu]. \quad (8.135)$$

Now we make the change of variables $(t, t') \rightarrow (t, \Delta t)$, where $\Delta t = t' - t$. With the assumption that $\langle f(t) f^*(t') \rangle = R(\Delta t)$ and a little algebra, we find

$$S_{ep}(\nu) = \lim_{T \rightarrow \infty} \int_{-\infty}^{\infty} d\Delta t R(\Delta t) \text{tri} \left(\frac{\Delta t}{T} \right) \exp(-2\pi i\nu \Delta t), \quad (8.136)$$

where the function $\text{tri}(\cdot)$ is defined in (3.139).

We can now use the convolution theorem (3.132) along with (3.142) to write

$$S_{ep}(\nu) = \lim_{T \rightarrow \infty} S_{ac}(\nu) * T \text{sinc}^2(T\nu). \quad (8.137)$$

But we know from (2.87) that $T \text{sinc}^2(T\nu)$ is a valid limiting representation of $\delta(\nu)$. From Sec. 3.3.6 we also know that convolution of $S_{ac}(\nu)$ with $\delta(\nu)$ reproduces $S_{ac}(\nu)$ if that function is either a good function (defined in Sec. 2.1.2) or a generalized function of compact support (defined in Sec. 3.3.6). The support can be chosen arbitrarily large, or we can argue as in Sec. 2.3.1 that any generalized function can be approximated arbitrarily closely by a good function.

Thus, with essentially no restrictions beyond stationarity, we have

$$S_{ep}(\nu) = S_{ac}(\nu). \quad (8.138)$$

Because of this equivalence, we shall delete the subscripts henceforth and denote the power spectral density simply by $S(\nu)$. Either definition, (8.133) or (8.134), will be used as convenient.

Spatial power spectra Stationary spatial random processes were discussed in Sec. 8.2.4. If this model is used, the spatial version of the Wiener-Khinchin theorem, (8.133), is

$$S(\boldsymbol{\rho}) = \int_{\infty} d^q \Delta \mathbf{r} R(\Delta \mathbf{r}) \exp(-2\pi i \boldsymbol{\rho} \cdot \Delta \mathbf{r}). \quad (8.139)$$

Stochastic Wigner distribution function A general way of applying Fourier analysis to nonstationary random processes is to make use of the Wigner distribution function, defined in Sec. 5.2.1. For a spatial random process $f(\mathbf{r})$, we define the stochastic Wigner function by [cf. (5.54)]

$$W_f(\mathbf{r}_0, \boldsymbol{\rho}) = \int_{\infty} d^q \Delta \mathbf{r} \langle f(\mathbf{r}_0 + \frac{1}{2} \Delta \mathbf{r}) f^*(\mathbf{r}_0 - \frac{1}{2} \Delta \mathbf{r}) \rangle \exp(-2\pi i \boldsymbol{\rho} \cdot \Delta \mathbf{r}). \quad (8.140)$$

This expression should be compared to the Wiener-Khinchin theorem for a stationary random process, (8.139), which can be written in symmetrized form as

$$\begin{aligned}
S(\boldsymbol{\rho}) &= \int_{-\infty}^{\infty} d^q \Delta \mathbf{r} \langle f(\mathbf{r} + \Delta \mathbf{r}) f^*(\mathbf{r}) \rangle \exp(-2\pi i \boldsymbol{\rho} \cdot \Delta \mathbf{r}) \\
&= \int_{-\infty}^{\infty} d^q \Delta \mathbf{r} \langle f(\mathbf{r}_0 + \frac{1}{2} \Delta \mathbf{r}) f^*(\mathbf{r}_0 - \frac{1}{2} \Delta \mathbf{r}) \rangle \exp(-2\pi i \boldsymbol{\rho} \cdot \Delta \mathbf{r}), \quad (8.141)
\end{aligned}$$

where the second equality follows since the autocorrelation function is independent of shifts of the coordinate system for a stationary process. Thus, if the process is stationary, the stochastic Wigner function is independent of \mathbf{r}_0 and is precisely the power spectral density.

For nonstationary processes, however, $W_f(\mathbf{r}_0, \boldsymbol{\rho})$ is a function of \mathbf{r}_0 as well as $\boldsymbol{\rho}$; it can be interpreted as the spectral content associated with point \mathbf{r}_0 . This interpretation is reinforced by examining the quasistationary case. From (8.119) and (8.140) we can write

$$W_f(\mathbf{r}_0, \boldsymbol{\rho}) = b(\mathbf{r}_0) \int_{-\infty}^{\infty} d^q \Delta \mathbf{r} a(\Delta \mathbf{r}) \exp(-2\pi i \boldsymbol{\rho} \cdot \Delta \mathbf{r}) = b(\mathbf{r}_0) A(\boldsymbol{\rho}). \quad (8.142)$$

Here the Wigner distribution function is just the Fourier transform of the short-range part of the autocorrelation function, modulated by the shift-variant strength of the slowly varying component at \mathbf{r}_0 .

8.2.6 Linear filtering of random processes

We now derive the autocorrelation function of the output process that results from linear filtering of a given random process. We shall consider stationary and nonstationary random processes and shift-invariant and shift-variant filters.

Nonstationary process, shift-variant filter We first consider the case where a random process $g(\mathbf{r})$ is generated as the output of the transformation of an input random process $f(\mathbf{r})$ by a linear shift-variant filter whose impulse response is denoted $h(\mathbf{r}, \mathbf{r}')$. The output of the filter at positions \mathbf{r} and $\mathbf{r} + \Delta \mathbf{r}$ can be written, respectively, as

$$g(\mathbf{r}) = \int_{-\infty}^{\infty} d^q r' h(\mathbf{r}, \mathbf{r}') f(\mathbf{r}'), \quad (8.143)$$

$$g(\mathbf{r} + \Delta \mathbf{r}) = \int_{-\infty}^{\infty} d^q r' h(\mathbf{r} + \Delta \mathbf{r}, \mathbf{r}') f(\mathbf{r}'). \quad (8.144)$$

By direct substitution of these expressions into the definition, (8.97), we obtain for the autocorrelation of the output process at positions \mathbf{r} and $\mathbf{r} + \Delta \mathbf{r}$:

$$\begin{aligned}
R_g(\mathbf{r} + \Delta \mathbf{r}, \mathbf{r}) &= \langle g(\mathbf{r} + \Delta \mathbf{r}) g^*(\mathbf{r}) \rangle \\
&= \left\langle \int_{-\infty}^{\infty} d^q r' h(\mathbf{r} + \Delta \mathbf{r}, \mathbf{r}') f(\mathbf{r}') \int_{-\infty}^{\infty} d^q r'' h^*(\mathbf{r}, \mathbf{r}'') f^*(\mathbf{r}'') \right\rangle \\
&= \int_{-\infty}^{\infty} d^q r' \int_{-\infty}^{\infty} d^q r'' h(\mathbf{r} + \Delta \mathbf{r}, \mathbf{r}') R_f(\mathbf{r}', \mathbf{r}'') h^*(\mathbf{r}, \mathbf{r}''). \quad (8.145)
\end{aligned}$$

The corresponding expression for the autocovariance is

$$\begin{aligned} K_g(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}) &= R_g(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}) - \langle g(\mathbf{r} + \Delta\mathbf{r}) \rangle \langle g^*(\mathbf{r}) \rangle \\ &= \int_{\infty} d^q r' \int_{\infty} d^q r'' h(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}') K_f(\mathbf{r}', \mathbf{r}'') h^*(\mathbf{r}, \mathbf{r}''). \end{aligned} \quad (8.146)$$

This is the most general form for the autocovariance after linear filtering. It is the continuous analog of the discrete result given in (8.50), as one can see by rewriting it in operator form:

$$\mathcal{K}_g = \mathcal{H}\mathcal{K}_f\mathcal{H}^\dagger, \quad (8.147)$$

where \mathcal{K}_f is the autocovariance operator, *i.e.*, the integral operator with kernel $K_f(\mathbf{r}, \mathbf{r}')$, and similarly for \mathcal{K}_g , while \mathcal{H} describes the filter. There are no restrictions on \mathcal{H} in this equation, except that it must be a linear operator. It even applies to linear CD operators, though in that case the left-hand side is a covariance matrix rather than an autocovariance operator.

Nonstationary process, shift-invariant filter We consider next the case where the random process $g(\mathbf{r})$ is generated as the output of the transformation of a general input random process $f(\mathbf{r})$ by a linear shift-invariant filter with impulse response $h(\mathbf{r})$. The processes $g(\mathbf{r})$ and $f(\mathbf{r})$ are now related by convolution:

$$g(\mathbf{r}) = \int_{\infty} d^q r' h(\mathbf{r} - \mathbf{r}') f(\mathbf{r}') = h(\mathbf{r}) * f(\mathbf{r}), \quad (8.148)$$

where the notation of Sec. 3.3.6 has been used.

We can obtain the autocorrelation of the output process $g(\mathbf{r})$ from that of the input process $f(\mathbf{r})$ by substituting (8.148) into (8.145):

$$\begin{aligned} R_g(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}) &= \langle g(\mathbf{r} + \Delta\mathbf{r}) g^*(\mathbf{r}) \rangle \\ &= \left\langle \int_{\infty} d^q r' h(\mathbf{r} + \Delta\mathbf{r} - \mathbf{r}') f(\mathbf{r}') \int_{\infty} d^q r'' h^*(\mathbf{r} - \mathbf{r}'') f^*(\mathbf{r}'') \right\rangle. \end{aligned} \quad (8.149)$$

Alternatively, we have

$$\begin{aligned} R_g(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}) &= \left\langle \int_{\infty} d^q r' h(\mathbf{r}') f(\mathbf{r} + \Delta\mathbf{r} - \mathbf{r}') \int_{\infty} d^q r'' h^*(\mathbf{r}'') f^*(\mathbf{r} - \mathbf{r}'') \right\rangle \\ &= \int_{\infty} d^q r' h(\mathbf{r}') \int_{\infty} d^q r'' h^*(\mathbf{r}'') R_f(\mathbf{r} + \Delta\mathbf{r} - \mathbf{r}', \mathbf{r} - \mathbf{r}''). \end{aligned} \quad (8.150)$$

We can use convolution shorthand to write this equation as

$$R_g(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}) = h(\mathbf{r} + \Delta\mathbf{r}) * R_f(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}) * h^*(\mathbf{r}), \quad (8.151)$$

where the notation indicates that the first convolution is evaluated at the position $\mathbf{r} + \Delta\mathbf{r}$ and the second is evaluated at the position \mathbf{r} .

Stationary random process, shift-invariant filter For the special case of a stationary input process, the input correlation function in (8.150) can be written solely in terms of the difference vector as

$$R_f(\mathbf{r} + \Delta\mathbf{r} - \mathbf{r}', \mathbf{r} - \mathbf{r}'') = \langle f(\mathbf{r} + \Delta\mathbf{r} - \mathbf{r}') f^*(\mathbf{r} - \mathbf{r}'') \rangle = R_f(\Delta\mathbf{r} - \mathbf{r}' + \mathbf{r}''). \quad (8.152)$$

Then (8.150) can be written

$$R_g(\Delta\mathbf{r}) = \int_{\infty} d^q r' h(\mathbf{r}') \int_{\infty} d^q r'' h^*(\mathbf{r}'') R_f(\Delta\mathbf{r} - \mathbf{r}' + \mathbf{r}''). \quad (8.153)$$

This equation is often written in a shorthand notation as (Papoulis, 1965)

$$R_g(\Delta\mathbf{r}) = \langle g(\mathbf{r} + \Delta\mathbf{r}) g^*(\mathbf{r}) \rangle = h(\Delta\mathbf{r}) * R_f(\Delta\mathbf{r}) * h^*(-\Delta\mathbf{r}). \quad (8.154)$$

This notation refers to the fact that the first operation is an ordinary convolution, but the second is actually a correlation. In this shorthand a correlation is written using the convolution notation with a change of sign of the argument. Alternatively, one can use \star to represent the correlation integral:

$$R_g(\Delta\mathbf{r}) = \langle g(\mathbf{r} + \Delta\mathbf{r}) g^*(\mathbf{r}) \rangle = [h * R_f \star h^*](\Delta\mathbf{r}). \quad (8.155)$$

Fourier transformation of (8.155) yields the important formula

$$S_g(\boldsymbol{\rho}) = S_f(\boldsymbol{\rho}) |H(\boldsymbol{\rho})|^2, \quad (8.156)$$

where $H(\boldsymbol{\rho}) = \mathcal{F}_q\{h(\mathbf{r})\}$. Thus, when a stationary random process is filtered by a linear shift-invariant filter, the power spectral density on the output of the filter is the power spectral density on the input times the squared modulus of the filter transfer function. This result should be compared to the familiar result for shift-invariant filtering of a deterministic signal. From (3.132) we know that

$$G(\boldsymbol{\rho}) = H(\boldsymbol{\rho}) F(\boldsymbol{\rho}). \quad (8.157)$$

In the context of stationary random processes, (8.157) applies to *individual sample functions* while (8.156) applies to the power spectral densities.

Filtering of delta-correlated processes We are often concerned with random processes where the correlation has such short range that $R_{\Delta f}(\mathbf{r}, \mathbf{r}')$ can be approximated by $b(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}')$. A prime example, the Poisson random process, will be discussed in detail in Chap. 11. Another example is *white noise*, a stationary process that has a flat power spectrum and hence a delta-function correlation. We now investigate the effect of linear filtering on delta-correlated processes.

With delta correlation, the general space-variant filter equation, (8.144), leads to

$$\begin{aligned} R_{\Delta g}(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}) &= \int_{\infty} d^q r' h(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}') \int_{\infty} d^q r'' b(\mathbf{r}') \delta(\mathbf{r}' - \mathbf{r}'') h^*(\mathbf{r}, \mathbf{r}'') \\ &= \int_{\infty} d^q r' h(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}') b(\mathbf{r}') h^*(\mathbf{r}, \mathbf{r}'). \end{aligned} \quad (8.158)$$

For shift-invariant filters, where $h(\mathbf{r}, \mathbf{r}') = h(\mathbf{r} - \mathbf{r}')$, this equation reduces to

$$\begin{aligned} R_{\Delta g}(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r}) &= \int_{\infty} d^q r' h(\mathbf{r} + \Delta\mathbf{r} - \mathbf{r}') b(\mathbf{r}') h^*(\mathbf{r} - \mathbf{r}') \\ &= b(\mathbf{r}) * [h(\mathbf{r} + \Delta\mathbf{r}) h^*(\mathbf{r})] . \end{aligned} \quad (8.159)$$

The shorthand here requires a brief comment. For purposes of the convolution, the function $[h(\mathbf{r} + \Delta\mathbf{r}) h^*(\mathbf{r})]$ is to be regarded as a function of \mathbf{r} for fixed $\Delta\mathbf{r}$. As shown by the integral in (8.158), this product function is then convolved with $b(\mathbf{r})$, and the convolution is repeated for different $\Delta\mathbf{r}$ to get the full dependence of the nonstationary autocorrelation $R_{\Delta g}(\mathbf{r} + \Delta\mathbf{r}, \mathbf{r})$.

Even though $f(\mathbf{r})$ is uncorrelated for any finite lag, the filtering results in a correlation on $g(\mathbf{r})$. Suppose $h(\mathbf{r})$ has a width w in each dimension, *i.e.*, $h(\mathbf{r})$ drops to zero if the magnitude of any component of \mathbf{r} exceeds $\frac{1}{2}w$. Then $[h(\mathbf{r} + \Delta\mathbf{r}) h^*(\mathbf{r})]$ drops to zero for all \mathbf{r} if the magnitude of any component of $\Delta\mathbf{r}$ exceeds w . The correlation in $g(\mathbf{r})$ thus has a width in $\Delta\mathbf{r}$ determined by the width of the point spread function.

If $b(\mathbf{r})$ is the constant b_0 , so that $R_{\Delta f}(\mathbf{r} - \mathbf{r}') = b_0 \delta(\mathbf{r} - \mathbf{r}')$, then we are dealing with stationary white noise and a frequency-domain description is appropriate. The power spectral density of $\Delta f(\mathbf{r})$ is just the constant b_0 , and by (8.156) that of $\Delta g(\mathbf{r})$ is given by

$$S_{\Delta g}(\boldsymbol{\rho}) = b_0 |H(\boldsymbol{\rho})|^2 . \quad (8.160)$$

The corresponding autocorrelation function is obtained by inverse Fourier transformation:

$$R_{\Delta g}(\Delta\mathbf{r}) = b_0 [h \star h^*](\Delta\mathbf{r}) . \quad (8.161)$$

Thus the statistical autocorrelation function for filtered white noise is proportional to the deterministic autocorrelation integral of the impulse response.

8.2.7 Eigenanalysis of the autocorrelation operator

In Sec. 8.1.6, we discussed the eigenvectors and eigenvalues of a covariance matrix. In particular, we showed how a random vector could be expanded in a series with uncorrelated coefficients by using eigenvectors of the covariance matrix as basis vectors. This expansion was called the Karhunen-Loève or KL expansion.

In this section we carry out a similar analysis for a random process, substituting the continuous autocovariance or autocorrelation function for the discrete covariance matrix. One result will be a continuous version of the KL expansion—a linear transformation that will render a correlated process uncorrelated for any finite shift.

To maintain parallelism with Sec. 8.1.6, we restrict attention initially to finite-energy random processes (thus ruling out stationarity), but later we extend the analysis to finite-power processes and in particular to wide-sense stationary ones. In that case we shall find that KL expansion is just Fourier analysis.

Autocorrelation operator It is arbitrary whether we develop KL analysis based on the autocorrelation or autocovariance function; from (8.98) we can easily convert between them. We choose the autocorrelation since we shall eventually make contact with the Wiener-Khinchin theorem (8.133) or (8.139), which defines the power spectral density as the Fourier transform of the autocorrelation function.

For a general, nonstationary, spatial random process $f(\mathbf{r})$, where \mathbf{r} is a q D position vector, the autocorrelation function $R(\mathbf{r}, \mathbf{r}')$ is defined by (8.97). For now we restrict attention to square-integrable random processes, so we can regard $R(\mathbf{r}, \mathbf{r}')$ as the kernel of an integral operator \mathcal{R} that maps $\mathbb{L}_2(\mathbb{R}^q)$ to itself. Operating on an arbitrary square-integrable function $t(\mathbf{r})$, the operator \mathcal{R} has the form

$$[\mathcal{R}t](\mathbf{r}) = \int_{\infty} d^q r' R(\mathbf{r}, \mathbf{r}') t(\mathbf{r}'). \quad (8.162)$$

Inspection of (8.97) shows that $[R(\mathbf{r}, \mathbf{r}')]^* = R(\mathbf{r}', \mathbf{r})$, so \mathcal{R} is Hermitian (see Sec. 1.3.5).

Moreover, as we shall now show, \mathcal{R} is compact. By the discussion in Sec. 1.3.3, an integral operator is compact if its kernel satisfies the Hilbert-Schmidt condition (1.33), which in the present multidimensional case generalizes to

$$\int_{\infty} d^q r \int_{\infty} d^q r' |\mathcal{R}(\mathbf{r}, \mathbf{r}')|^2 < \infty. \quad (8.163)$$

Denoting this integral by I_{HS} and inserting (8.97), we can rewrite this condition as

$$I_{HS} = \int_{\infty} d^q r \int_{\infty} d^q r' |\langle f(\mathbf{r}) f^*(\mathbf{r}') \rangle|^2 < \infty. \quad (8.164)$$

Now, for any random variable x we know from App. C that $|\langle x \rangle|^2 \leq \langle |x|^2 \rangle$. With $x = f(\mathbf{r}) f^*(\mathbf{r}')$, this implies that

$$I_{HS} \leq \int_{\infty} d^q r \int_{\infty} d^q r' \langle |[f(\mathbf{r}) f^*(\mathbf{r}')]|^2 \rangle. \quad (8.165)$$

As discussed in Sec. 8.2.2, we can interchange expectation and integration, yielding

$$I_{HS} \leq \left\langle \int_{\infty} d^q r |f(\mathbf{r})|^2 \int_{\infty} d^q r' |f(\mathbf{r}')|^2 \right\rangle. \quad (8.166)$$

Every sample function $f(\mathbf{r})$ is assumed to be square-integrable, so each integral in (8.166) is finite. The output of the expectation operation is therefore finite and $I_{HS} \leq \infty$. Thus we have shown that \mathcal{R} satisfies the Hilbert-Schmidt condition and is therefore compact.

As discussed in Sec. 1.4.4, a compact Hermitian operator has a denumerable set of eigenfunctions and real eigenvalues. Thus \mathcal{R} satisfies an eigenvalue equation of the form

$$\mathcal{R}\phi_n(\mathbf{r}) = \mu_n \phi_n(\mathbf{r}). \quad (8.167)$$

We noted in (8.106) that \mathcal{R} is nonnegative-definite, so $\mu_n \geq 0$. It is convenient to order the eigenvalues by decreasing value:

$$\mu_1 \geq \mu_2 \geq \mu_3 \geq \cdots \geq 0. \quad (8.168)$$

Except in very special cases, none of these eigenvalues will be zero, so \mathcal{R} has infinite rank.

Karhunen-Loève expansions Since the eigenfunctions of a Hermitian operator can be chosen to form an orthonormal basis, any function $f(\mathbf{r})$ in the domain of \mathcal{R} , *i.e.*, $\mathbb{L}_2(\mathbb{R}^q)$, can be expanded in the form

$$f(\mathbf{r}) = \sum_{n=1}^{\infty} \alpha_n \phi_n(\mathbf{r}), \quad (8.169)$$

where the coefficients are given by scalar products of the form

$$\alpha_n = (\phi_n(\mathbf{r}), f(\mathbf{r})). \quad (8.170)$$

If $f(\mathbf{r})$ is a sample function of a random process, then the coefficients α_n are random variables. If $f(\mathbf{r})$ is drawn from the ensemble described by \mathcal{R} , then these coefficients are uncorrelated, as we shall now demonstrate. The cross-correlation of two coefficients, α_n and α_m , is given by

$$\langle \alpha_n \alpha_m^* \rangle = \langle (\phi_n(\mathbf{r}), f(\mathbf{r})) (\phi_m(\mathbf{r}'), f(\mathbf{r}'))^* \rangle. \quad (8.171)$$

Writing out the scalar products as integrals and again interchanging integration and expectation, we find

$$\langle \alpha_n \alpha_m^* \rangle = \int_{\infty} d^q r \int_{\infty} d^q r' \phi_n^*(\mathbf{r}) \phi_m(\mathbf{r}') \langle f(\mathbf{r}) f^*(\mathbf{r}') \rangle. \quad (8.172)$$

By (8.97) and (8.167), we have

$$\langle \alpha_n \alpha_m^* \rangle = \mu_m \int_{\infty} d^q r \phi_n^*(\mathbf{r}) \phi_m(\mathbf{r}), \quad (8.173)$$

and the orthonormality of the eigenfunctions yields, finally,

$$\langle \alpha_n \alpha_m^* \rangle = \mu_n \delta_{nm}. \quad (8.174)$$

Thus the expansion in (8.169) generalizes the Karhunen-Loève expansion of random vectors, as discussed in Sec. 8.1.6, to random processes.

Stationary random processes The derivation above of the KL expansion is not directly applicable to stationary random processes since their sample functions are not square-integrable. Hence the autocorrelation operator is not compact and its eigenvalues are not denumerable.

Since the discrete index n on $\phi_n(\mathbf{r})$ and μ_n is no longer appropriate, we shall leave off any index until we discover what to use. The eigenvalue equation for a stationary random process is then

$$\int_{\infty} d^q r' R(\mathbf{r} - \mathbf{r}') \phi(\mathbf{r}') = \mu \phi(\mathbf{r}). \quad (8.175)$$

A simple change of variables yields

$$\int_{\infty} d^q r' R(\mathbf{r}') \phi(\mathbf{r} - \mathbf{r}') = \mu \phi(\mathbf{r}). \quad (8.176)$$

Direct substitution shows that the solution of this equation is

$$\phi(\mathbf{r}) = \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}), \quad (8.177)$$

$$\mu = \int_{\infty} d^q r' R(\mathbf{r}') \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}') = \mathcal{F}_q\{R(\mathbf{r})\} = S(\boldsymbol{\rho}), \quad (8.178)$$

where $S(\boldsymbol{\rho})$ is the power spectral density as defined in (8.139). Thus, for a stationary random process, the eigenfunctions of the autocorrelation operator are Fourier basis functions (or plane waves), and the eigenvalues are given by the power spectral density. The problem is mathematically equivalent to singular-value decomposition of a linear, shift-invariant system as discussed in Sec. 7.2.5

The eigenfunctions and eigenvalues are distinguished by a continuous vector index $\boldsymbol{\rho}$ (the spatial frequency), rather than by a discrete index n . Thus we denote the eigenfunction in (8.177) as $\phi_{\boldsymbol{\rho}}(\mathbf{r})$ and the eigenvalue as $\mu_{\boldsymbol{\rho}}$. With this notation, the KL expansion (8.169) becomes

$$f(\mathbf{r}) = \int_{\infty} d^q \rho F(\boldsymbol{\rho}) \phi_{\boldsymbol{\rho}}(\mathbf{r}) = \int_{\infty} d^q \rho F(\boldsymbol{\rho}) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \quad (8.179)$$

By analogy with (8.170), the expansion coefficients $F(\boldsymbol{\rho})$ are given by

$$F(\boldsymbol{\rho}) = \int_{\infty} d^q r f(\mathbf{r}) \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}). \quad (8.180)$$

Formally, (8.179) states that the KL expansion is simply the representation of a sample function of the stationary random process by its inverse Fourier transform, while (8.180) says that the expansion coefficient is the Fourier transform of the sample function. In this sense, KL expansion reduces to Fourier analysis in the stationary case. In a strict mathematical sense, however, this interpretation raises some problems. If $f(\mathbf{r})$ is a sample function from a stationary random process, it must have the same mean value at all points in the infinite domain \mathbb{R}^q . Hence it is not square-integrable or absolutely integrable, and the classical Fourier existence and convergence theorems do not apply.

We can fix these problems in one of two ways. One approach is to presume that each sample function is truncated by a window function of finite size, and then let this size go to infinity as in Sec. 8.2.5. A neater approach is simply to regard $f(\mathbf{r})$ as a generalized function related to a tempered distribution. This requires only that the sample function be integrable when multiplied by a good function such as a Gaussian, which is an easy condition to satisfy. From the discussion in Sec. 3.3.4, we know that $F(\boldsymbol{\rho})$ is also a generalized function in that case. For example, if $f(\mathbf{r})$ has a nonzero mean \bar{f} (which must be independent of \mathbf{r} because of the stationarity), then $F(\boldsymbol{\rho})$ must contain a term $\bar{f} \delta(\boldsymbol{\rho})$.

From the viewpoint of generalized functions, we can now discuss the correlation properties of the expansion coefficients $F(\boldsymbol{\rho})$. A derivation paralleling the one that led to (8.173) shows that

$$\langle F(\boldsymbol{\rho}) F^*(\boldsymbol{\rho}') \rangle = S(\boldsymbol{\rho}) \delta(\boldsymbol{\rho} - \boldsymbol{\rho}'). \quad (8.181)$$

Just as in (8.173), the KL expansion coefficients are orthogonal for a stationary random process, but now orthogonality is defined with a Dirac delta rather than a Kronecker delta. Thus Fourier transformation of a stationary random process

results in a delta-correlated random process. We shall make use of this result in the next chapter on Poisson random processes.

Another important conclusion from (8.181) is that the second moment $\langle |F(\boldsymbol{\rho})|^2 \rangle$ is infinite for a stationary random process. Since the mean of the Fourier transform, $\langle F(\boldsymbol{\rho}) \rangle$, is the same as the Fourier transform of the mean, $\mathcal{F}\{\langle f(\mathbf{r}) \rangle\}$, we would not expect $|\langle F(\boldsymbol{\rho}) \rangle|^2$ to be infinite (except possibly for $\boldsymbol{\rho} = 0$), so (8.181) implies that the variance of the Fourier transform of a stationary random process is also infinite.

8.2.8 Discrete random processes

As we discussed in Chap. 7, digital images are discrete vectors, and it is often useful to model actual, physical objects as discrete vectors also. When we analyze the stochastic properties of digital images or discrete object models, then, they become random vectors. The general treatment of random vectors from Sec. 8.1 is applicable here, but there is also an additional structure we can exploit. If a random vector \mathbf{g} represents an image and each component of the vector represents a pixel, we are interested above all in the relationship between the values at different pixels. If we shuffled the pixels into a different arrangement, they would not represent the same image.

A similar situation occurs in discussing random temporal signals, where the temporal ordering of the signal values is key. For example, if a random analog waveform $f(t)$ is sampled at regular time points for further digital processing, the sequence of values $\{f(t_n)\}$ constitutes a random vector in which the order of the elements must be maintained.

We shall use the term *discrete random process*⁵ to mean a random vector in which crucial information is contained in the temporal or spatial arrangement of the component values. Loosely, a discrete random process is a random vector endowed with a topology. For temporal processes, the term *random sequence* is often used, and some books adopt this term for the spatial case as well.

Discrete stationarity in 1D Suppose the sequence $\{f_n\}$ is obtained by sampling a stationary temporal random process $f(t)$ at regular intervals $t = t_n = n\Delta t$. The sampling could be simple point sampling where $f_n = f(t_n)$, but a more general form is

$$f_n = \int_{-\infty}^{\infty} dt f(t) s(t_n - t). \quad (8.182)$$

The sampling function $s(t)$ is a delta function for point sampling, but in general it is unrestricted in what follows. Note that (8.182) is in the form of a convolution, so f_n consists of point samples of the random process $[f * s](t)$.

If $f(t)$ is wide-sense stationary, so is $[f * s](t)$. It then follows that the covariance matrix of the samples $\{f_n\}$ satisfies [cf. (8.112)]

$$K_{nn'} = k_{n-n'}. \quad (8.183)$$

Note that the left-hand side of this equation has two indices but the right-hand side has just one; if there are N elements in the sequence $\{f_n\}$, there are N^2 elements

⁵Note that the elements of the random vector need not be discrete random variables; the term *discrete* here refers to the temporal or spatial variable.

in the matrix \mathbf{K} but only N independent ones. Each row of the matrix is a shifted version of every other row. Matrices with this structure are said to be *Toeplitz*.

Circulant covariance matrices We encountered Toeplitz matrices in a deterministic context in Chap. 7. Specifically, we saw in Sec. 7.4.4 that a considerable mathematical simplification resulted if we could approximate the Toeplitz matrix by a circulant one, where the difference $n - n'$ in (8.183) is interpreted modulo N , with N being the total number of samples. For example, if n and n' run from 0 to 255, then the pairs $(n = 10, n' = 5)$ and $(n = 2, n' = 253)$ have the same value for $n - n'$ modulo 256 and hence the same correlation if \mathbf{K} is a 256×256 circulant matrix. Physically, of course, this makes no sense; elements 5 and 10 of the sequence are close together and might be expected to be correlated, but elements 2 and 253 are widely separated, and there is no reason to believe that they should have the same correlation as elements 5 and 10.

Nevertheless, the circulant approximation to a Toeplitz covariance matrix is often used, just as is the circulant approximation to a discrete convolution [see Sec. 7.4.4, especially (7.344)]. The error might be tolerable if the kernel ($k_{n-n'}$ in the stochastic problem or h_{m-n} in the deterministic problem) is compact and our interest does not extend to the extreme elements in the sequence. Some vigilance is required to be sure that we do not fall into a trap when we assume that a Toeplitz matrix is approximately circulant.

The reason we might want to make this approximation was laid out in Sec. 7.4.4: a circulant matrix is diagonalized by a DFT [see (7.352)]. For the deterministic DD problem considered in Sec. 7.4.4, that meant that the DFT basis was essentially the SVD basis when the system was described by a circulant \mathbf{H} matrix. In the stochastic context of this chapter, the DFT basis is the KL basis when we can use the circulant form for the covariance.

Discrete spatial stationarity Circulant stationarity is even more suspect than continuous stationarity in imaging applications, but for completeness we state the mathematical results explicitly. If we consider an image \mathbf{g} to be a q D discrete random process, then the elements of the image can be denoted by $g_{\mathbf{m}}$, where \mathbf{m} is a q D multi-index as introduced in Sec. 3.4.6. If each component m_i of \mathbf{m} runs from 0 to $M - 1$, then circulant stationarity means that $[\mathbf{K}_{\mathbf{g}}]_{\mathbf{m}\mathbf{m}'}$ depends on $m_i - m'_i$ modulo M for all i . In that case, as discussed in Sec. 7.4.4, the circulant covariance matrix is diagonalized by a q D DFT, and the basis vectors in this transform comprise the KL basis.

The cyclic character of the covariance matrix becomes less objectionable as the array gets larger if the correlation length is constant. In the limit as $M \rightarrow \infty$, the distinction between Toeplitz and circulant vanishes. In that case, the Toeplitz/circulant matrix is diagonalized by the discrete-space Fourier transform (DSFT) introduced in Sec. 3.6.4, and the KL basis vectors form a continuous basis indexed by the spatial-frequency vector $\boldsymbol{\rho}$. To use this basis, however, we must now make two unphysical assumptions: an infinite amount of data and discrete stationarity over an infinite domain.

8.3 NORMAL RANDOM VECTORS AND PROCESSES

Among the many probability laws for continuous random variables, the normal probability law is certainly the most commonly encountered. The fundamental reason for this is that when statistically independent random variables are added together, their sum asymptotically follows the normal distribution. (We shall provide a more rigorous treatment of this principle later in this section.) The second reason for the popularity of the normal law is that, as we shall soon see, its structure leads to straightforward and well-understood manipulations. The third reason follows from the first two: a great collection of practically useful statistical tools develop as elaborations upon the normal probability law.

The normal law is frequently named for C. F. Gauss (1777–1855), whose *Theory of the Combination of Observations* (1823) has earned him this eponymity. We shall use the terms *normal* and *Gaussian* interchangeably.

8.3.1 Probability density functions

For simplicity we consider here only real random variables and vectors, but the complex case is treated in Sec. 8.3.6. The PDF of a real normal random variable g is given (see App. C) by

$$\text{pr}(g) = \left[\frac{1}{2\pi\sigma^2} \right]^{\frac{1}{2}} \exp \left[-\frac{(g - \bar{g})^2}{2\sigma^2} \right], \quad (8.184)$$

where \bar{g} is the mean of the random variable and σ^2 is its variance. To indicate that a random variable g is drawn from a normal distribution with parameters \bar{g} and σ^2 , we write $g \sim \mathcal{N}(\bar{g}, \sigma^2)$.

A multivariate normal random vector is a straightforward generalization of the univariate or scalar case. If each component of an *MD* random vector \mathbf{g} is a normal random variable, the full probability law on \mathbf{g} is a multivariate normal PDF $\text{pr}(\mathbf{g})$, given by

$$\text{pr}(\mathbf{g}) = [(2\pi)^M \det(\mathbf{K})]^{-1/2} \exp \left[-\frac{1}{2}(\mathbf{g} - \bar{\mathbf{g}})^t \mathbf{K}^{-1}(\mathbf{g} - \bar{\mathbf{g}}) \right], \quad (8.185)$$

where $\bar{\mathbf{g}}$ is the mean vector and \mathbf{K} is the covariance matrix of \mathbf{g} as defined in Sec. 8.1.3. As shown in that section, \mathbf{K} is an $M \times M$, positive-semidefinite Hermitian matrix. The diagonal element K_{mm} of the covariance matrix is the variance of the m^{th} component of \mathbf{g} , and the off-diagonal elements of \mathbf{K} are related by $K_{nm} = K_{mn}$ for real vectors. We denote an $M \times 1$ random vector drawn from a multivariate normal distribution with parameters $\bar{\mathbf{g}}$ and \mathbf{K} by $\mathbf{g} \sim \mathcal{N}_M(\bar{\mathbf{g}}, \mathbf{K})$. Its density function is seen from (8.185) to be the exponential of a quadratic form in the random vector.

Diagonalization of the covariance matrix of a Gaussian random vector In Sec. 8.1.6 we showed how the KL expansion of a random vector in terms of the eigenvectors of its covariance matrix results in uncorrelated components. We now revisit the KL expansion procedure for the particular case of Gaussian random vectors. We shall show that, for a multivariate normal, the KL transformation yields a vector with uncorrelated components that are also statistically independent.

From (8.64) we know we can express the inverse of the covariance matrix \mathbf{K} as

$$\mathbf{K}^{-1} = \mathbf{\Phi} \mathbf{M}^{-1} \mathbf{\Phi}^\dagger, \quad (8.186)$$

where again $\mathbf{\Phi}$ is the matrix formed from the eigenvectors ϕ_m of \mathbf{K} , and \mathbf{M} is a diagonal matrix with the m^{th} diagonal element equal to the eigenvalue μ_m . We can use (8.186) to rewrite the quadratic form of (8.185) as

$$\begin{aligned} (\mathbf{g} - \bar{\mathbf{g}})^t \mathbf{K}^{-1} (\mathbf{g} - \bar{\mathbf{g}}) &= (\mathbf{g} - \bar{\mathbf{g}})^t \mathbf{\Phi} \mathbf{M}^{-1} \mathbf{\Phi}^\dagger (\mathbf{g} - \bar{\mathbf{g}}) \\ &= \left[\mathbf{\Phi}^\dagger (\mathbf{g} - \bar{\mathbf{g}}) \right]^\dagger \mathbf{M}^{-1} \left[\mathbf{\Phi}^\dagger (\mathbf{g} - \bar{\mathbf{g}}) \right], \end{aligned} \quad (8.187)$$

where we have used the unitarity of $\mathbf{\Phi}$. We define the random vector $\Delta\boldsymbol{\beta}$ by [cf. (8.60)]

$$\Delta\boldsymbol{\beta} = \mathbf{\Phi}^\dagger (\mathbf{g} - \bar{\mathbf{g}}). \quad (8.188)$$

Combining (8.187) and (8.188), we obtain

$$\left[\mathbf{\Phi}^\dagger (\mathbf{g} - \bar{\mathbf{g}}) \right]^\dagger \mathbf{M}^{-1} \left[\mathbf{\Phi}^\dagger (\mathbf{g} - \bar{\mathbf{g}}) \right] = \Delta\boldsymbol{\beta}^\dagger \mathbf{M}^{-1} \Delta\boldsymbol{\beta} = \sum_{m=1}^M \Delta\beta_m^2 / \mu_m. \quad (8.189)$$

From (A.73) in App. A, we know that the determinant of \mathbf{K} is the product of its eigenvalues. Using this fact and (8.189), we can rewrite (8.185) as

$$\begin{aligned} \text{pr}(\mathbf{g}) &= (2\pi)^{-M/2} \left[\prod_{m=1}^M \mu_m \right]^{-1/2} \exp \left(-\frac{1}{2} \sum_{m=1}^M \frac{\Delta\beta_m^2}{\mu_m} \right) \\ &= \prod_{m=1}^M (2\pi\mu_m)^{-1/2} \exp \left(-\frac{1}{2} \frac{\Delta\beta_m^2}{\mu_m} \right) = \text{pr}(\boldsymbol{\beta}), \end{aligned} \quad (8.190)$$

where the last step is valid since the transformation from \mathbf{g} to $\boldsymbol{\beta}$ is unitary and hence the Jacobian is unity.

Thus, when the quadratic form is diagonalized, the Gaussian multivariate PDF can be written as a product of univariate PDFs, which means that the new variables, $\Delta\beta_m$, are statistically independent. While the components of the random vector \mathbf{g} may covary (as represented by the elements of the covariance matrix \mathbf{K}), the components of the random vector $\Delta\boldsymbol{\beta}$ are uncorrelated, with diagonal covariance matrix \mathbf{M} , and statistically independent. The mean of each component $\Delta\beta_m$ is 0 and its variance is simply μ_m . The product form of the PDF in (8.190) also makes the normalization of the multivariate Gaussian density readily verifiable.

Fig. 8.2 Contours of constant probability density for a multivariate normal, before and after diagonalization.

Figure 8.2 depicts contours of constant probability for the multivariate normal PDF before and after the diagonalization of \mathbf{K} . Following the diagonalization operation the surfaces are found to be ellipsoids whose axes have lengths proportional to the square root of the corresponding eigenvalues μ_m . The diagonalization operation rotates the coordinate axes to coincide with the eigenvectors of \mathbf{K} .

When does uncorrelated imply independent? We have just seen that a normal random vector with uncorrelated components also has statistically independent components. The converse always holds—statistically independent components must be uncorrelated—but it is *only* the normal law for which uncorrelated components are statistically independent.

8.3.2 Characteristic function

The diagonalized form of the PDF given in Sec. 8.3.1 provides an easy way to derive the characteristic function of a multivariate normal random vector. From (8.188) and the unitarity of Φ , we can write \mathbf{g} as

$$\mathbf{g} = \Phi\Delta\boldsymbol{\beta} + \bar{\mathbf{g}}. \tag{8.191}$$

Thus the characteristic function for \mathbf{g} is given by

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \langle \exp[-2\pi i \boldsymbol{\xi}^t (\Phi\Delta\boldsymbol{\beta} + \bar{\mathbf{g}})] \rangle = \exp(-2\pi i \boldsymbol{\xi}^t \bar{\mathbf{g}}) \langle \exp[-2\pi i (\Phi^\dagger \boldsymbol{\xi})^t \Delta\boldsymbol{\beta}] \rangle, \tag{8.192}$$

where we removed a constant factor from the expectation and used the definition of adjoint, (1.39), to get the last form. Using (8.190) for the PDF and writing out the expectation in detail, we find

$$\begin{aligned} \psi_{\mathbf{g}}(\boldsymbol{\xi}) &= \prod_{m=1}^M (2\pi\mu_m)^{-1/2} \exp(-2\pi i \xi_m \bar{g}_m) \\ &\times \int_{-\infty}^{\infty} d\Delta\beta_m \exp\left(-\frac{1}{2} \frac{\Delta\beta_m^2}{\mu_m}\right) \exp\left[-2\pi i (\boldsymbol{\Phi}^\dagger \boldsymbol{\xi})_m \Delta\beta_m\right]. \end{aligned} \quad (8.193)$$

Now we have a product of 1D integrals, each of which is just the Fourier transform of a Gaussian; by (3.180) we have

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \prod_{m=1}^M \exp(-2\pi i \xi_m \bar{g}_m) \exp\left[-2\pi^2 \mu_m (\boldsymbol{\Phi}^\dagger \boldsymbol{\xi})_m^2\right]. \quad (8.194)$$

From (8.186) we can see that

$$\sum_{m=1}^M \mu_m (\boldsymbol{\Phi}^\dagger \boldsymbol{\xi})_m^2 = \boldsymbol{\xi}^t \mathbf{K} \boldsymbol{\xi}, \quad (8.195)$$

so we have, finally,

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \exp(-2\pi i \boldsymbol{\xi}^t \bar{\mathbf{g}}) \exp(-2\pi^2 \boldsymbol{\xi}^t \mathbf{K} \boldsymbol{\xi}). \quad (8.196)$$

For $\bar{\mathbf{g}} = \mathbf{0}$, we obtain $\exp(-2\pi^2 \boldsymbol{\xi}^t \mathbf{K} \boldsymbol{\xi})$, which is easy to remember since it is Gaussian in the Fourier domain with spread inverse to that in the domain of the random variable (*i.e.*, \mathbf{K} occurs in place of \mathbf{K}^{-1}). The complete form, (8.196), may then be recalled by invoking the Fourier shift theorem (3.108).

Moments We can use the characteristic function given in (8.196) to determine the moments of a multivariate normal random vector. If we apply (8.30) and (8.31) to (8.196), we obtain $\langle \mathbf{g} \rangle = \bar{\mathbf{g}}$ and $\langle \mathbf{g} \mathbf{g}^t \rangle = \mathbf{K} + \bar{\mathbf{g}} \bar{\mathbf{g}}^t$. If $\bar{\mathbf{g}} = \mathbf{0}$, then $\langle \mathbf{g} \mathbf{g}^t \rangle = \mathbf{K}$. By continuing along this path we find that all odd moments of this distribution are zero for $\bar{\mathbf{g}} = \mathbf{0}$, and all even moments are expressible in terms of \mathbf{K} .

We shall find that we frequently need fourth moments of the form $\langle g_i g_j g_k g_l \rangle$, where the g_i , etc., are components of a four-dimensional vector \mathbf{g} distributed as $\mathcal{N}_4(\mathbf{0}, \mathbf{K})$. We can obtain the desired result, referred to as the Gaussian moment theorem, by using the rules for differentiation with respect to a real vector given in Sec. A.9.2. We find that

$$\langle g_i g_j g_k g_l \rangle = \left(\frac{\partial^4 \psi_{\mathbf{g}}(\boldsymbol{\xi})}{\partial \xi_i \partial \xi_k \partial \xi_j \partial \xi_l} \right)_{\boldsymbol{\xi}=\mathbf{0}} = K_{ij} K_{kl} + K_{jk} K_{il} + K_{ik} K_{jl}. \quad (8.197)$$

For the case where $i = j = k = l$, we find $\langle g_i^4 \rangle = 3\sigma_i^4$, which is a familiar result for univariate normals given in (C.112).

8.3.3 Marginal densities and linear transformations

In this section we derive various descriptors of the behavior of subsets and transformations of the components of a multivariate Gaussian random vector. We start by analyzing the behavior of a single component, regardless of the behavior of the other components, as described by the marginal PDF. We then discuss the behavior of a

random vector obtained from linear transformation of a Gaussian random vector.

According to (8.5), the marginal PDF on component g_i of an MD vector \mathbf{g} is obtained by integrating the multivariate PDF over all g_m except for $m = i$. From the central-ordinate theorem of Fourier analysis, (3.104), we know that integrating a function over $(-\infty, \infty)$ is equivalent to setting the frequency to zero in its Fourier transform. Thus the univariate characteristic function for g_i is related to the multivariate characteristic function for \mathbf{g} by

$$\psi_{g_i}(\xi_i) = \psi_{\mathbf{g}}(0, 0, \dots, \xi_i, \dots, 0). \tag{8.198}$$

With (8.196), we have

$$\psi_{g_i}(\xi_i) = \exp(-2\pi i \xi_i \bar{g}_i) \exp(-2\pi^2 K_{ii} \xi_i^2). \tag{8.199}$$

This is just the characteristic function for a univariate normal with mean \bar{g}_i and variance K_{ii} . Perhaps surprisingly, the form of the marginal on g_i does not depend on K_{im} for $i \neq m$, even though g_i may be correlated with the other components.

Similarly, the bivariate characteristic function for g_i and g_j is given by

$$\begin{aligned} \psi_{g_i, g_j}(\xi_i, \xi_j) &= \psi_{\mathbf{g}}(0, 0, \dots, \xi_i, \dots, \xi_j, \dots, 0) \\ &= \exp\left(-2\pi i \tilde{\boldsymbol{\xi}}^t \tilde{\mathbf{g}}\right) \exp\left[-2\pi^2 \tilde{\boldsymbol{\xi}}^t \tilde{\mathbf{K}} \tilde{\boldsymbol{\xi}}\right], \end{aligned} \tag{8.200}$$

where $\tilde{\boldsymbol{\xi}}^t = (\xi_i, \xi_j)$, $\tilde{\mathbf{g}} = (\bar{g}_i, \bar{g}_j)^t$ and

$$\tilde{\mathbf{K}} = \begin{bmatrix} K_{ii} & K_{ij} \\ K_{ij} & K_{jj} \end{bmatrix}. \tag{8.201}$$

Inverse Fourier transformation of (8.200) yields a bivariate normal PDF with the expected mean and covariance. Again, we do not need to know covariance components other than the ones represented in the marginal of interest.

Other linear transformations of normal random vectors Computation of a marginal is equivalent to finding the PDF for the output of a linear transformation of a random vector. For example, the component g_i can be singled out by computing the scalar product of \mathbf{g} with an $1 \times M$ row vector having a one in the i^{th} column and a zero in all others. Similarly, the 2D vector (g_i, g_j) results from applying a $2 \times M$ matrix operator with ones in positions $(1, i)$ and $(2, j)$ and zeros in all other locations. We now compute the PDF for a random vector formed from a general linear transformation.

Consider the random vector $\mathbf{y} = \mathbf{O}\mathbf{g}$, where \mathbf{y} is a $K \times 1$ vector, \mathbf{O} is a real $K \times M$ matrix and $\mathbf{g} \sim \mathcal{N}_M(\bar{\mathbf{g}}, \mathbf{K})$. The characteristic function for \mathbf{y} follows from (8.43) and (8.196):

$$\psi_{\mathbf{y}}(\boldsymbol{\xi}) = \psi_{\mathbf{g}}(\mathbf{O}^t \boldsymbol{\xi}) = \exp(-2\pi i \boldsymbol{\xi}^t \mathbf{O}\bar{\mathbf{g}}) \exp(-2\pi^2 \boldsymbol{\xi}^t \mathbf{O}\mathbf{K}\mathbf{O}^t \boldsymbol{\xi}). \tag{8.202}$$

By inspection, then, $\mathbf{y} \sim \mathcal{N}_K(\mathbf{O}\bar{\mathbf{g}}, \mathbf{O}\mathbf{K}\mathbf{O}^t)$. Thus *any* linear transformation of a normal random vector leaves it normal.

In fact, the converse of (8.202) also holds: An $M \times 1$ random vector is normal if and only if its scalar products with all $M \times 1$ vectors are univariate normal (Mardia *et al.*, 1979).

8.3.4 Central-limit theorem

In this section we show that the sum of a large number of random variables tends to be normally distributed. This property, known as the central-limit theorem, is one of the reasons for the prominence of the Gaussian law in probability theory.

We shall introduce the central-limit theorem in stages. Initially we consider *i.i.d.* (independent and identically distributed) scalar random variables, where all moments are finite. These assumptions allow an elementary derivation, though one with restricted validity. Next we discuss the case of *i.i.d.* random variables where some of the higher moments may be infinite. Then we allow the variables to have different variances and some degree of statistical dependence. Finally we comment briefly on the vector case.

Independent and identically distributed random variables Consider a set of J *i.i.d.* random variables u_j , $1 \leq j \leq J$, with means \bar{u} and variances σ^2 . First we define standardized (zero-mean, unit-variance) random variables by

$$x_j = \frac{u_j - \bar{u}}{\sigma}. \quad (8.203)$$

Then we construct a new random variable z , defined by

$$z = \frac{1}{\sqrt{J}} \sum_{j=1}^J x_j. \quad (8.204)$$

Because the variance of a sum of J *i.i.d.* random variables is J times the individual variances, and the variance of x_j/\sqrt{J} is $1/J$, z has unit variance. Moreover, since z is a sum of zero-mean random variables, it also has zero mean. We want to show that as $J \rightarrow \infty$ the PDF on z tends toward a standard normal distribution, from which it follows readily that the sum of the u_j is normal with mean $J\bar{u}$ and variance $J\sigma^2$.

The derivation proceeds most easily with the aid of characteristic functions. We shall denote the characteristic function of x_j as $\psi_x(\xi)$; no index j is needed since the characteristic function has the same form for all of the x_j . If we assume initially that all moments of x_j are finite, we can expand $\psi_x(\xi)$, in a Taylor series:

$$\begin{aligned} \psi_x(\xi) &= \langle \exp(-2\pi i \xi x_j) \rangle = 1 - 2\pi i \xi \langle x_j \rangle - \frac{4\pi^2}{2!} \xi^2 \langle x_j^2 \rangle + \dots \\ &= 1 - \frac{4\pi^2}{2!} \xi^2 + \dots, \end{aligned} \quad (8.205)$$

where the second line follows since $\langle x_j \rangle = 0$ and $\langle x_j^2 \rangle = 1$.

The characteristic function of z is given by

$$\begin{aligned} \psi_z(\xi) &= \langle \exp(-2\pi i \xi z) \rangle = \left\langle \exp \left[-2\pi i \left(\frac{\xi}{\sqrt{J}} \right) \sum_{j=1}^J x_j \right] \right\rangle \\ &= \prod_{j=1}^J \left\langle \exp \left[-2\pi i \left(\frac{\xi}{\sqrt{J}} \right) x_j \right] \right\rangle = \prod_{j=1}^J \psi_x \left(\frac{\xi}{\sqrt{J}} \right) = \left[\psi_x \left(\frac{\xi}{\sqrt{J}} \right) \right]^J, \end{aligned} \quad (8.206)$$

where the independence of the x_j has been invoked on the second line to write the expectation of a product as the product of the expectations, and the fact that the x_j are identically distributed is the key to the last step.

We can now insert the Taylor expansion (8.205) into (8.206), yielding

$$\psi_z(\xi) = \left[1 - \frac{2\pi^2\xi^2}{J} + R_J(\xi) \right]^J, \quad (8.207)$$

where $R_J(\xi)$ is the remainder if the Taylor expansion is truncated with the quadratic term. By Taylor's theorem (Rade and Westgren, 1990), $R_J(\xi)$ tends to zero (for any fixed ξ) at least as fast as $J^{-3/2}$ when $J \rightarrow \infty$. Thus, in spite of the J^{th} power, these higher terms vanish in the limit. The quadratic term must be retained, however, so that

$$\lim_{J \rightarrow \infty} \psi_z(\xi) = \lim_{J \rightarrow \infty} \left(1 - \frac{2\pi^2\xi^2}{J} \right)^J = \exp(-2\pi^2\xi^2), \quad (8.208)$$

which is the characteristic function of a standard-normal random variable. It then follows from the celebrated *continuity theorem* of Paul Lévy (see Loève, 1963) that $z \sim \mathcal{N}(0, 1)$.⁶

It is straightforward to go from (8.208) to the probability law for the sum of the original random variables u_j . Defining

$$s_J = \sum_{j=1}^J u_j, \quad (8.209)$$

the reader may show that $s_J \sim \mathcal{N}(J\bar{u}, J\sigma^2)$

We have therefore seen that an infinite sum of independent, identically distributed random variables follows a normal distribution, at least when the individual characteristic functions admit of a Taylor expansion. It must be emphasized, however, that the central-limit theorem guarantees normality only asymptotically; it might not be a good approximation for large but finite J . Often the convergence to normality is rapid, requiring as few as perhaps 5–10 terms, but we should be cautious about finite sums of skewed or otherwise long-tailed PDFs. An extreme example is the case of sums of log-normal distributions, which converge very slowly to the central limit (Barakat, 1976).

Infinite moments There are common PDFs where some of the higher moments are infinite. In Sec. C.5.10, we encountered the Lévy family of distributions, and we noted that the mean was zero but the variance was infinite. A special case of the Lévy distribution is the Cauchy distribution, where $\text{pr}(x) \propto (a^2 + x^2)^{-1}$, a well-known and broadly useful PDF of infinite variance. On the other hand, if we consider $\text{pr}(x) \propto (a^2 + x^2)^{-2}$, then the variance is finite but the fourth moment is infinite. The common feature of these examples is that the characteristic function is not differentiable to all orders and hence cannot be expanded in a Taylor series. Therefore we need to inquire whether it is possible to derive a central-limit theorem.

⁶Thanks to Jack Denny for calling our attention to this theorem.

The key is a theorem proved in Shirayev (1984). If $\langle |x|^n \rangle$ exists for some $n \geq 1$, then the k^{th} derivative of $\psi_x(\xi)$, denoted $\psi_x^{(k)}(\xi)$, exists for every $k \leq n$, and

$$\psi_x(\xi) = \sum_{k=0}^n \frac{(2\pi i \xi)^k}{k!} \langle x^k \rangle + \frac{(2\pi i \xi)^n}{n!} \epsilon_n(\xi), \tag{8.210}$$

where $|\epsilon_n(\xi)| \leq 3 \langle |x|^n \rangle$ and $\epsilon_n(\xi) \rightarrow 0$ as $\xi \rightarrow 0$. So long as $\langle |x_j|^3 \rangle$ is finite, this theorem justifies the steps from (8.205) to (8.208), even when the full Taylor expansion for $\psi_x(\xi)$ does not exist.

For the examples given above, $\langle |x_j|^3 \rangle$ is infinite for the Lévy and Cauchy PDFs, so the limiting PDF is not normal; in fact, a sum of any number of Lévy random variables is still a Lévy random variable. For $\text{pr}(x) \propto (a^2 + x^2)^{-2}$, however, $\langle |x_j|^3 \rangle$ is finite and there is a normal central limit.⁷

Independent but not identically distributed random variables Now suppose that the random variables u_j are independent but have different means and variances. Let the mean of u_j be denoted by \bar{u}_j and the variance by σ_j^2 , and define

$$x_{jJ} = \frac{u_j - \bar{u}_j}{\sqrt{\sum_{j=1}^J \sigma_j^2}}. \tag{8.211}$$

The extra subscript is needed since the denominator depends on J . Note that

$$\langle x_{jJ} \rangle = 0 \quad \text{and} \quad \sum_{j=1}^J \text{Var}(x_{jJ}) = 1. \tag{8.212}$$

Now we can define a standardized random variable z by

$$z = \sum_{j=0}^J x_{jJ}. \tag{8.213}$$

If the means and variances are independent of j , this definition of z reduces to (8.204).

Shirayev (1984) discusses various sufficient conditions under which z will tend to a standard normal as $J \rightarrow \infty$. They all amount to saying that the variables x_{jJ} are *asymptotically infinitesimal*, in the sense that $\langle x_{jJ}^2 \rangle \rightarrow 0$ as $J \rightarrow \infty$, or equivalently that, for every ϵ ,

$$\text{Pr}(|x_{jJ}| > \epsilon) \rightarrow 0 \quad \text{as} \quad J \rightarrow \infty. \tag{8.214}$$

This condition is plausible in most practical circumstances because of the denominator in (8.211); so long as the variances σ_j^2 do not themselves tend to zero rapidly as j gets large, the sum of the variances will increase as the number of terms increases, so x_{jJ} , which is normalized by this sum, must get smaller in virtually any sense.

Thus the central-limit theorem states that a sum of asymptotically infinitesimal, zero-mean random variables tends to a standard normal, so long as the sum

⁷We thank Dana Clarke for helpful discussions on these examples.

of their variances is normalized to unity (Shiryayev, 1984). From this statement, it is again straightforward to show that the sum of the original variables u_j is also asymptotically normal. Specifically, as $J \rightarrow \infty$, s_J becomes distributed as $\mathcal{N}_J[\sum_j \bar{u}_j, \sum_j \text{Var}(u_j)]$.

Sums of dependent random variables Though the central-limit theorem is usually stated for sums of independent random variables, strict independence is not required. For a detailed discussion, see Shiryayev (1984).

Sums of i.i.d. random vectors Central-limit theorems can also be stated for random vectors. We mention here only the simplest case of i.i.d. random vectors where all moments exist.

Let \mathbf{u}_j be an $M \times 1$ random vector with mean $\bar{\mathbf{u}}$ and covariance $\mathbf{K}_{\mathbf{u}}$, both independent of j , and assume that \mathbf{u}_j is independent of \mathbf{u}_k for $j \neq k$. Also let

$$\mathbf{s}_J = \sum_{j=1}^J \mathbf{u}_j. \quad (8.215)$$

Then, as $J \rightarrow \infty$, $\mathbf{s}_J \sim \mathcal{N}_M(J\bar{\mathbf{u}}, J\mathbf{K}_{\mathbf{u}})$. The proof of this statement involves multivariate characteristic functions and the multivariate Taylor expansion (A.179). With this hint, the reader should be able to retrace the steps leading up to (8.208).

8.3.5 Normal random processes

As we shall see in more detail in Sec. 8.4.3, we can sometimes apply the central-limit theorem and argue that the random process representing an object or image is normal. In preparation for that discussion, we examine here some of the mathematical properties of normal random processes. We initially adopt a rather unconventional starting point and define normal random processes in terms of characteristic functionals, but then we shall show that this definition is equivalent to a more common one.

Characteristic functional and linear operators The general form of the characteristic function of a normal random vector is given in (8.196); it can be extended to random processes by use of the characteristic functional, as introduced in Sec. 8.2.3. By analogy to (8.196), we define a real-valued normal random process by requiring that its characteristic functional be given by

$$\Psi_{\mathbf{f}}(\mathbf{s}) = \exp(-2\pi i \mathbf{s}^\dagger \bar{\mathbf{f}}) \exp(-2\pi^2 \mathbf{s}^\dagger \mathcal{K}_{\mathbf{f}} \mathbf{s}), \quad (8.216)$$

where $\mathcal{K}_{\mathbf{f}}$ is the autocovariance operator, *i.e.*, the integral operator with kernel $K_{\mathbf{f}}(\mathbf{r}, \mathbf{r}')$.

From (8.216) and (8.96) we can readily show that all linear functionals of a normal random process are normal. If we let $\mathbf{g} = \mathcal{H}\mathbf{f}$, where \mathcal{H} is a linear CD mapping (see Sec. 7.3) defined by

$$g_m = \int_{\infty} d^q r h_m(\mathbf{r}) f(\mathbf{r}), \quad m = 1, \dots, M, \quad (8.217)$$

then (8.96) becomes

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \exp(-2\pi i \mathbf{s}^\dagger \mathcal{H}\bar{\mathbf{f}}) \exp(-2\pi^2 \mathbf{s}^\dagger \mathcal{H}\mathcal{K}_{\mathbf{f}}\mathcal{H}^\dagger \mathbf{s}). \quad (8.218)$$

By comparison with (8.196), we see that \mathbf{g} is an MD random vector with mean $\mathcal{H}\bar{\mathbf{f}}$ and covariance $\mathcal{H}\mathbf{K}_f\mathcal{H}^\dagger$.

Exactly the same conclusion holds when \mathcal{H} is an integral operator. Linear filtering of a normal random process yields another normal random process. Since normal processes are fully determined by their mean and autocovariance (or autocorrelation) function, the formulas given in Sec. 8.2.6 are all we need for a complete statistical description of the output of a linear filter *if* we know that the input is a normal process.

Multipoint densities and autocovariance functions One way of defining a normal random vector is to require that all of its marginals must be normal (Sec. 8.3.3). Similarly, a normal random process can be defined as one for which all univariate or multivariate marginals are normal. In that approach, a random process $f(\mathbf{r})$ is normal if all M -point PDFs, $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2), \dots, f(\mathbf{r}_M)]$ for all M , are normal. We can use (8.218) to show that defining a normal random process by (8.216) is equivalent to requiring that all multipoint densities be normal. Evaluating the random process at the M points $\{\mathbf{r}_m, m = 1, \dots, M\}$ is a CD mapping with

$$h_m(\mathbf{r}) = \delta(\mathbf{r} - \mathbf{r}_m). \quad (8.219)$$

Thus $g_m = f(\mathbf{r}_m)$, and it follows at once from (8.218) that $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2), \dots, f(\mathbf{r}_M)]$ is an MD normal density. An explicit form for this density can be stated most compactly by defining an $M \times 1$ vector \mathbf{f}_M with m^{th} component given by $f(\mathbf{r}_m)$. For simplicity we assume that $f(\mathbf{r})$ is real. Then the M -point PDF is given by

$$\begin{aligned} \text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2), \dots, f(\mathbf{r}_M)] &= \text{pr}(\mathbf{f}_M) \\ &= (2\pi)^{-\frac{1}{2}M} |\det \mathbf{K}_M|^{-\frac{1}{2}} \exp \left[-\frac{1}{2}(\mathbf{f}_M - \bar{\mathbf{f}}_M)^t \mathbf{K}_M^{-1} (\mathbf{f}_M - \bar{\mathbf{f}}_M) \right], \end{aligned} \quad (8.220)$$

where $\bar{\mathbf{f}}_M$ is the $M \times 1$ mean vector, with components $\langle f(\mathbf{r}_m) \rangle$, and \mathbf{K}_M is the $M \times M$ covariance matrix, with components given by

$$[\mathbf{K}_M]_{mn} = \langle [f(\mathbf{r}_m) - \langle f(\mathbf{r}_m) \rangle] [f(\mathbf{r}_n) - \langle f(\mathbf{r}_n) \rangle] \rangle. \quad (8.221)$$

Comparison with (8.98) shows that

$$[\mathbf{K}_M]_{mn} = K_f(\mathbf{r}_m, \mathbf{r}_n). \quad (8.222)$$

Thus the covariance *matrix* in an M -point PDF for a normal random process is fully determined by the autocovariance *function* of the process. Knowledge of this function and $\langle f(\mathbf{r}) \rangle$ is therefore sufficient to specify all M -point densities and hence to fully characterize a normal process.

For completeness, we next show that (8.222) also follows from the transformation rule, $\mathbf{K}_g = \mathcal{H}\mathbf{K}_f\mathcal{H}^\dagger$. With $\mathbf{K}_g = \mathbf{K}_M$, and the kernel of \mathcal{H} as given by (8.219), we can write

$$\begin{aligned} [\mathbf{K}_M]_{mn} &= \left[\mathcal{H}\mathbf{K}_f\mathcal{H}^\dagger \right]_{mn} \\ &= \int_{-\infty}^{\infty} d^q r \int_{-\infty}^{\infty} d^q r' \delta(\mathbf{r} - \mathbf{r}_m) K_f(\mathbf{r}, \mathbf{r}') \delta(\mathbf{r}' - \mathbf{r}_n) = K_f(\mathbf{r}_m, \mathbf{r}_n), \end{aligned} \quad (8.223)$$

where the last step has used the sifting property of delta functions.

Ergodicity and stationarity Stationarity is defined for normal random processes just as for any other random process. A useful simplification, however, is that we do not have to distinguish wide-sense and narrow-sense stationarity in the normal case. Since the full statistics are inherent in the mean and autocovariance function, wide-sense stationarity (stationary mean and autocovariance) implies narrow-sense or strict stationarity (Papoulis, 1965).

For stationary Gaussian random processes, a straightforward criterion for ergodicity can be stated. Cornfield *et al.* (1982) show that such a process is ergodic if and only if its power spectral density is continuous. From (3.107) and the Wiener-Khinchin theorem (8.133), an equivalent statement is that a stationary Gaussian random process is ergodic if and only if its autocorrelation function vanishes at infinity. Since many physical processes are Gaussian as a result of the central-limit theorem, we can quite often invoke ergodicity on the basis of this theorem.

8.3.6 Complex Gaussian random fields

It is often useful to describe a wave by its complex amplitude. If the wave is regarded as random, perhaps because it has been scattered from a random object, then the wave amplitude $u(\mathbf{r}_1)$ at any point \mathbf{r}_1 is a complex random variable. Similarly, the set of amplitudes at K different points, $\{u(\mathbf{r}_k), k = 1, \dots, K\}$, is a KD complex vector, and $u(\mathbf{r})$ itself is a complex random process. Moreover, a wave amplitude is usually computed as a diffraction integral or some other linear superposition. If different elements of this superposition are linearly independent random variables, then the central-limit theorem will lead to normal distributions, so we often encounter complex Gaussian random fields.

In one sense, there is nothing new about complex Gaussian random fields; we can describe them with the tools already developed for real Gaussian fields just by considering the real and imaginary parts separately. For example, a $K \times 1$ complex vector can also be written as a $2K \times 1$ real vector, where the first K components are the real parts and the second K are the imaginary parts. The covariance matrix in the first case is a $K \times K$ Hermitian matrix with complex off-diagonal elements, and in the second case it is a $2K \times 2K$ real, symmetric matrix.

Random phase If the complex variables result from random waves, the physics of wave propagation may allow us to impose some additional restrictions, thereby simplifying the mathematics. The phase of a wave relates to the total optical pathlength from a radiation source to the point at which the phase is measured. The natural unit of this pathlength is the wavelength, and typically the paths are very long compared to a wavelength. That means that if we alter the pathlength by a small fraction in absolute terms, it may nevertheless change by several wavelengths, and each change of one wavelength alters the phase by 2π . Now, the pathlength (in units of wavelength) may be random for many reasons: we may consider an ensemble of objects with different positions and different rough surfaces, or we may interpose random phase-altering elements such as diffuse reflectors or ground-glass screens, or we may consider a broad spectrum of wavelengths. The result is that it is frequently an excellent approximation to assume that the phase is completely random.

To state this approximation more mathematically, we denote the wave amplitude (at some unspecified point) by $u = Ae^{i\phi} = x + iy$, where $x = \text{Re}(u)$ and

$y = \text{Im}(u)$ and A is a real number. We do not need to consider phase angles ϕ outside the range $[0, 2\pi)$ since $e^{i\phi}$ is periodic. The phase randomness implies that the PDF on ϕ is constant in this range. The constant can be fixed since the PDF must be normalized to unity, and we can write

$$\text{pr}(\phi) = \frac{1}{2\pi}, \quad 0 \leq \phi < 2\pi. \quad (8.224)$$

We assume that this PDF on ϕ is valid for all A , so $\text{pr}(\phi|A) = \text{pr}(\phi)$, and ϕ and A are statistically independent.

We can use this density to deduce some important properties of u even without specifying the statistics of A . Since the real and imaginary parts of u are given by

$$x = A \cos \phi, \quad y = A \sin \phi, \quad (8.225)$$

we see that (8.224) implies

$$\langle x \rangle = \langle A \cos \phi \rangle = 0, \quad \langle y \rangle = \langle A \sin \phi \rangle = 0. \quad (8.226)$$

Thus x and y are both zero-mean, and hence so is the complex u .

The variances of x and y must be equal since

$$\langle x^2 \rangle = \langle A^2 \cos^2 \phi \rangle = \frac{1}{2} \langle A^2 \rangle, \quad \langle y^2 \rangle = \langle A^2 \sin^2 \phi \rangle = \frac{1}{2} \langle A^2 \rangle. \quad (8.227)$$

The marginal PDFs on x and y must also be the same, regardless of the PDF of A , since $\sin \phi$ and $\cos \phi$ have the same PDFs if ϕ is uniform. (As an exercise, the reader can determine what this PDF is.) Moreover, x and y are uncorrelated since

$$\langle xy \rangle = \langle A^2 \cos \phi \sin \phi \rangle = 0. \quad (8.228)$$

We can summarize the last two equations in complex form by writing

$$\langle u^2 \rangle = \langle u^{*2} \rangle = 0, \quad \langle uu^* \rangle = \langle u^*u \rangle = \langle A^2 \rangle \neq 0. \quad (8.229)$$

Invocation of the central-limit theorem If we now assume that the wave amplitude at any point is the sum of contributions from many independent sources (perhaps points on an illuminated rough surface), then the real and imaginary parts are normal by the central-limit theorem. That means that x and y are not only uncorrelated but also statistically independent; we say that x and y are i.i.d. (independently and identically distributed). Their joint density is given by

$$\text{pr}(x, y) = \frac{1}{2\pi\sigma^2} \exp\left(-\frac{x^2 + y^2}{2\sigma^2}\right), \quad (8.230)$$

where σ^2 is the common variance of x and y . Contours of constant PDF in the x - y plane are circles (see Fig. 8.3), so u is referred to as a *circular Gaussian* random variable.

Fig. 8.3 Surfaces of constant probability density for a circular Gaussian random variable.

Other useful PDFs Since $A = \sqrt{x^2 + y^2}$ and $\phi = \tan^{-1}(y/x)$, we can convert $\text{pr}(x, y)$ in (8.230) to $\text{pr}(A, \phi)$ by means of (C.104). The result is the *Rayleigh distribution*, given in (C.140) as

$$\text{pr}(A, \phi) = \frac{A}{2\pi\sigma^2} \exp\left(-\frac{A^2}{2\sigma^2}\right). \quad (8.231)$$

We shall see in Chap. 11 that the irradiance $I = |u|^2$ plays a key role in photodetection and photon counting. If $\text{pr}(x, y)$ is given by (8.230), the PDF on I and ϕ is

$$\text{pr}(I, \phi) = \frac{1}{2\pi\bar{I}} \exp\left(\frac{-I}{\bar{I}}\right), \quad (8.232)$$

where $\bar{I} = 2\sigma^2$. The PDF on I alone, obtained by omitting the 2π in (8.232), is a chi-squared PDF with two degrees of freedom (see Sec. C.5.5). In general, a chi-squared random variable with N degrees of freedom is the sum of the squares of N i.i.d. normal random variables; here $N = 2$ since $I = x^2 + y^2$.

Two-point densities for circular Gaussians Next we examine two-point PDFs involving a complex circular Gaussian random process $u(\mathbf{r})$ at points $\mathbf{r} = \mathbf{r}_1$ and $\mathbf{r} = \mathbf{r}_2$. For notational simplicity, we write $u(\mathbf{r}_1) = u_1 = x_1 + iy_1 = A_1 \exp(i\phi_1)$, and similarly for $u(\mathbf{r}_2)$. One way we could specify the two-point density would be to construct the real 4D vector $\mathbf{U} = (x_1, x_2, y_1, y_2)^t$ and give the 4D PDF for it. If $u(\mathbf{r})$ is to be circular Gaussian, this PDF has to satisfy some constraints. For one thing, if we want u_1 and u_2 to be individual circular Gaussians, the marginals on (x_1, y_1) and (x_2, y_2) must both satisfy (8.230), possibly with different variances. In addition, the joint density on all four variables must be consistent with the autocovariance function of the process,

$$K_{\mathbf{u}}(\mathbf{r}_1, \mathbf{r}_2) = \langle u_1 u_2^* \rangle \equiv k = k' + ik''. \quad (8.233)$$

These conditions lead to

$$\langle x_1 x_2 \rangle = \langle y_1 y_2 \rangle = \frac{1}{2}k', \quad -\langle x_1 y_2 \rangle = \langle y_1 x_2 \rangle = \frac{1}{2}k'' \quad \langle x_1 y_1 \rangle = \langle x_2 y_2 \rangle = 0. \quad (8.234)$$

All of these conditions are satisfied if $\mathbf{U} \sim \mathcal{N}_4(\mathbf{0}, \mathbf{K}_U)$, where

$$\mathbf{K}_U = \begin{bmatrix} \sigma_1^2 & \frac{1}{2}k' & 0 & -\frac{1}{2}k'' \\ \frac{1}{2}k' & \sigma_2^2 & \frac{1}{2}k'' & 0 \\ 0 & \frac{1}{2}k'' & \sigma_1^2 & \frac{1}{2}k' \\ -\frac{1}{2}k'' & 0 & \frac{1}{2}k' & \sigma_2^2 \end{bmatrix}. \quad (8.235)$$

The redundancy in the elements of this matrix should be noted. A general 4×4 covariance matrix would have 10 independent elements, but only four real numbers ($\sigma_1^2, \sigma_2^2, k'$ and k'') are required to specify \mathbf{K}_U . This redundancy is required in order to represent a circular Gaussian as opposed to a more general complex Gaussian random vector.

Two-dimensional formulation To go from the covariance in (8.235) to the PDF for \mathbf{U} requires inverting \mathbf{K}_U and computing the quadratic form $\mathbf{U}^t \mathbf{K}_U^{-1} \mathbf{U}$. The algebra is not terrible, but a simpler approach, and one that extends more readily to higher dimensions, is to use a 2D complex vector rather than a 4D real one. If we define a 2D vector \mathbf{u} with complex components u_1 and u_2 , its covariance matrix is

$$\mathbf{K}_u = \begin{bmatrix} 2\sigma_1^2 & k \\ k^* & 2\sigma_2^2 \end{bmatrix}. \quad (8.236)$$

The inverse covariance, which is what we need in the PDF, is given by

$$\mathbf{K}_u^{-1} = \frac{1}{4\sigma_1^2\sigma_2^2 - |k|^2} \begin{bmatrix} 2\sigma_2^2 & -k \\ -k^* & 2\sigma_1^2 \end{bmatrix}. \quad (8.237)$$

The quadratic form in the PDF is thus

$$\mathbf{u}^\dagger \mathbf{K}_u^{-1} \mathbf{u} = \frac{2\sigma_2^2|u_1|^2 + 2\sigma_1^2|u_2|^2 - ku_1^*u_2 - k^*u_2^*u_1}{4\sigma_1^2\sigma_2^2 - |k|^2}, \quad (8.238)$$

and the corresponding PDF is given by (Neuser and Massey, 1993; Mandel and Wolf, 1995)

$$\text{pr}(\mathbf{u}) = \frac{1}{\pi^2 \det(\mathbf{K}_u)} \exp(-\mathbf{u}^\dagger \mathbf{K}_u^{-1} \mathbf{u}). \quad (8.239)$$

The reader might have expected a factor of $\frac{1}{2}$ in the exponent and a different normalizing factor [*cf.* (8.185)], but (8.239) is correct as written. One way to make it plausible is to assume there is no correlation, so $k = 0$, so that (8.237) becomes

$$\mathbf{K}_u^{-1} = \begin{bmatrix} \frac{1}{2\sigma_1^2} & 0 \\ 0 & \frac{1}{2\sigma_2^2} \end{bmatrix}. \quad (8.240)$$

Hence, (8.239) becomes

$$\text{pr}(\mathbf{u}) = \frac{1}{4\pi^2\sigma_1^2\sigma_2^2} \exp\left[-\frac{x_1^2 + y_1^2}{2\sigma_1^2} - \frac{x_2^2 + y_2^2}{2\sigma_2^2}\right], \quad (8.241)$$

which is just what one would get with the 4D real formulation, using (8.235) with $k = 0$ and (8.185). The reader may check that the 2D complex and 4D real formulations also agree when $k \neq 0$. (The 4D determinant must be evaluated by minors.)

Complex Gaussian vectors Most authors use the $2ND$ real formulation to deal with ND complex random vectors, but there is a significant literature on the complex formulation. The classic text by Doob (1953) discusses the problem, and Wooding (1956) first derived a form like (8.239).

Later authors, however, recognized some surprising features of the complex case (Reed, 1962; Goodman, 1963; Neeser and Massey, 1993). For example, we must revisit the familiar statement that the PDF for a Gaussian random vector is fully determined by its covariance matrix. For a complex random vector, the covariance is defined by $\mathbf{K}_{\mathbf{u}} = \langle (\mathbf{u} - \bar{\mathbf{u}})(\mathbf{u} - \bar{\mathbf{u}})^\dagger \rangle$, but the most general PDF for a Gaussian random vector also involves the *pseudocovariance* $\langle (\mathbf{u} - \bar{\mathbf{u}})(\mathbf{u} - \bar{\mathbf{u}})^t \rangle$, with a transpose in place of the adjoint.

As defined by Neeser and Massey (1993), a complex random vector is said to be *proper* if its pseudocovariance vanishes identically. Any subvector of a proper random vector is proper, but two individually proper random vectors are not necessarily jointly proper. These authors also show that any linear or affine transformation of a proper random vector is another proper random vector, and that a real random vector can be proper if and only if it is a constant.

The condition that the pseudocovariance of a complex vector vanish can be restated in terms its real and imaginary components. If we write $\mathbf{u} = \mathbf{x} + i\mathbf{y}$, then \mathbf{u} is proper if and only if

$$\langle (\mathbf{x} - \bar{\mathbf{x}})(\mathbf{x} - \bar{\mathbf{x}})^t \rangle = \langle (\mathbf{y} - \bar{\mathbf{y}})(\mathbf{y} - \bar{\mathbf{y}})^t \rangle \quad \text{and} \quad \langle (\mathbf{x} - \bar{\mathbf{x}})(\mathbf{y} - \bar{\mathbf{y}})^t \rangle = -\langle (\mathbf{x} - \bar{\mathbf{x}})(\mathbf{y} - \bar{\mathbf{y}})^t \rangle^t. \quad (8.242)$$

Thus \mathbf{x} and \mathbf{y} must have identical autocovariance matrices, and their cross-covariance matrix must be skew-symmetric.

For optical applications, we are often interested in zero-mean proper Gaussian random vectors and processes, for which the term *circular Gaussian* is commonly used. To be explicit, an ND complex vector \mathbf{u} will be said to obey a circular Gaussian law if all marginals are normal, all components have zero mean and the conditions in (8.242) hold; these conditions can be stated in complex form as

$$\langle u_n u_m \rangle = \langle u_n^* u_m^* \rangle = 0, \quad 1 \leq n, m \leq N \quad (8.243)$$

and

$$\langle u_n u_m^* \rangle = \langle u_m u_n^* \rangle^* = K_{nm}. \quad (8.244)$$

The intuition behind (8.243) is that u_n can be written as $|u_n| \exp(i\phi_n)$, where ϕ_n is uniformly distributed over $(0, 2\pi)$ but possibly correlated with ϕ_m for $n \neq m$. The expectation $\langle u_n u_m \rangle$ is zero because $\exp[i(\phi_n + \phi_m)]$ takes any value on the unit circle with equal probability. One can think of choosing a ϕ_n from the conditional density $\text{pr}(\phi_n | \phi_m)$ and then choosing ϕ_m from the uniform density; no matter what ϕ_n is chosen in the first step, the second choice means that $\phi_n + \phi_m$ (modulo 2π) is equally likely to be anywhere in $(0, 2\pi)$. On the other hand, $\langle u_n u_m^* \rangle$ depends on $\exp[i(\phi_n - \phi_m)]$, and this average is not zero if ϕ_n and ϕ_m tend to fluctuate together; the second choice tends to undo the first.

The PDF of an ND circular Gaussian random vector is a generalization of (8.239):

$$\text{pr}(\mathbf{u}) = \frac{1}{\pi^N \det(\mathbf{K}_{\mathbf{u}})} \exp(-\mathbf{u}^\dagger \mathbf{K}_{\mathbf{u}}^{-1} \mathbf{u}). \quad (8.245)$$

Thus the only change in going from 2D to ND is the power of π . It is proven in Bellman (1995) that this density is properly normalized, and the reader can check it by considering the basis in which $\mathbf{K}_{\mathbf{u}}$ is diagonal.

The characteristic function for complex random vectors is defined in (8.33); for an ND circular Gaussian it is given by

$$\psi_{\mathbf{u}}(\boldsymbol{\xi}) = \exp(-\pi^2 \boldsymbol{\xi}^\dagger \mathbf{K}_{\mathbf{u}} \boldsymbol{\xi}), \quad (8.246)$$

where $\boldsymbol{\xi}$ is an ND complex vector. Note the absence of a factor of 2 in the exponent when compared to the corresponding expression (8.196) for a real Gaussian random vector.

Moments The characteristic function can be used to derive all moments of a random vector. For complex random vectors, the rules for complex differentiation given in Sec. A.9.5 must be used. The reader may use these rules to verify that (8.246) is consistent with the second moments stated in (8.243) and (8.244).

Higher moments are also of interest in many problems. For circular Gaussians, all odd moments vanish, as do all even moments where the number of factors without the complex conjugate is not equal to the number with the conjugate. All other even moments can be expressed in terms of components of the covariance matrix via the *complex Gaussian moment theorem*, first derived by Reed (1962) and discussed by Goodman (1985) in terms of real components and by Osche (2002) in complex form. Osche's statement of the theorem is

$$\langle u_{n_1} u_{n_2} \cdots u_{n_t} u_{m_1}^* u_{m_2}^* \cdots u_{m_t}^* \rangle = \sum_{\pi} \langle u_{n_1} u_{m_{\pi(1)}}^* \rangle \langle u_{n_2} u_{m_{\pi(2)}}^* \rangle \cdots \langle u_{n_t} u_{m_{\pi(t)}}^* \rangle, \quad (8.247)$$

where $\pi(\cdot)$ is a permutation of the set of integers $\{1, 2, \dots, t\}$, and the sum is over all possible permutations. Some useful special cases are:

$$\langle |u_i|^{2n} \rangle = n! \langle |u_i|^2 \rangle^n = n! \sigma_i^{2n}; \quad (8.248)$$

$$\langle (u_i u_j^*)^n \rangle = n! \langle u_i u_j^* \rangle^n = n! K_{ij}^n; \quad (8.249)$$

$$\langle u_i u_j u_k^* u_\ell^* \rangle = \langle u_i u_k^* \rangle \langle u_j u_\ell^* \rangle + \langle u_j u_k^* \rangle \langle u_i u_\ell^* \rangle = K_{ik} K_{j\ell} + K_{jk} K_{i\ell}. \quad (8.250)$$

This latter equation should be compared to the corresponding real result in (8.197); the complex expression has a sum of two covariances while the real expression has three. We see that $\langle |u_i|^4 \rangle = 2\sigma_i^4$, but for a real, zero-mean, Gaussian random variable, $\langle g_i^4 \rangle = 3\sigma_i^4$. The reader can verify this result by writing $u_i = x_i + iy_i$ and using the real Gaussian moment theorem.

Circular Gaussian random processes A complex random process $u(\mathbf{r})$ will be said to be circular Gaussian if all N -point PDFs are multivariate circular Gaussian random vectors. We can specify this process, as in Sec. 8.3.5, by its characteristic *functional*, given by [cf. (8.216)]

$$\Psi_{\mathbf{u}}(\mathbf{s}) = \exp(-\pi^2 \mathbf{s}^\dagger \mathcal{K}_{\mathbf{u}} \mathbf{s}), \quad (8.251)$$

where \mathbf{s} is a square-integrable function and $\mathcal{K}_{\mathbf{f}}$ is the autocovariance operator, *i.e.*, the integral operator with kernel $K_{\mathbf{u}}(\mathbf{r}, \mathbf{r}') = \langle u(\mathbf{r}) u^*(\mathbf{r}') \rangle$. We shall make good use of (8.251) in Chap. 18 when we discuss speckle.

8.4 STOCHASTIC MODELS FOR OBJECTS

We argued in Chap. 7 that an object was best described by a function $f(\mathbf{r})$ (where \mathbf{r} is usually a position vector); now we shall regard this function as a sample function of a random process. The random process is the collection of all possible objects of a given category that might be presented to the imaging system. For example, in computed tomography of the brain, a particular object $f(\mathbf{r})$ is one patient's brain at the time of one imaging procedure, but we can imagine an infinite ensemble of brains from which this one object is drawn. Ideally we would like to specify the full, infinite-dimensional, probability density function (PDF) of the process. As we shall see in Sec. 8.4.1, however, a full PDF is seldom possible, even in principle, and we must make do with less complete models.

The literature on stochastic models in image science is rich and varied, but often the distinction between an object model and an image model is not clear. Many papers claim to address the statistics of images but leave out any consideration of measurement noise or system blur. Moreover, these papers often treat the image as a function of continuous spatial coordinates rather than as a discrete array. Thus they really apply more to objects than to real-world images. On the other hand, if we want to verify our theories by measurements, all we have access to is images, and there is a gap in the current literature on how one can verify stochastic models of objects from observations on noisy, blurred, discrete images.

Another confusing aspect of much of the literature has to do with the meaning of probability. First, there is an unfortunate emphasis on ergodic models where it is assumed, often tacitly, that probabilistic statements can be made for a single object or image. Thus a gray-level histogram of a single image is treated as a probability distribution for pixel values. At best the histogram is an estimate of the probability law for an ensemble of similar images, and then only if ergodicity and hence stationarity are assumed. Except for relatively contrived situations, stationarity is unlikely to hold over the full expanse of an object or image (though local stationarity may be more defensible).

Closely associated with the emphasis on stationarity is the use of loosely defined Fourier measures called *power spectra*. Often this term refers to nothing more than the square modulus of the Fourier transform of a single image. With an assumption of ergodicity this quantity is an estimate of the power spectral density, defined in Sec. 8.2.5 as the Fourier transform of the statistical autocorrelation function. We know from Fig. 8.1, however, that the estimate is poor, and in any case the implicit statistical ensemble is seldom specified, and the underlying stationarity assumption is almost never justified.

Another issue is the conflict between Bayesian and frequentist interpretations of probability, introduced in the Prologue. For many purposes, we want models that emulate reality, in the sense that the model predictions can be verified in principle by measurements on real objects, so we are using a frequentist interpretation of probability. Bayesian interpretations of probability are often useful, however, especially in drawing inferences from images when we have some degree of prior belief

about the structure of the object but the frequentist information is incomplete (as it always is). The use of Bayesian priors will be explored further in Chaps. 13 and 15, but the emphasis in this section is descriptive: What can we say about collections of real objects?

In practice, even the very concept of a *real object* must often be expanded. Computer simulations are becoming ever more realistic and ever more essential in image science, and we do not rule out collections of simulations as the ensemble of objects for which we seek a stochastic model.

To state clearly the focus of this section, then, we are considering an ensemble interpretation of probability as applied to objects regarded as sample functions of a random process. The sample function can, in principle, be an actual object $f(\mathbf{r})$, but in practice it may be some approximate representation $f_a(\mathbf{r})$ as introduced in Sec. 7.1.3, and the object can be simulated rather than real.

We begin in Sec. 8.4.1 with a general discussion of just what we mean by the probability density function for an object class and how we might approach the problem experimentally. Included in this section is an introduction to the important concept of independent components.

In Sec. 8.4.2 we revisit the discussion from Sec. 8.2.2 on multipoint densities, but now specifically for objects. Again the focus is on experimental determination of stochastic models.

In Sec. 8.4.3 we do what all statisticians do when problems get difficult: we assume normality. Some implications of the central-limit theorem are discussed, and Gaussian mixture models are introduced. Surprisingly, Gaussian mixture models turn out to account for the highly non-Gaussian character of many filtered images.

In Sec. 8.4.4 we turn to the widely studied but loosely defined topic of texture. For purposes of this section, a texture is regarded as any random field with some degree of stationarity. We discuss here ways of synthesizing sample textures as well as mathematical models for the PDFs.

Sec. 8.4.5 is prelude to the discussion of signal detection in Chap. 13. We make a distinction between signals and backgrounds, and we look at how various assumptions about the signal affect the overall object PDF.

8.4.1 Probability density functions in Hilbert space

To develop a Hilbert-space PDF for objects, we assume that a function $f(\mathbf{r})$ representing a particular object is square-integrable and therefore corresponds to a vector \mathbf{f} in $\mathbb{L}_2(\mathbf{S}_f)$, where \mathbf{S}_f is a support region that will cover all object functions under consideration. Then \mathbf{f} can be expanded as in (8.76):

$$\mathbf{f} = \sum_{n=1}^{\infty} \alpha_n \psi_n, \quad (8.252)$$

where the set $\{\psi_n\}$ is some convenient basis for $\mathbb{L}_2(\mathbf{S}_f)$. The coefficients $\{\alpha_n\}$ are the components of \mathbf{f} in this basis. If the basis is orthonormal, the infinite-dimensional vector of coefficients, denoted $\boldsymbol{\alpha}$, is a unitary transformation of \mathbf{f} .

Intuitively, \mathbf{f} corresponds to a single point in the space (or a vector from the origin to the point), and the density $\text{pr}(\mathbf{f})$ is a measure of how these points cluster in the Hilbert space. The density $\text{pr}(\boldsymbol{\alpha})$ describes this same clustering in terms of specific basis vectors ψ_n .

A graphical depiction of this clustering is shown in Fig. 8.4. The two axes shown can be construed as any two components $\{\alpha_n, \alpha_m\}$ out of the infinite set.

Fig. 8.4 Graphical depiction of the clustering of an object PDF. Two axes out of an infinite-dimensional Hilbert space are shown, and each point corresponds to a different object.

Subspaces We can never hope to know the full PDF in an infinite-dimensional space (and we wouldn't know what to do with it if we had it), but our ultimate goal is always to obtain a PDF $\text{pr}(\mathbf{g})$ for images (see Sec. 8.5). Since the data are insensitive to null functions of the imaging operator \mathcal{H} , and all real measurement operators have finite rank R , we can always get by with a finite-dimensional subspace of the object space \mathbb{U} . As we know from Sec. 7.4.3, we can use the singular vectors of \mathcal{H} as the expansion functions and truncate the expansion at $n = R$; this truncation produces no error in the data and hence no error in $\text{pr}(\mathbf{g})$.

Another way to restrict the dimensionality is to construct an approximate representation of \mathbf{f} , just as we did in Chap. 7, and then consider the PDF of the approximate vector \mathbf{f}_a . This procedure can lead to an error in $\text{pr}(\mathbf{g})$, but it will be small if the image error defined in Sec. 7.4.3 is small for all objects in the ensemble. In fact, the image error will be zero if we use natural pixels as the expansion functions (see Sec. 7.4.3).

Experimental determination of the object density We can imagine obtaining information about the object density by examining a large number of typical object functions. There are several ways we could know the object function. For example, we might use a computer program that can simulate sample functions $f(\mathbf{r})$, and for each sample function we could obtain components α_n by computing scalar products with the corresponding basis functions $\psi_n(\mathbf{r})$. (In fact, if a set of components is chosen in advance, the computer program could advantageously generate the sample functions in this basis in the first place.)

Alternatively, we may want to construct a stochastic model useful for one particular imaging system, say a relatively low-resolution, noisy one, but we might have available images from another system with better resolution and less noise. We could then treat the *images* from the better system as good representations of *objects* for the poorer system.

Finally, we might have some physical model, known as a phantom in the medical-imaging literature. If the phantom can be reconfigured into different objects by moving components around in a controllable fashion, it can generate a set of known sample objects.

With any of these sources of sample objects, a histogram estimate of, say, $\text{pr}(\alpha_n, \alpha_m)$ could be obtained by a frequentist interpretation of the PDF. By a

multivariate generalization of (C.21), we can write⁸

$$\begin{aligned} & \text{pr}_{(\alpha_n, \alpha_m)}(\alpha_{nk}, \alpha_{mk}) \\ \equiv & \lim_{\Delta\alpha \rightarrow 0} \frac{1}{(\Delta\alpha)^2} \text{Pr}(\alpha_{nk} - \frac{1}{2}\Delta\alpha \leq \alpha_n < \alpha_{nk} + \frac{1}{2}\Delta\alpha, \alpha_{mk} - \frac{1}{2}\Delta\alpha \leq \alpha_m < \alpha_{mk} + \frac{1}{2}\Delta\alpha). \end{aligned} \tag{8.253}$$

The histogram estimate is obtained by considering finite bins of width $\Delta\alpha$ (hence omitting the limit) and approximating the probabilities on the right with observed frequencies of occurrence in a finite number of sample objects. Thus we approximate the density as

$$\widehat{\text{pr}}_{(\alpha_n, \alpha_m)}(\alpha_{nk}, \alpha_{mk}) \equiv \frac{1}{(\Delta\alpha)^2} \frac{J(\alpha_{nk}, \alpha_{mk})}{J}, \tag{8.254}$$

where $J(\alpha_{nk}, \alpha_{mk})$ is the number of times (out of J sample objects) that the computed value of (α_n, α_m) falls in a square of size $(\Delta\alpha)^2$ centered on point $(\alpha_{nk}, \alpha_{mk})$. This estimate can, in principle, be extended to an arbitrary number of dimensions.

The problem with this scenario is that the required number of samples may be impractical. As a numerical example, suppose the objects can be adequately specified by 10^4 terms in (8.252), so we are seeking to construct a histogram approximation to a PDF in a ten-thousand-dimensional space. If we choose to use just 10 bins along each axis in the space, then there are $10^{10,000}$ total bins to fill. This is an immense⁹ number, and there is no hope of filling the bins with experimental samples. Even with a drastically truncated set of components, $\text{pr}(\boldsymbol{\alpha})$ cannot be interpreted in frequentist terms.

Independent components The number of samples required for a histogram estimate would be much smaller if the components were statistically independent. In that case, for an ND representation, we would have

$$\text{pr}(\boldsymbol{\alpha}) = \prod_{n=1}^N \text{pr}(\alpha_n), \tag{8.255}$$

so we would need only a set of N univariate densities instead of an N -dimensional multivariate one.

In contrast to $\text{pr}(\boldsymbol{\alpha})$, the univariate density $\text{pr}(\alpha_n)$ does admit of a frequentist interpretation and a histogram estimate. Suppose, as above, that we have some source of object functions $f(\mathbf{r})$, perhaps a computer simulation code. For each sample function we can evaluate α_n by the usual scalar product, and the histogram estimate of $\text{pr}(\alpha_n)$ is defined by [cf. (8.254)]

$$\widehat{\text{pr}}_{\alpha_n}(\alpha_{nk}) = \frac{1}{\Delta\alpha} \frac{J_{nk}}{J}, \tag{8.256}$$

⁸Recall our notational convention that subscripts on PDFs are deleted where they are redundant with the argument. Thus $\text{pr}(x)$ and $\text{pr}_x(x)$ mean the same thing but the subscript is reinstated on $\text{pr}_x(x_0)$, which means $\text{pr}_x(x)$ evaluated at $x = x_0$.

⁹We use the term *immense* here in its literal sense: incapable of mensuration, immeasurable. Certainly any number exceeding the number of atoms in the universe (of order 10^{80}) qualifies as immense.

where α_{nk} is the specific value of α_n centered on the k^{th} bin, and J_{nk} is the number of times α_n falls in that bin.

The number J_{nk} is a random variable; if the experiment is repeated many times with different sample objects, J_{nk} will be binomially distributed, and the full set of J_{nk} values will be multinomially distributed (see Secs. C.6.1. and 11.2.1). The mean value of J_{nk} will be J times the probability that α_n falls in bin k , or

$$\langle J_{nk} \rangle \approx J \text{pr}_{\alpha_n}(\alpha_{nk}) \Delta\alpha. \quad (8.257)$$

If the number of bins is large, the probability that α_n will fall in one particular bin is small, and any reasonable experiment will use a large value for J , so we are dealing with rare events (see Sec. 11.1.2) where the binomial law on J_{nk} is well approximated by a Poisson.

As a practical example, suppose we want to construct a 100-bin histogram. By the Poisson statistics, a relative error (standard deviation divided by mean) of 10% in the value estimated for the k^{th} bin requires $\langle J_{nk} \rangle = 100$, and a relative error of 1% requires $\langle J_{nk} \rangle = 10^4$. To relate these numbers to the required number of images, we must make some assumptions about the underlying distribution of α_n . If we assume that $\text{pr}(\alpha_n)$ is relatively flat over the range from 0 to α_{max} , then each $\langle J_{nk} \rangle$ is approximately J divided by the number of bins, or $0.01J$ in our example. Thus we require $J = 10^4$ for 10% accuracy and 10^6 for 1% accuracy in a 100-bin histogram. These numbers are large but not immense; they are well within the capabilities of modern computers if the sample objects are simulated. Moreover, each simulated object can be used to evaluate each α_n , so we get the full multivariate PDF for this amount of simulation effort, but only if the components are independent.

Finding the independent components One approach to finding approximately independent components is the Karhunen-Loève (KL) expansion, introduced in Sec. 7.2.4. In Sec. 8.2.7 we showed that the KL expansion yields uncorrelated coefficients, and if we can argue that the process is Gaussian (see Sec. 8.4.3), then uncorrelated implies independent.

To use this argument, we must know the KL expansion. For stationary random processes, as discussed in Sec. 8.2.4, KL expansion is Fourier analysis, but with nonstationary models it can be difficult to determine the autocorrelation function, much less to diagonalize it and find the KL basis. As we shall see in Sec. 8.4.5, some authors argue that wavelet coefficients are approximately uncorrelated for natural scenes, so a wavelet transformation is approximately a KL transformation. Even when this argument can be justified, however, it is still necessary to show that the wavelet coefficients are Gaussian random variables if we want to use (8.255), and we shall present an argument in Sec. 8.4.3 showing why this is *not* the case for a wide class of natural scenes.

When the process is not Gaussian or when we do not know the KL expansion, it may nevertheless be possible to find a transformation that makes the expansion coefficients approximately independent. To make this statement more precise, we need some definition of degree of dependence.

One way to define degree of dependence is in terms of the distance, in some sense, between the multivariate density and the product of its marginals. One distance measure used for this purpose is the *Kullback-Leibler distance*, known also as the *cross-entropy* or *mutual information*. If we consider an $N \times 1$ vector β with

density $\text{pr}(\boldsymbol{\beta})$, the Kullback-Leibler distance between this density and the product of its marginals is defined by (Comon, 1994)

$$I(\boldsymbol{\beta}) = \int_{\infty} d^N \boldsymbol{\beta} \text{pr}(\boldsymbol{\beta}) \ln \left\{ \frac{\text{pr}(\boldsymbol{\beta})}{\prod_{n=1}^N \text{pr}(\beta_n)} \right\}. \quad (8.258)$$

Note that $I(\boldsymbol{\beta})$ is not a true distance, as defined in Sec. 1.1.2, since it is not symmetric in interchange of $\text{pr}(\boldsymbol{\beta})$ and $\prod_{n=1}^N \text{pr}(\beta_n)$. It does, however, vanish when these two densities are equal, since the argument of the logarithm is unity in that case, and it follows from the convexity of the logarithm that $I(\boldsymbol{\beta}) \geq 0$ (Kendall and Stuart, 1979). Thus independent components can be sought by attempting to find a basis that minimizes $I(\boldsymbol{\beta})$.

Many other measures of degree of dependence are discussed by Comon (1994). In particular, he uses an Edgeworth approximation to argue that independent components will have marginals with large kurtoses, as defined in (C.41). He therefore suggests maximizing the sum of the squares of the marginal kurtoses as a way of finding approximately independent components. We refer the reader to Comon (1994) for a full justification of this approach.

Independent components analysis A structured approach to minimizing some measure of statistical dependence is *independent components analysis* or ICA. ICA is a refinement of *principal components analysis* or PCA, which we shall discuss first.

Though the terms PCA and KL are often used interchangeably in the literature, we make the distinction that PCA is diagonalization of the sample covariance matrix and KL is based on the ensemble covariance. Thus PCA approaches KL analysis as the number of samples goes to infinity.

Suppose we are given J samples of a random vector $\boldsymbol{\alpha}$, denoting the j^{th} sample by $\boldsymbol{\alpha}^{(j)}$. The sample covariance matrix $\widehat{\mathbf{K}}_{\boldsymbol{\alpha}}$ is defined by

$$\widehat{\mathbf{K}}_{\boldsymbol{\alpha}} = \frac{1}{J} \sum_{j=1}^J [\Delta \boldsymbol{\alpha}^{(j)}] [\Delta \boldsymbol{\alpha}^{(j)}]^{\dagger}, \quad (8.259)$$

where $\Delta \boldsymbol{\alpha}^{(j)}$ is $\boldsymbol{\alpha}^{(j)}$ minus the sample mean. PCA seeks to find a matrix \mathbf{M} such that the transformed sample vectors,

$$\boldsymbol{\beta}^{(j)} = \mathbf{M} \boldsymbol{\alpha}^{(j)}, \quad (8.260)$$

are uncorrelated and hence the transformed sample covariance matrix $\widehat{\mathbf{K}}_{\boldsymbol{\beta}}$ is diagonal. By retracing the discussion in Sec. 8.1.6 but with $\widehat{\mathbf{K}}$ in place of \mathbf{K} , we can see that this diagonalization is accomplished by using the eigenvectors of $\widehat{\mathbf{K}}_{\boldsymbol{\alpha}}$ as the columns of \mathbf{M} .

ICA also uses a transformation of the form (8.260), but now the goal is to minimize some measure of statistical dependence as discussed above or in much more detail in Comon (1994) and subsequent literature. Since statistically independent components are necessarily uncorrelated, ICA usually proceeds by first computing the PCA, so that the spectral decomposition of $\widehat{\mathbf{K}}_{\boldsymbol{\alpha}}$ is known, and then applying a prewhitening transformation as in (8.67). At this point we have a set of sample vectors such that the sample covariance matrix is the unit matrix, and all further

unitary transformations preserve this property. We thus decompose the matrix \mathbf{M} as

$$\mathbf{M} = \mathbf{U} \widehat{\mathbf{K}}_{\alpha}^{-\frac{1}{2}}, \quad (8.261)$$

where \mathbf{U} is unitary. ICA amounts to choosing \mathbf{U} so as to minimize the chosen measure of statistical dependence.

When ICA is carried out on training sets of natural scenes, the results are quite striking (see Bell and Sejnowski, 1997; Field, 1987; Olshausen and Field, 1996). The columns of \mathbf{M} turn out to be localized, bandpass functions similar to wavelets or to the channels in the human visual system (a topic to be treated in more detail in Chap. 14), suggesting that humans may have evolved in such a way as to process natural scenes through statistically independent channels (see also Barlow, 1989).

One practical implication of the observation that the independent components are localized is that we can treat small pieces of the same object (or image) as independent samples. Bell and Sejnowski (1997), for example, consider 12×12 segments of an image as the samples on which they perform ICA. The resulting ICA filters are smaller than 12 pixels, even though the corresponding PCA filters tend to fill the 12×12 region. The authors note, however, that the restriction to such a small region may be an unrealistic feature of their approach. In addition, pixels themselves are unrealistic if we wish to draw conclusions about “natural scenes.”

We shall revisit ICA in the context of texture analysis in Sec. 8.4.4. In that application, ICA is considerably simplified because textures are at least approximately stationary.

8.4.2 Multipoint densities

As we saw in Sec. 8.2.2, another kind of PDF for a random process is a collection of P -point densities of the form $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2), \dots, f(\mathbf{r}_P)]$. In principle one needs densities like this for all P to completely characterize the process, but often we must be content with $P = 1$ and 2.

In a sense, multipoint densities are just special cases of the Hilbert-space densities discussed above. If we use delta functions as basis functions for the space (see Sec. 2.2.6), then $f(\mathbf{r}_p)$ is the coefficient α_p associated with basis function $\delta(\mathbf{r} - \mathbf{r}_p)$, and $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2), \dots, f(\mathbf{r}_P)]$ is a P -dimensional marginal of a Hilbert-space density. This marginal is, however, a function of P spatial variables, so it is a richer description of the statistics of the random process than $\text{pr}(\alpha_1, \alpha_2, \dots, \alpha_P)$ would be with preselected basis functions.

If we have a means of computing $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2), \dots, f(\mathbf{r}_P)]$, we can in principle do it for all values of each of the spatial arguments, but a less ambitious goal is to sample the function on a regular spatial grid, making it a discrete random process. If \mathbf{r} is a q D vector and we sample each component to L values, then \mathbf{f} is specified by $N = L^q$ numbers, and the full density is defined in an ND space. In this sampled case, therefore, all of the P -fold multipoint densities can be computed from the ND density on \mathbf{f} . Nevertheless, it may be computationally or conceptually simpler to compute the multipoint densities directly rather than as marginals of a high-dimensional multivariate density.

Pointwise evaluation of random functions Before analyzing multipoint densities in more detail, we have to deal with one mathematical subtlety. So far we have assumed only that each sample function $f(\mathbf{r})$ is in an \mathbb{L}_2 space, but we noted in Sec. 1.8 that

not all functions in \mathbb{L}_2 are defined pointwise. If we want an expression like $f(\mathbf{r}_1)$ to be rigorously defined, we must assume that $f(\mathbf{r})$ lies in a reproducing-kernel Hilbert space (RKHS), which might be a subspace of \mathbb{L}_2 . For imaging purposes, this restriction entails no loss of generality; we saw in Chap. 7 that the imaging operator $\mathcal{H}^\dagger \mathcal{H}$ is a nonnegative-definite Hermitian operator, and we know from Sec. 1.8.2 that such an operator can be used to define an RKHS. Assuming that $f(\mathbf{r})$ lies in that particular RKHS is equivalent to saying that we are discussing the statistics of the measurement component of the object, and that component is necessarily in an RKHS and hence defined pointwise.

The same conclusion can be reached by assuming that we are not interested in the statistics of an actual $f(\mathbf{r})$ but rather those of some linear approximation to it, such as the functions $f_a(\mathbf{r})$ or $f_t(\mathbf{r})$ discussed in Sec. 7.1.3. As we saw there, these functions lie in an RKHS called representation space, so they too can be defined pointwise. For example, we might construct a linear approximation by use of pixel functions, so $f_a(\mathbf{r}_1)$ would refer to the gray level¹⁰ of a pixel centered at $\mathbf{r} = \mathbf{r}_1$.

In what follows we shall use the notation $f(\mathbf{r})$ but always with the implicit assumption that the function corresponds to a vector in an RKHS. Thus we might really mean $f_{meas}(\mathbf{r})$ or $f_a(\mathbf{r})$, but we shall omit subscripts for convenience. As a practical matter, essentially the only thing we rule out with this assumption is that $f(\mathbf{r})$ is white noise or some other generalized, infinite-energy random process.

Single-point PDFs For $P = 1$ and a fixed choice of \mathbf{r} , $\text{pr}[f(\mathbf{r})]$ is a univariate PDF for the gray level $f(\mathbf{r})$ at point \mathbf{r} . This density can be represented as an ordinary 1D function as in Fig. 8.5. Of course, this function may depend in general on the choice of evaluation point \mathbf{r} , so it can also be plotted as a function of the Cartesian coordinates of \mathbf{r} , as shown in Fig. 8.6.

Fig. 8.5 Univariate PDF $\text{pr}[f(\mathbf{r})]$ plotted as a function of $f(\mathbf{r})$ for fixed \mathbf{r} .

¹⁰Even though we are talking about pixels and gray levels here—terms often associated with images—we emphasize that we are discussing *object* models.

Fig. 8.6 Same PDF as in Fig. 8.5 but now plotted as a function of both $f(\mathbf{r})$ and \mathbf{r} .

Since it is univariate, $\text{pr}[f(\mathbf{r})]$ admits of a frequentist interpretation and a histogram estimate. The considerations are essentially the same as for the univariate density $\text{pr}(\alpha_n)$; if we have a source of object functions $f(\mathbf{r})$, such as a computer simulation code, we can evaluate each sample function at any chosen point, say $\mathbf{r} = \mathbf{r}_1$, and define a histogram estimate analogous to (8.256):

$$\hat{\text{pr}}_{f(\mathbf{r})}[f_k(\mathbf{r}_1)] = \frac{1}{\Delta f} \frac{J [f_k(\mathbf{r}_1) - \frac{1}{2}\Delta f \leq f(\mathbf{r}_1) < f_k(\mathbf{r}_1) + \frac{1}{2}\Delta f]}{J}, \quad (8.262)$$

where the numerator is the number of sample objects for which the value $f(\mathbf{r}_1)$ falls in an interval of width Δf centered on the chosen value $f_k(\mathbf{r}_1)$, and J is the total number of samples. The number of bins in this histogram is just $f_{max}/\Delta f$, where f_{max} is the maximum value of $f(\mathbf{r})$. The k^{th} bin is centered on the point $f_k(\mathbf{r}_1)$ if

$$k = \frac{f_k(\mathbf{r}_1)}{\Delta f}. \quad (8.263)$$

For notational simplicity, we denote the numerator in (8.262) as J_k , which is just the observed number of samples in bin k , but we must keep in mind that the histogram is specific to the point \mathbf{r}_1 .

The same statistical considerations apply here as in the last section. If the experiment is repeated many times with different sample objects, J_k will be approximately a Poisson random variable. The mean value of J_k will be J times the probability that the gray level will fall in bin k , or

$$\langle J_k \rangle = J \text{Pr} [f_k(\mathbf{r}_1) - \frac{1}{2}\Delta f \leq f(\mathbf{r}_1) < f_k(\mathbf{r}_1) + \frac{1}{2}\Delta f] \approx \text{pr}_{f(\mathbf{r})}[f_k(\mathbf{r}_1)] \Delta f. \quad (8.264)$$

As in the previous section, we can construct a 100-bin histogram with a relative error of 10% in the value estimated for the k^{th} bin if $\langle J_k \rangle = 100$; a relative error of 1% requires $\langle J_k \rangle = 10^4$. If we assume that $\text{pr}[f(\mathbf{r})]$ is relatively flat over the range from 0 to f_{max} , then we require $J = 10^4$ for 10% accuracy and 10^6 for 1% accuracy in a 100-bin. Again, these numbers are within the capabilities of modern computers if the sample objects are simulated.

One might think that we are far from characterizing the object random process even to order $P = 1$ since we have fixed the evaluation point at $\mathbf{r} = \mathbf{r}_1$ in the

discussion above. In fact, however, once we have a source of sample objects $f(\mathbf{r})$, we can evaluate them at as many points as we please, and we can construct histogram estimates of $\text{pr}[f(\mathbf{r})]$ on a grid of spatial points with very little increased effort. A 100×100 grid for a 2D object, for example, requires that we construct 10,000 histograms. If k ranges from 1 to 100 for each sample \mathbf{r} and the observed value of J_k does not exceed 255, then we can store the results in just 1 Megabyte of memory.

As a semantic point, each of the histograms discussed above is a histogram of gray levels; it is not, however, what is usually called a gray-level histogram in the image-processing community. In that community, it is common to compute a histogram of the gray levels at *all points within a single image* for purposes of display manipulation or data compression. The histograms we are discussing here describe the distribution of gray levels *at a single point in an ensemble of images*. Where confusion may result, we shall distinguish between *single-image* histograms and *single-point* or ensemble histograms.

For stationary, ergodic random processes, the single-image histogram can be used in place of the ensemble histogram as an estimator of the single-point PDF, but these two histograms should not be equated in general. The single-image histogram can give a very biased estimate of the PDF if there is even a slight deviation from stationarity across the image. Consider, for example, the common situation where the mean gray level varies slowly across the image; in that case the single-image histogram can be much broader than the ensemble histogram at a fixed point and hence a fixed mean gray level.

Two-point PDFs For fixed \mathbf{r}_1 and \mathbf{r}_2 , the two-point density $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]$ is a bivariate density on the two scalar random variables $f(\mathbf{r}_1)$ and $f(\mathbf{r}_2)$. This density can be represented by a 2D plot, where the axes are $f(\mathbf{r}_1)$ and $f(\mathbf{r}_2)$. A full characterization to order $P = 2$ requires evaluation of such bivariate densities for all \mathbf{r}_1 and \mathbf{r}_2 in \mathbf{S}_f .

The two-point density can also be interpreted in frequentist terms, though more sample objects are required than in the single-point case. If we again choose $f_{\max}/\Delta f = 100$, then there are 10,000 bins in a histogram representing $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]$. A calculation similar to the one above shows that J must be about 10^6 for 10% accuracy and 10^8 for 1% accuracy if the underlying PDF is relatively flat. Moreover, 10^8 such histograms would be required if \mathbf{r} is 2D and both \mathbf{r}_1 and \mathbf{r}_2 are sampled on 100×100 spatial grids, and 10 GB of storage would be needed to hold the results. In short, full experimental characterization of the random process to order P becomes rapidly more difficult as P increases.

The histogram approximation to the bivariate density $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]$ is related to, but not identical to, the *co-occurrence matrix* used in image processing and pattern recognition (Pratt, 1991). The distinction is the same as the one between single-point and single-image histograms. The co-occurrence matrix is a random matrix characteristic of a single image or a smaller region within a single image. It is a histogram of the joint occurrence of binned or quantized gray levels in that image. It is independent of absolute position within the region or image but it does depend on the relative position $\mathbf{r}_2 - \mathbf{r}_1$. The density $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]$, on the other hand, is a nonrandom characteristic of the ensemble and a function of two position vectors. A histogram approximation to $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]$ is also random since it is formed from a finite number of samples, but this randomness can in principle be reduced arbitrarily by letting the number of samples grow.

If each sample function is drawn from an ergodic random process (see Sec. 8.2.4), then the co-occurrence matrix computed from one sample function is also an estimator of $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]$.

Local models If \mathbf{r}_1 and \mathbf{r}_2 are far apart in an object, $f(\mathbf{r}_1)$ and $f(\mathbf{r}_2)$ might be statistically independent, or nearly so. For example, in a computed-tomography scan of the chest, the gray level at a point in the lungs would be expected to be independent of the gray level at a point in the spine. Two nearby points in the same lung would, however, be expected to be dependent. A stochastic model that takes account of this property is called a *local model*.

To see the structure of a local model, let us first consider two well-separated points. If the gray levels at these two points are statistically independent, the two-point PDFs are determined uniquely from the single-point ones:

$$\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)] = \text{pr}[f(\mathbf{r}_1)] \text{pr}[f(\mathbf{r}_2)]. \quad (8.265)$$

As discussed in Sec. C.1.6, the independence condition in (8.265) can also be written as

$$\text{pr}[f(\mathbf{r}_1)|f(\mathbf{r}_2)] = \text{pr}[f(\mathbf{r}_1)]. \quad (8.266)$$

Now consider a countable set of points, say on a regular lattice in object space. The gray level at some particular point \mathbf{r}_k will often depend on the values at other points \mathbf{r}_i provided they are close to the chosen point \mathbf{r}_k , but it could be statistically independent of the values at more distant points. We define the *neighborhood* \mathcal{N}_k of the point \mathbf{r}_k as the set of points close to \mathbf{r}_k in this sense, and we denote the complete set of points in the object support as \mathcal{S} . Then a local statistical model is one for which [cf. (8.266)]

$$\text{pr}[f(\mathbf{r}_k)|\{f(\mathbf{r}_i), \mathbf{r}_i \in \mathcal{S}, i \neq k\}] = \text{pr}[f(\mathbf{r}_k)|\{f(\mathbf{r}_i), \mathbf{r}_i \in \mathcal{N}_k\}], \quad (8.267)$$

where $\mathbf{r}_i \in \mathcal{N}_k$ is read “point \mathbf{r}_i is an element of the set \mathcal{N}_k ,” or somewhat more colloquially, “ \mathbf{r}_i is a neighbor of \mathbf{r}_k .” As we see from (8.267), the form of the marginal density on $f(\mathbf{r}_k)$ in a local model is determined fully by the values in the neighborhood \mathcal{N}_k , and points outside this neighborhood can be neglected for purposes of describing the statistics at \mathbf{r}_k .

A local model defined on a discrete lattice as in (8.267) is called a *Markov random field* or MRF. Developed by Besag (1973) and Cross and Jain (1983) for describing textures, MRFs have received considerable attention as Bayesian priors in image reconstruction (see Sec. 15.3.3), but relatively little effort has been expended on establishing their validity as empirical distributions in a frequentist sense. One exception is Herman and Chan (1995), who discussed so-called *image-modeling MRFs* where a sample drawn from the MRF density would have the same neighborhood statistics as the image (object) being modeled.

Regional models and mixture models Often objects can be divided into distinct regions with different statistical properties. In a chest radiograph, for example, the lungs are in more or less the same place for all patients, and the heart is generally situated below the left lung. Before seeing a particular patient’s radiograph, we can define a region that is likely to contain lung and another that is likely to contain heart. Of course, this definition is not absolute; a collapsed lung or an enlarged heart, or simply normal variations in patient size and positioning, could mean that

the *a priori* region assignment is incorrect. Various strategies are available for refining the region assignments, including image recentering and warping and various segmentation algorithms. None of these methods is perfect, however, and the best we can do is to assess the probability that a particular point is associated with a given region.

If we denote by \mathcal{S}_i the set of points associated with region i , the univariate PDF on the gray level at point \mathbf{r} is given by

$$\text{pr}[f(\mathbf{r})] = \sum_i \text{pr}[f(\mathbf{r})|\mathbf{r} \in \mathcal{S}_i] \Pr(\mathbf{r} \in \mathcal{S}_i). \quad (8.268)$$

An analogous expression can be given for the two-point PDF:

$$\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)] = \sum_i \sum_k \text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)|\mathbf{r}_1 \in \mathcal{S}_i, \mathbf{r}_2 \in \mathcal{S}_k] \Pr(\mathbf{r}_1 \in \mathcal{S}_i, \mathbf{r}_2 \in \mathcal{S}_k). \quad (8.269)$$

If gray levels in different regions are statistically independent, this equation becomes

$$\begin{aligned} & \text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)] \\ &= \sum_i \sum_k (1 - \delta_{ik}) \text{pr}[f(\mathbf{r}_1)|\mathbf{r}_1 \in \mathcal{S}_i] \text{pr}[f(\mathbf{r}_2)|\mathbf{r}_2 \in \mathcal{S}_k] \Pr(\mathbf{r}_1 \in \mathcal{S}_i, \mathbf{r}_2 \in \mathcal{S}_k) \\ & \quad + \sum_i \text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)|\mathbf{r}_1 \in \mathcal{S}_i, \mathbf{r}_2 \in \mathcal{S}_i] \Pr(\mathbf{r}_1 \in \mathcal{S}_i, \mathbf{r}_2 \in \mathcal{S}_i). \end{aligned} \quad (8.270)$$

Another special case is a *piecewise-constant model* where all points within a given region have the same gray level in each sample function of the random process, though that value (as well as the borders of the region) can vary randomly from one sample function to the next. In that case,

$$\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)|\mathbf{r}_1 \in \mathcal{S}_i, \mathbf{r}_2 \in \mathcal{S}_i] = \delta[f(\mathbf{r}_1) - f(\mathbf{r}_2)] \text{pr}[f(\mathbf{r}_1)|\mathbf{r}_1 \in \mathcal{S}_i]. \quad (8.271)$$

The density in (8.268) is an example of a *mixture model* where the random quantity is divided into classes, and the overall density is a weighted sum of the densities for different classes. In (8.268), a class is identified with a spatial region, but other kinds of classes are important in imaging as well. In medical imaging, for example, different disease states are (we hope) described by different PDFs. Similarly, in aerial photography, crops, cities, oceans and forests would require different statistical models.

In such cases, the general form of the object PDF is

$$\text{pr}(\mathbf{f}) = \sum_i \text{pr}[\mathbf{f}|\text{class } i] \Pr(\text{class } i). \quad (8.272)$$

The key difference between (8.268) and (8.272) is that the former applies to a univariate density at a specific point \mathbf{r} , while the latter is a general statement applying to the entire density of the process.

Specifically, if we represent \mathbf{f} by an $N \times 1$ coefficient vector $\boldsymbol{\alpha}$, the mixture density (8.272) takes the form

$$\text{pr}(\boldsymbol{\alpha}) = \sum_i \text{pr}(\boldsymbol{\alpha}|\text{class } i) \Pr(\text{class } i), \quad (8.273)$$

and the marginal on a single component of α is

$$\text{pr}(\alpha_n) = \sum_i \text{pr}(\alpha_n | \text{class } i) \text{Pr}(\text{class } i). \quad (8.274)$$

8.4.3 Normal models

The basic properties of normal random processes and random vectors were introduced in Sec. 8.3. Here we revisit normal models with the goal of understanding when and how they apply specifically to the statistical description of objects.

When it is possible to use normal models in imaging, a considerable mathematical simplification results. As we saw in Sec. 8.3, the PDF for a normal random vector is fully determined by the mean vector and the covariance matrix. Moreover, any linear transformation of a normal random vector leaves it normal, so a full analysis of the effect of a linear operator requires only that we transform the mean and covariance, using simple formulas developed in Sec. 8.1.5.

These properties of normal random vectors extend readily to normal random processes. The full PDF of any random process is infinite-dimensional, but in the normal case we can take advantage of the fact that any marginal or conditional density derived from a normal PDF, even an infinite-dimensional one, is also normal. Thus if we choose to describe a normal random process by Hilbert-space marginal densities of the form $\text{pr}(\alpha_1, \alpha_2, \dots, \alpha_P)$ or by multipoint densities like $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2), \dots, f(\mathbf{r}_P)]$, we can be assured that these densities will all be normal.

Central limits To establish the validity of a normal model, we must usually argue that the central-limit theorem applies, as it does when independent random variables or vectors are added together. One way this can happen is when a pixel or voxel representation is used for the object, and subregions of the pixel or voxel are statistically independent. As an example, consider an airborne optical camera viewing a meadow. The camera does not resolve individual blades of grass, and an adequate 2D object representation can use a pixel that covers many blades. It is reasonable to argue that the blades reflect light independently, so the total reflected light in one pixel tends to a normal distribution, at least when we consider only meadows and do not include, say, forests or beaches.

A somewhat more subtle example is nuclear medicine imaging of perfusion patterns in the lungs. In this technique, radioactive albumin particles are injected into a vein and get trapped in the alveoli (the functional units of the lungs where blood becomes oxygenated). The distribution of the trapped tracer is indicative of the perfusion of the lung, and it is this distribution that we regard as the object. Since nuclear medicine systems have very poor spatial resolution compared to the size of alveoli, we can choose a voxel size that contains many alveoli, and the voxel value is the sum of the activities in many alveoli. It is reasonable to presume that these activities are statistically independent, at least when one particular patient is considered. If we were to consider an ensemble of patients, some would have higher perfusion in a particular region than others, and all alveoli in this region would tend to fluctuate together; we avoid this kind of dependence by conditioning the PDF on a particular patient and hence a particular perfusion pattern. In a frequentist sense, this conditional PDF describes the hypothetical distribution that would result from making many different injections of albumin particles into a single patient.

Gaussian mixture models In the two examples just given to justify use of the central-limit theorem, we had to be careful to restrict the ensemble of objects under consideration. In the aerial photography example, we had to consider only meadows and not forests or beaches, and in the nuclear medicine example we had to consider repeated injections into one patient rather than a more realistic ensemble of patients.

To analyze a broader ensemble, we do not necessarily have to abandon the central-limit theorem; instead, we can divide the different objects (or different regions of the same object) into classes and use a mixture density as in (8.272). If we can argue that a normal PDF applies to each component of the mixture, then the resulting model is called a *Gaussian mixture model*.

If α is conditionally multivariate normal for each class, then α_n is conditionally univariate normal, so $\text{pr}(\alpha_n|\text{class } i)$ in (8.274) is fully specified by the conditional mean $\bar{\alpha}_{ni}$ and the conditional variance σ_{ni}^2 :

$$\text{pr}(\alpha_n) = \sum_i \frac{1}{\sqrt{2\pi\sigma_{ni}^2}} \exp\left[-\frac{(\alpha_n - \bar{\alpha}_{ni})^2}{2\sigma_{ni}^2}\right] \text{Pr}(\text{class } i). \quad (8.275)$$

If we must use a large number of classes in order to justify the normal law for each class, it might be better to consider a continuum of classes and write

$$\text{pr}(\alpha_n) = \int_{-\infty}^{\infty} d\bar{\alpha}_n \int_0^{\infty} d\sigma_n^2 \text{pr}(\bar{\alpha}_n, \sigma_n^2) \frac{1}{\sqrt{2\pi\sigma_n^2}} \exp\left[-\frac{(\alpha_n - \bar{\alpha}_n)^2}{2\sigma_n^2}\right]. \quad (8.276)$$

Similarly, the multivariate density on α for a discrete set of classes is

$$\text{pr}(\alpha) = \sum_i \frac{1}{\sqrt{(2\pi)^N \det(\mathbf{K}_i)}} \exp\left[-\frac{1}{2}(\alpha - \bar{\alpha}_i)^t \mathbf{K}_i^{-1} (\alpha - \bar{\alpha}_i)\right] \text{Pr}(\text{class } i), \quad (8.277)$$

where $\bar{\alpha}_i$ and \mathbf{K}_i are, respectively, the mean vector and covariance matrix for α under class i . For a continuum of classes, we can write

$$\text{pr}(\alpha) = \int_{\infty} d^N \bar{\alpha} \int_{\infty} d\mathbf{K} \frac{1}{\sqrt{(2\pi)^N \det(\mathbf{K}_i)}} \exp\left[-\frac{1}{2}(\alpha - \bar{\alpha})^t \mathbf{K}^{-1} (\alpha - \bar{\alpha})\right], \quad (8.278)$$

where $d\mathbf{K}$ is a shorthand for the differential of all components of \mathbf{K} .

No matter which of these mixture formulas we use, we do not expect the resulting PDF to be normal. For example, in the simple case of the univariate expression (8.275) with just two classes, we would get a bimodal PDF with one Gaussian peak for each class.

High-pass and band-pass filters There are many circumstances where we either pass an image through a high-pass or band-pass spatial filter or consider an object to consist of a superposition of such components. For example, edges in an image are often detected with some sort of derivative filter, and derivatives suppress the DC component¹¹ of the image. Other examples of filters with zero DC response include

¹¹The common jargon, *DC component*, does not, of course refer to direct current. Instead it implies zero spatial frequency, by analogy to the zero temporal frequency of a steady current. In coherent optical processing, the Fourier transform of an object is displayed as an optical amplitude distribution centered on the optical axis of a lens system, and in that case it has been suggested that *DC* stands for *dot in the center*.

wavelets (see Sec. 5.3), channels in the human visual system (see Sec. 14.2) and filters used to extract discrete cosine transforms (except, of course, the DC term in the transform). Continuous objects can be represented by zero-DC components, for example in the Fourier-series basis of (7.13), a wavelet basis or a basis of Gabor functions (see Sec. 5.1.4). As we noted in Sec. 8.4.1, approximately independent components can be obtained by filtering with localized band-pass filters.

In all of these cases, an expansion coefficient is computed by forming a scalar product of the object function with a zero-DC function. For both objects and images, therefore, it is of considerable interest to have a stochastic model for the output of a high-pass filter.

In Sec. 8.3.3 we showed that linear filtering of a Gaussian random process yields a Gaussian random process, so if the input to a filter is Gaussian, the output must be also. It has been observed empirically, however, many images have a decidedly non-Gaussian distribution results after high-pass or band-pass filtering. As seen in the example in Fig. 8.7, the gray-level histograms are typically sharply peaked around zero and display long tails (Heine *et al.*, 1999; Bell and Sejnowski, 1997). In statistical lingo, these histograms have a large kurtosis. As defined in (C.41), the kurtosis for a Gaussian is 3 (though many books subtract off the 3 and make the kurtosis of a Gaussian 0), and gray-level histograms following high-pass filtering often have kurtosis substantially larger than 3. Statistical pedants refer to such distributions as *leptokurtic* (Greek *lepto*, thin or fine); the opposite condition, kurtosis less than that of a Gaussian, is referred to as *platykurtic* (Greek *platys*, broad or flat — behold the platypus!).

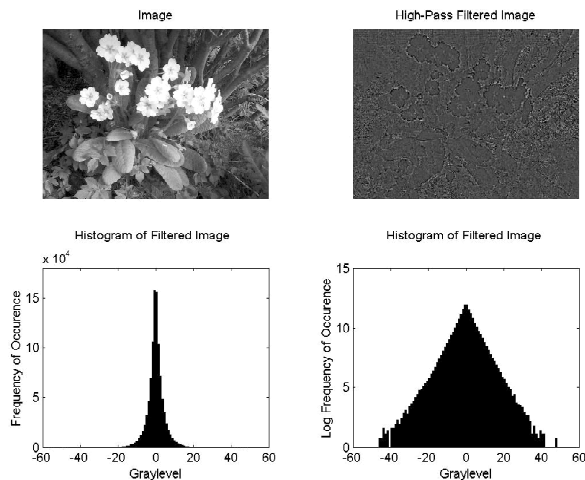

Fig. 8.7 *Top:* A typical image before and after high-pass filtering. *Bottom:* Gray-level histogram of the high-pass filtered image (note that the right plot is vs. log frequency of occurrence).

Filtering of Gaussian mixtures Heine *et al.* (1999) offered an explanation for high kurtosis after wavelet filtering, but it made assumptions about scale-invariance that were specific to wavelets. Lam and Goodman (2000) derived the PDF of the coefficients in a discrete cosine transform from a Gaussian mixture model. Clarkson and Barrett (2001) extended that argument and showed that kurtotic distributions were

an inevitable consequence of high-pass or band-pass filtering of Gaussian mixtures; we shall sketch here the derivation given by Clarkson and Barrett.

If we think of high-pass filtering as a convolution, then the output is a scalar product of the shifted kernel function with the input. If the kernel contains both positive and negative components, we can suppress the shift variable and write the output for one position of the kernel as

$$z = u - v, \quad (8.279)$$

where u arises from the positive part of the filter and v from the negative part. This equation applies whether we think of the input to the filter as a random process or a random vector in a pixel representation. Moreover, it applies also to computation of an expansion coefficient in a representation where the expansion function has positive and negative parts.

We expect u and v to be highly correlated since they come from the same region of the input, but it is reasonable to assume that they have the same mean if the filter has zero DC response. This conclusion follows rigorously if we can assume that all points within the region spanned by the kernel (at a specific shift) have the same mean, and it may also be a good approximation even with a space-variant mean since it requires only that the spatial average of the mean over the positive regions of the kernel equal that over the negative regions. (Consider a difference-of-Gaussians filter, where a positive central peak is surrounded by a negative ring; the means of u and v will be equal if the spatial average of the input mean in the negative ring is the same as the spatial average in the central peak.) Thus we assume

$$\bar{u} = \bar{v}; \quad \bar{z} = 0. \quad (8.280)$$

Note that the overbar here implies an ensemble mean; it has nothing to do with spatial averages. We make no assumptions about stationarity or ergodicity, and there is no implication that ensemble averages can be approximated by spatial ones.

Now let us assume that u and v are drawn from a Gaussian mixture. To see the essential results, we assume first that u and v are *conditionally* uncorrelated, for any one component of the mixture, so that the entire correlation between the two variables results from averaging over components in the mixture. Similarly, we assume that u and v have the same conditional variances, so in fact they are conditionally i.i.d. These assumptions may not always be justified, and they will be relaxed below; for now, we write

$$\text{pr}(u, v | \sigma, m) = \frac{1}{2\pi\sigma^2} \exp \left[-\frac{(u-m)^2 + (v-m)^2}{2\sigma^2} \right], \quad (8.281)$$

where m is the common mean of u and v , and σ is the common standard deviation.

The corresponding conditional density on z is given by

$$\text{pr}(z | \sigma, m) = \int_{-\infty}^{\infty} du \text{pr}(u, u-z | \sigma, m). \quad (8.282)$$

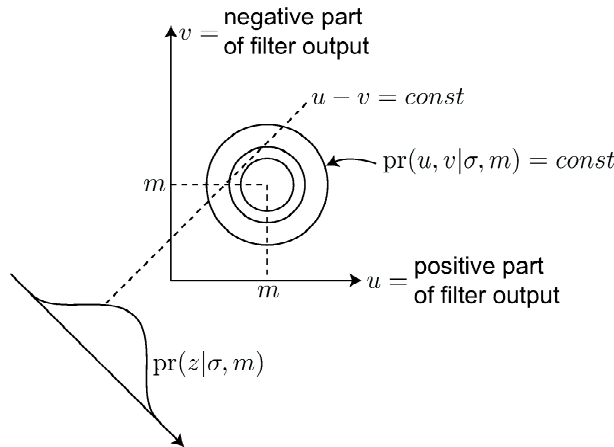

Fig. 8.8 Illustration of the integral encountered in analyzing Gaussian mixture models.

As illustrated in Fig. 8.8, this integral can be interpreted as a 1D projection or Radon transform (see Sec. 4.4) of the 2D function $\text{pr}(u, v | \sigma, m)$. We see graphically that the result is independent of m , and by completing the square we obtain

$$\text{pr}(z | \sigma) = \frac{1}{2\pi\sigma^2} \int_{-\infty}^{\infty} du \exp \left[-\frac{u^2 + (u - z)^2}{2\sigma^2} \right] = \frac{1}{2\sigma\sqrt{\pi}} \exp \left(-\frac{z^2}{4\sigma^2} \right). \quad (8.283)$$

Note that we have written this density as conditional on the standard deviation σ rather than the variance σ^2 . We are free to choose either, but the standard deviation is convenient when we write out the overall density on z . Since the conditional mean does not influence the statistics of z , the mixture can be specified by a univariate prior on σ , and we find

$$\text{pr}(z) = \frac{1}{2\sqrt{\pi}} \int_0^{\infty} \frac{d\sigma}{\sigma} \exp \left(-\frac{z^2}{4\sigma^2} \right) \text{pr}(\sigma). \quad (8.284)$$

By comparison with (4.85), we recognize (8.284) as a Mellin convolution, and many interesting properties of $\text{pr}(z)$ follow from this observation. Since Mellin transforms convert Mellin convolutions into products, and since Mellin transforms can be interpreted as moments (see Sec. 4.2.2), it follows that moments of z are related simply to moments of σ ; from Clarkson and Barrett (2001), the relation is

$$\langle z^k \rangle = \frac{2^k \Gamma \left(\frac{k+1}{2} \right)}{\sqrt{\pi}} \langle \sigma^k \rangle, \quad (8.285)$$

where $\Gamma(\cdot)$ is the gamma function.

From this moment relation and a little algebra, we find

$$\langle z^4 \rangle - 3\langle z^2 \rangle^2 = 12[\langle \sigma^4 \rangle - \langle \sigma^2 \rangle^2]. \quad (8.286)$$

The kurtosis, defined as $\langle z^4 \rangle / \langle z^2 \rangle^2$, is 3 for a Gaussian, so the left-hand side of this expression would be zero for a Gaussian. By the Schwarz inequality, however, the right-hand side is ≥ 0 , so z always has a kurtosis greater than or equal to that of a Gaussian, with equality if and only if $\text{pr}(\sigma)$ is a delta function. In short, leptokurtic

distributions are inevitable when a Gaussian mixture is filtered with a high-pass or band-pass filter. Moreover, the resulting densities for z often take simple, symmetric forms, quite robust to the detailed assumptions about $\text{pr}(\sigma)$.

Several different analytical forms have been suggested as empirical descriptions of long-tailed densities like those shown in Fig. 8.8. When there is a sharp cusp at the origin, a natural choice is the Laplace or double-exponential density. A family of densities intermediate between Laplace and Gaussian can also be defined with $\text{pr}(z) \propto \exp(-a|z|^p)$, so $p = 1$ is the Laplace density and $p = 2$ is the Gaussian. The parameters p and a can be adjusted to fit empirical densities. Another option is the Lévy family, defined not by the density but by the characteristic function, which has the form $\psi(\xi) = \exp(-b|\xi|^q)$. The corresponding densities cannot be stated as simple analytic functions except when $q = 2$, which is the Gaussian, and $q = 1$, which is the Cauchy density (see Sec. C.5.10). Again, q and b can be treated as adjustable parameters.

Mixtures of correlated Gaussians So far we have considered only a specific Gaussian mixture where u and v were i.i.d. normal, but the result can readily be generalized. Suppose u and v are bivariate normal with a covariance matrix of the form

$$\mathbf{K}_{uv} = \begin{bmatrix} a & b \\ b & c \end{bmatrix}. \tag{8.287}$$

As the reader may show, (8.284) is still valid with this model, only now σ^2 is not a univariate variance but rather $\frac{1}{2}(a + c - 2b)$ (see Clarkson and Barrett, 2001). Thus the initial assumption that u and v are i.i.d. has no essential effect on the conclusions.

Normals and entropy It is not always necessary to invoke the central-limit theorem in order to arrive at a normal probability law. It occurs also in a Bayesian context when one has partial information about a distribution and wishes to complete the description as noncommittally as possible. One way to do this is to use the principle of maximum entropy. A critique of this approach in the context of image reconstruction is given in Sec. 15.3.3, but here we can be content to paraphrase Zhu *et al.* (1998): Entropy is a measure of randomness, and we should choose the density that is as random as possible in all unobserved dimensions and does not attempt to represent information that we do not have.

If we know the mean and variance of a random variable (or mean vector and covariance matrix of a random vector), these moments serve as constraints on the density, and we would like to find the density of maximum entropy consistent with these constraints. We shall carry through the calculation in the univariate case and simply state the multivariate result.

Consider a random variable x and suppose we know that its mean is \bar{x} and its variance is σ^2 . According to the principle of maximum entropy, we must choose $\text{pr}(x)$ to maximize $\int_{-\infty}^{\infty} dx \text{pr}(x) \ln \text{pr}(x)$, subject to the constraints

$$\int_{-\infty}^{\infty} dx \text{pr}(x) = 1; \quad \int_{-\infty}^{\infty} dx x \text{pr}(x) = \bar{x}; \quad \int_{-\infty}^{\infty} dx x^2 \text{pr}(x) = \sigma^2 + \bar{x}^2. \tag{8.288}$$

The maximization can be performed by the method of Lagrange multipliers. We require that the Lagrangian functional,

$$L\{\text{pr}(x)\} \equiv \int_{-\infty}^{\infty} dx \text{pr}(x) \ln \text{pr}(x) + \alpha \left[\int_{-\infty}^{\infty} dx \text{pr}(x) - 1 \right] \\ + \beta \left[\int_{-\infty}^{\infty} dx x \text{pr}(x) - \bar{x} \right] + \gamma \left[\int_{-\infty}^{\infty} dx x^2 \text{pr}(x) - (\sigma^2 + \bar{x}^2) \right], \quad (8.289)$$

be unchanged by small perturbations of $\text{pr}(x)$. Here, α , β and γ are the Lagrange multipliers, to be fixed by the constraint equations. If we perturb $\text{pr}(x)$ by a small amount $\eta(x)$, and retain only terms linear in the perturbation, we find

$$L\{\text{pr}(x) + \eta(x)\} - L\{\text{pr}(x)\} = \int_{-\infty}^{\infty} dx \eta(x) \{1 + \ln \text{pr}(x) + \alpha + \beta x + \gamma x^2\} = 0. \quad (8.290)$$

Since $\eta(x)$ is arbitrary, this equation can hold only if the quantity in braces in the integrand is zero, so $\text{pr}(x)$ must take the form

$$\text{pr}(x) = \exp(-1 - \alpha - \beta x - \gamma x^2). \quad (8.291)$$

Both this form and the constraints are satisfied if

$$\text{pr}(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left[-\frac{(x - \bar{x})^2}{2\sigma^2}\right]. \quad (8.292)$$

Thus, if all we know about a random variable is its mean and variance, the maximum-entropy choice for its density is a normal. A similar calculation shows that if all we know about a random vector is its mean vector and covariance matrix, the maximum-entropy density is multivariate normal.

Positivity Appealing though normal distributions may be, they have one serious deficiency in many imaging applications. If the random variable or vector in question is inherently nonnegative, as physical objects often are, then the normal law cannot be strictly correct; it always predicts some finite probability of negative values. We shall now discuss several possible fixes for this problem.

One simple fix is just to consider situations where the standard deviation of the random variable is small compared to its mean; then the probability of getting a negative value is small and can perhaps be neglected without serious error. For the normal law to represent a nonnegative object, in particular, we must consider low-contrast scenes where the variation we are trying to describe is small compared to some spatial-average value. Such situations arise often in medical imaging or other applications involving a faint object on a bright background. They can be particularly useful for local statistical descriptions where the background may vary substantially over the whole scene but relatively little over a region of interest.

Another approach is to use a truncated Gaussian which is not allowed to go negative. Perhaps surprisingly, this is the maximum-entropy choice if we know the mean and variance of a random variable and also know that it is nonnegative. Retracing the calculation above, we see that (8.290) still holds with the simple modification of setting the lower limit of integration to zero, and (8.291) holds without

modification. A more substantial modification does occur in (8.292), which can now be written as

$$\text{pr}(x) = N \exp \left[-\frac{(x - x_0)^2}{2v^2} \right] \text{step}(x), \quad (8.293)$$

where N is a normalizing constant, x_0 is *not* the mean and v^2 is *not* the variance. Instead these quantities must be determined by numerically solving constraint equations like (8.288) but with a lower integration limit of 0.

Similarly, if we know the mean and covariance of a nonnegative random vector, a truncated multivariate normal is the maximum-entropy density. Again, however, the known mean and covariance cannot simply be plugged into the standard multivariate normal form.

Log-normals Another solution to the positivity problem is to use log-normals rather than normals. Since a log-normal is a density for a random variable whose log is normal, it is defined for any nonnegative variable, and the density is taken to be zero for negative values of the variable.

The density for a univariate log-normal is given in Sec. C.5.9 of App. C; the corresponding multivariate form is

$$\text{pr}(\mathbf{f}) = \left[\prod_i \frac{1}{\sqrt{2\pi}f_i} \right] \frac{1}{\sqrt{\det(\mathbf{K})}} \exp \left\{ -\frac{1}{2} [\ln(\mathbf{f}) - \boldsymbol{\mu}]^t \mathbf{K}^{-1} [\ln(\mathbf{f}) - \boldsymbol{\mu}] \right\}, \quad (8.294)$$

where the logarithm is to be interpreted componentwise, and $\boldsymbol{\mu}$ and \mathbf{K} are the mean vector and covariance matrix of the Gaussian random vector $\ln \mathbf{f}$, not \mathbf{f} itself. The reader may test her understanding of transformations of random variables by showing that the log of \mathbf{f} is indeed a multivariate normal.

Often we can argue on physical grounds that the PDF for an object or image should tend to a log-normal. Consider, for example, transmission x-ray imaging of a thick, inhomogeneous 3D object. The 3D object can be divided into slabs, and the overall transmission of the object is the product of the slab transmissions. If the transmission of each slab is a random process, then the log of the product of the slab transmissions is also a random process, and if the individual slabs are statistically independent, then the log of the product is the sum of logarithms of independent random processes. Thus, regardless of the statistics of the slab log-transmissions, the overall log-transmission tends to a normal by the central-limit theorem, and hence the overall transmission itself tends to a log-normal.

In other situations as well, we can decompose the object function into a product of independent random variables. For example, in nuclear medicine we might inject a radioactive tracer into the blood stream and watch its migration through the circulatory system to some target organ. At each branching of the blood vessels, a tracer molecule can go in one of two directions, and if we consider a point in the vasculature after many branchings, then the number of molecules arriving there is the injected number times a product of a large number of random variables, one for each branch. The central-limit theorem suggests that the log of the tracer concentration at this point is normally distributed, so the concentration itself is log-normal.

There is an essential difference between log-normals and truncated normals as densities for nonnegative random variables or vectors. As the examples above suggest, we can expect the log-normal to be experimentally verifiable, in principle,

so it can be interpreted in a frequentist sense. If the variable of interest is a product of many independent random variables, and each experiment results in different values for the individual variables, we can repeat the experiment many times, and the resulting histogram estimate of the density for the product variable will tend to a log-normal, and indeed this distribution is frequently observed experimentally.¹²

There is, in fact, a frequentist rationale for maximum entropy, and it will be sketched in Sec. 15.3.3, but it conceives of the object being constructed by throwing imaginary grains or blobs of gray level; it definitely does not suggest a concrete physical experiment. Thus, even though the truncated normal might be a maximum-entropy density, we should not expect to encounter it as the limit of an experimental histogram. Maximum entropy, as we used it above, is merely a way of going from known moments to a noncommittal PDF.

8.4.4 Texture models

A significant portion of the image-science literature deals with analysis, synthesis, recognition and segmentation of *textures*, defined loosely as spatial random fields with some degree of stationarity. Sometimes the stationarity is periodic, with basic repeating elements such as bricks in a wall or fibers in a woven¹³ fabric. Sometimes it is continuous, as with a stucco wall rather than a brick one or the surface of the ocean, where the light reflected from the object can be described as a stationary random process. Sometimes the stationarity is only approximate, in one of the senses discussed in Sec. 8.2.4; the correlation properties might vary slowly, or they might be stationary only within some region boundaries. Sometimes, in fact, the stationarity is purely visual; two regions are said to be the same texture simply because a human observer cannot tell them apart.

Since textures are essentially stationary random processes, Fourier analysis is an important tool for analyzing them. We shall therefore start this section with a discussion of the role of Fourier analysis and power spectral densities, and then we shall briefly discuss methods for estimating power spectra.

Even when stationarity is a good approximation, an autocorrelation function or power spectral density may not capture all of the essential properties of a texture field. It may be necessary to specify also some aspects of the multivariate PDF in order to adequately describe a texture, and we shall describe several means of doing so.

Throughout this section we shall discuss not only methods of characterizing texture as a random process, but also methods for generating sample functions of the random process. An excellent general reference on methods of constructing sample functions with specified correlation properties and marginal distributions is Johnson (1994).

¹²Above we presented an argument that the total amount of tracer in a voxel should tend to a normal, and here we argue that the concentration at a point should be log-normal. These two arguments are not necessarily inconsistent, since a sum of log-normals can converge to a normal, but in fact this convergence is very slow (Barakat, 1976). Which distribution is actually observed is best resolved empirically.

¹³Texture comes from the Latin *texere*, to weave, so a fabric is the prototype of a texture.

Fourier Phase and magnitude Any spatial pattern, whether regarded as a deterministic function or as a sample function of a random process, is completely specified by its Fourier transform. This (continuous or discrete) Fourier transform is complex, but the modulus and phase convey essentially different information about the object. Fourier phase tells you where things are—if the position of an object is shifted, the phase changes but the modulus does not. Fourier modulus, on the other hand, tells you only how strongly different spatial frequencies contribute to the object.

In many cases, Fourier phase is more important than Fourier modulus in conveying the essence of an object. In a famous experiment, Oppenheim and Lim (1981) Fourier-transformed two images, one of the television news anchor Walter Cronkite and one of a clock. They then interchanged the Fourier phases, putting Walter's phase with the clock modulus and vice versa. After inverse transformation, the image with Walter's Fourier phase still looked like Walter, and the one with the phase of a clock looked like a clock.

With textures, on the other hand, the situation can be reversed. In a stationary random process we do not care where things are. One location is as good as another, at least statistically, so Fourier phase is much less important than Fourier modulus. Two stationary random processes with the same modulus but different phases are recognized as sample functions of the same texture. One common way of synthesizing sample textures, therefore, is to generate samples of white noise and pass them through a linear filter.

As an example, Bochud *et al.* (1999b) examined the relative importance of Fourier amplitude and phase in describing coronary angiograms (x-ray images of blood vessels after injection of an x-ray-absorbing material into the blood stream). In agreement with the remarks above, they found that the phase was important for describing the vessel, but not for the random anatomical background against which the vessel was seen. Though the background was not rigorously stationary, they showed that realistic images could be simulated by filtering white noise through a space-variant filter.

Estimation of power spectra or autocorrelation functions of images Suppose we have one or more sample images, and we want to generate additional images with similar texture by filtering white noise. To the extent that the texture is a stationary random process, we need to know the power spectral density or the stationary autocorrelation function. There is a large literature on estimating these quantities from sample images, and we confine ourselves here to a few general observations.

In Sec. 8.2.5 we mentioned—and dismissed—an apparently obvious approach to spectral estimation, the periodogram of a single sample image. Figure 8.1 illustrates the difficulty with this approach. Mallat (1999) refers to periodogram analysis as “naive spectral estimation;” one meaning of *naive* is “lacking information, uninformed” and the periodogram is naive in the sense that it does not incorporate prior information or beliefs into the spectral estimate. We certainly do not believe that the rapid fluctuations seen in Fig. 8.1 are meaningful features of the power spectrum (or if we did, we would need only to repeat the experiment to change our belief system). The situation is very similar to image reconstruction, discussed in much more detail in Chap. 15, where naive attempts at inverse filtering yield large fluctuations in the reconstructed image.

The Bayesian approach to this problem, in both image reconstruction and spectral estimation, is to define a prior probability on the function being estimated and then to seek an estimate consistent with both the data and this prior. In the Bayesian community, a preferred prior is the entropy, and maximum-entropy reconstructions do indeed eliminate the rapid fluctuations and yield smooth estimates. The details of this procedure, in the context of image reconstruction, are given in Sec. 15.3.3.

As we shall also see in Chap. 15, there are many other approaches, referred to collectively as *regularization*, that can be used to suppress fluctuations in reconstructed images, and each of these methods has its analog in spectral estimation. Many of these methods can also be described as Bayesian, but with priors other than entropy (see Sec. 15.3.3); all of them attempt to enforce our prior belief that the function being reconstructed (power spectrum or image) is smooth in some sense.

One way to enforce smoothness in spectral estimation is to model the spectrum as a smooth function with unknown parameters and then to estimate the parameters. For example, we could model the spectrum as a Gaussian and estimate its width, or as a Gaussian times a polynomial and estimate the polynomial coefficients also. One popular model, especially for time-series analysis, is the *autoregressive, moving average* or ARMA model where the spectrum is modeled as a ratio of polynomials (Oppenheim and Schaffer, 1989).

Another model is to assume that the power spectrum varies as a power law, $\rho^{-\beta}$, and then to estimate the exponent β . Many images exhibit this behavior in practice (even when there is no reason to assume stationarity), and β is a useful phenomenological descriptor. Physical mechanisms that lead to power-law power spectra in the context of electrical noise are surveyed in Sec. 12.2.3.

Which regularization method is chosen depends on what one wants to do with the spectral estimate. If we want to simulate images that appear realistic to a human observer, we can use one of the psychophysical tests detailed in Sec. 14.2.3 to measure how well the observer can distinguish real texture images from white noise filtered with the estimated spectrum. If the real and simulated images are indistinguishable, it means that the estimated spectrum is good enough for this purpose; on the other hand, if they are readily distinguishable, it may mean that the spectral estimate is poor, or it may mean that the texture is more complicated than just filtered noise.

For many purposes, however, we need more than just visual realism. In texture recognition or discrimination, for example, we need a stochastic model in order to design an optimal discriminant function (see Sec. 13.2.12). If we use a Gaussian model, we need to know the inverse of the covariance matrix, and if we also assume stationarity, that means we need to know the reciprocal of the power spectrum. Even if the spectral estimate accurately represents the actual spectrum for the spatial frequencies where the spectrum is large, it may be a poor estimate in the tails and hence a poor estimate of the reciprocal spectrum. The best spectral estimate in this case is the one that leads to the best discrimination performance for a discriminant function based on the estimated spectrum (but tested on real images—not ones simulated from the estimated spectrum!).

As another example, we shall see in Chaps. 13 and 14 that some important measures of image quality are expressed in terms of the image power spectrum. If we do not know the actual spectrum, we must estimate it, and the adequacy of the

spectral estimate must be judged by the accuracy of the corresponding estimates of figures of merit for image quality.

Estimation of power spectra or autocorrelation functions of objects Above we stated our goal as estimation of the power spectral density or autocorrelation function of a set of images. Often, however, what we really want to know is the power spectral density or autocorrelation function of the objects that formed the images.

Suppose we have a set of sample images $\{\mathbf{g}_j, j = 1, \dots, J\}$, where the j^{th} image is related to an object \mathbf{f}_j by $\mathbf{g}_j = \mathcal{H}\mathbf{f}_j + \mathbf{n}_j$. We must assume that \mathbf{f}_j is a sample function of a stationary (or at least quasistationary) random process in order to define an object power spectral density $S_f(\boldsymbol{\rho})$, and we need knowledge of \mathcal{H} and of the noise statistics in order to estimate $S_f(\boldsymbol{\rho})$.

As a simple example, suppose the imaging system is well approximated as a convolution (a CC LSIV system in the language of Sec. 7.2.3). Then \mathbf{g}_j is a sample function of a stationary random process, and its power spectrum is denoted by $S_g(\boldsymbol{\rho})$. If we also assume that \mathbf{n}_j is a sample function of a stationary random process, with power spectrum $S_n(\boldsymbol{\rho})$, then use of (8.156) shows that the image power spectrum is given by

$$S_g(\boldsymbol{\rho}) = |H(\boldsymbol{\rho})|^2 S_f(\boldsymbol{\rho}) + S_n(\boldsymbol{\rho}). \quad (8.295)$$

The image spectrum $S_g(\boldsymbol{\rho})$ can be estimated by any of the methods suggested above, and the result can be denoted as $\widehat{S}_g(\boldsymbol{\rho})$. If we know the noise spectrum $S_n(\boldsymbol{\rho})$ independently from the physics of the imaging problem, then one reasonable estimate of the object spectrum is

$$\widehat{S}_f(\boldsymbol{\rho}) = \frac{\widehat{S}_g(\boldsymbol{\rho}) - S_n(\boldsymbol{\rho})}{|H(\boldsymbol{\rho})|^2}. \quad (8.296)$$

This method gives little information about $S_f(\boldsymbol{\rho})$ at frequencies for which $H(\boldsymbol{\rho})$ is small, and large errors in $S_f(\boldsymbol{\rho})$ can result from small errors in either $S_n(\boldsymbol{\rho})$ or $\widehat{S}_g(\boldsymbol{\rho})$. Moreover, the whole approach depends on modeling the system as CC LSIV and the noise as stationary.

A better approach is to use some parametric description of the object power spectrum, perhaps one that allows quasistationarity, and then to estimate the parameters from the data. This way, the system operator \mathcal{H} can be a general CD mapping and the noise can have an arbitrary covariance matrix \mathbf{K}_n , so long as both of these quantities are known. Methods of parameter estimation to be developed in Chap. 13 can then be used to estimate the spectral parameters. Thus a stationary or quasistationary texture field can be imaged through a shift-variant imaging system and have nonstationary noise added to it, yet the parameters describing the spectrum of the texture field can still be estimated.

Gray-level statistics When the correlation properties are not sufficient to characterize a texture, we can also use the single-point PDF $\text{pr}[f(\mathbf{r})]$. For a stationary texture, this density is independent of \mathbf{r} , and we might want to generate samples of the texture with this density and some specified autocorrelation function or power spectral density. We shall sketch an iterative algorithm for this purpose.

The algorithm begins by filtering white noise to obtain several samples with the requisite power spectrum. It is probably valid to invoke the central-limit theorem on the filter output since the filter will serve to add up many independent samples of

the white noise, so the single-point PDF on the filter output is probably Gaussian, but in any case we can estimate the PDF from the average gray-level histogram of the samples. At this stage we can perform a process known as *histogram equalization*, a pointwise nonlinear transformation that changes the gray-level distribution as described in Sec. C.3.1, and the form of the transformation can be chosen to yield the required PDF. This transformation changes the power spectrum in a complicated way, and it is necessary to estimate the new spectrum from the samples. From the new spectrum, we can devise a new filter to match the current spectrum to the required one, but this changes the PDF so a new histogram-equalization step is needed. The process is then repeated iteratively. Each iteration is a projection onto convex sets, as discussed in detail in Sec. 15.4.5, and convergence can be proven by use of a theorem quoted there. The result is a set of samples that have both the specified power spectrum and the specified single-point PDF.

Texture synthesis with wavelet channels It has been found (Bergen and Adelson, 1991; Chubb and Landy, 1991) that textures that give similar gray-level histograms through a series of wavelet filters appear similar to a human observer. Heeger and Bergen (1995) and Rolland and co-workers (Rolland and Strickland, 1997; Rolland *et al.*, 1998; Rolland, 2000) have used this observation to develop algorithms for synthesizing textures.

The Rolland group uses a digital image of a reference texture and synthesizes additional sample textures of similar visual appearance. The reference texture is decomposed into subbands by means of a discrete wavelet transform (see Sec. 5.3.3). This transform is invertible, so the original reference texture can be recovered by the inverse transform. The stochastic model, however, is that the texture can be characterized by means of gray-level histograms for each subband, basically a histogram estimate of the univariate PDFs for the output of each wavelet filter. In principle, multiple reference images could be used to improve this estimate, but the Rolland algorithm uses just one and implicitly assumes ergodicity.

To synthesize a sample texture, a discrete white noise field is generated, and it is also passed through the same discrete wavelet transform. The histogram of each filter output is computed, just as for the reference texture. A nonlinear point operation is applied in each subband to convert the histograms of the transformed white noise to histograms that match those of the reference texture. An inverse wavelet transform then yields the synthesized texture. The visual correspondence between the reference texture and the synthesized textures is striking, yet all of the synthesized textures are statistically independent since independent noise fields are used.

Multiple filters and maximum entropy The method of Heeger and Bergen permits the synthesis of textures from one or more training images, but it does not give a probability model for the synthesized images. This gap was filled by Zhu *et al.* (1998), whose work can be seen as a combination of wavelet-based texture synthesis and independent components analysis. Rather than restricting attention to some chosen set of wavelets, as in Heeger's method, Zhu *et al.* use a large library of linear filters and compute marginal histograms of the filter outputs for some training set of images (which may consist of just a single image plus an ergodicity assumption). They then use the principle of maximum entropy to construct a multivariate distribution that agrees with the marginals estimated from training data.

The rationale for maximum entropy is the one mentioned in Sec. 8.4.3: maximum-entropy densities are maximally noncommittal and do not attempt to represent information not available empirically. According to Zhu, the maximum-entropy density is the “purest fusion” of the empirical marginals.

Suppose we have a set of linear operators $\mathcal{L}^{(j)}$ in object space, with the output of the j^{th} operator given by $q^{(j)}(\mathbf{r}) = [\mathcal{L}^{(j)}\mathbf{f}](\mathbf{r})$. In the abstract notation of Sec. 8.2.2, the single-point marginal density on the output can be written as

$$\text{pr} [q^{(j)}(\mathbf{r})] = \int d\mathbf{f} \text{pr} [q^{(j)}(\mathbf{r})|\mathbf{f}] \text{pr}(\mathbf{f}). \quad (8.297)$$

But the linear operator is deterministic, so $q^{(j)}(\mathbf{r})$ is known exactly once \mathbf{f} is specified, and we can write

$$\text{pr} [q^{(j)}(\mathbf{r})] = \int d\mathbf{f} \delta\{q^{(j)}(\mathbf{r}) - [\mathcal{L}^{(j)}\mathbf{f}](\mathbf{r})\} \text{pr}(\mathbf{f}), \quad (8.298)$$

where $\delta\{q^{(j)}(\mathbf{r}) - [\mathcal{L}^{(j)}\mathbf{f}](\mathbf{r})\}$ is simply a 1D delta function. Comparing this expression to (4.173), we see that the single-point marginal on the filter output is a Radon-transform projection of the object density $\text{pr}(\mathbf{f})$, where \mathbf{f} here corresponds to the position vector \mathbf{r} in (4.173), and choice of the linear operator here corresponds to the projection direction $\hat{\mathbf{n}}$ in (4.173).

Now suppose we have a set of training “objects” (either good computer simulations or images from a high-resolution, low-noise imaging system as discussed in Sec. 8.4.1) from which we can form a histogram estimate of $\text{pr} [q^{(j)}(\mathbf{r})]$. If we denote this histogram, defined as in (8.262), by $\hat{\text{pr}}_{q^{(j)}(\mathbf{r})} [q^{(j)}(\mathbf{r})]$, then we can pose the maximum-entropy density-estimation problem as

$$- \int d\mathbf{f} \text{pr}(\mathbf{f}) \ln[\text{pr}(\mathbf{f})] = \max, \quad (8.299)$$

subject to the constraints of normalization,

$$\int d\mathbf{f} \text{pr}(\mathbf{f}) = 1, \quad (8.300)$$

and agreement with the empirical histograms,

$$\hat{\text{pr}}_{q^{(j)}(\mathbf{r})}(z) = \int d\mathbf{f} \delta\{z - [\mathcal{L}^{(j)}\mathbf{f}](\mathbf{r})\} \text{pr}(\mathbf{f}). \quad (8.301)$$

If we assume stationarity, at least over some restricted region, then the histogram should be the same for all positions, and we can drop the argument \mathbf{r} on the subscript, but we still have to satisfy the constraint at all \mathbf{r} . In practice, the matching will be done for a discrete set of points \mathbf{r}_i , usually on a pixel grid.

This problem can be solved by the method of Lagrange multipliers, just as in (8.288) *ff.*, but now we have an infinite number of constraints! For each operator $\mathcal{L}^{(j)}$, we must satisfy (8.301) for all \mathbf{r} and all z . We thus have a continuum of unknown Lagrange multipliers, which we can express as an unknown function $\Phi^{(j)}\{z\}$. With this view, the general form of the maximum-entropy object density turns out

to be [see Zhu *et al.* (1998) for details]

$$\begin{aligned} \text{pr}(\mathbf{f}) &= \frac{1}{Z} \exp \left\{ - \sum_i \sum_j \int dz \Phi^{(j)}\{z\} \delta \left\{ z - \left[\mathcal{L}^{(j)} \mathbf{f} \right] (\mathbf{r}_i) \right\} \right\} \\ &= \frac{1}{Z} \exp \left\{ - \sum_i \sum_j \Phi^{(j)} \left(\left[\mathcal{L}^{(j)} \mathbf{f} \right] (\mathbf{r}_i) \right) \right\}, \end{aligned} \quad (8.302)$$

where Z is a normalizing constant.

The problem is not yet solved since we still have to find the functionals $\Phi^{(j)}$ such that the constraints are satisfied. Zhu *et al.* propose an iterative algorithm for this purpose.

One remaining question is how to choose the operators $\mathcal{L}^{(j)}$ in the first place. Since stationarity is probably required to make this whole approach computationally feasible, it is natural to choose the operators as LSIV filters, but another consideration is independence. The maximum-entropy estimate in (8.302) shows that the filter outputs are statistically independent, even if this is not the case in reality. Zhu *et al.* propose use of a large library of filters and an iterative algorithm to select a subset of them that optimize a measure of independence, as in ICA, and Zhang (2001) suggests a Metropolis algorithm.

Parametric descriptions of the marginals The filters chosen in the Zhu approach (or discovered in ICA) are mostly band-pass filters (though Zhu includes a low-pass filter as well). As discussed in Sec. 8.4.3 and illustrated in Fig. 8.7, the outputs of band-pass filters tend to have simple cuspy shapes with long, kurtotic tails. Empirically, we can describe these marginals by simple analytical forms such as Laplacian or Levy densities, with only one or two free parameters per filter output.

This observation suggests an alternative to the Zhu method: instead of trying to choose the functions $\Phi^{(j)}\{z\}$ to match the empirical marginal histograms, we can directly estimate the free parameters in the assumed analytical densities (Kupinski *et al.*, 2003c).

Lumpy backgrounds Another way to generate images (or simulated objects) with specified correlation properties and controllable gray-level statistics is the *lumpy background*, introduced by Rolland and Barrett (1992). In this method, spatial elements, called *lumps* and denoted $l(\mathbf{r})$, are randomly distributed over some area, so the distribution has the form

$$f(\mathbf{r}) = \sum_{n=1}^N l(\mathbf{r} - \mathbf{r}_n). \quad (8.303)$$

A common choice for $l(\mathbf{r})$ is a Gaussian spatial distribution,

$$l(\mathbf{r}) = A \exp \left(- \frac{r^2}{2s^2} \right). \quad (8.304)$$

The positions \mathbf{r}_n and possibly also the total number of lumps N are random variables.

One important special case is where N is a Poisson random variable; the mathematical tools for analyzing this case will be developed in Sec. 11.3.9, and the characteristic functional for the random process (8.303) will be derived in Sec. 11.3.10.

As we shall see there, $f(\mathbf{r})$ is a stationary random process if the positions \mathbf{r}_n are uniformly distributed over some area, and the statistical autocorrelation function turns out to be just the autocorrelation integral of the lump profile [see (11.140)].

If N is large and the lump positions are statistically independent, the single-point PDF of a lumpy background approaches a Gaussian by the central-limit theorem. In this limit, the details of the lump profile are irrelevant, and the resulting functions are indistinguishable from ones obtained by filtering white, Gaussian noise. If N is small, on the other hand, then the lump profile controls the single-point PDF as well as the correlation properties; for more details, see Sec. 11.3.10.

More general lumpy backgrounds As originally defined by Rolland, the lump profile $l(\mathbf{r})$ in (8.303) is a nonrandom function; the only randomness is in the lump location \mathbf{r}_n . To allow more freedom in synthesizing lumpy backgrounds, we can let the lump profile also be random. For example, the amplitude or the width of each blob could vary according to some specified probability law.

One very useful variant of the simple lumpy background is the *clustered lumpy background*, suggested by Bochud *et al.* (1999a), where a cluster of identical blobs forms a *superblob*, and the final model is a superposition of superblobs. With this scheme, (8.303) becomes

$$f(\mathbf{r}) = \sum_{k=1}^{N_s} \sum_{n=1}^{N_k} l_k(\mathbf{r} - \mathbf{r}_{nk} - \mathbf{R}_k), \quad (8.305)$$

where N_s is the number of superblobs, N_k is the number of blobs within the k^{th} superblob, \mathbf{R}_k is the center of the k^{th} superblob, \mathbf{r}_{nk} is the center of the n^{th} blob within the k^{th} superblob, and $l_k(\mathbf{r})$ is the random lump profile associated with that superblob. It is useful to make N_k and N_s Poisson random variables, so we must wait until Chap. 11 to analyze the statistics of (8.305).

Bochud *et al.* chose elongated Gaussians for the lump profiles and used their orientation as the random parameter in $l_k(\mathbf{r})$. With this simple model they were able to synthesize images strikingly similar to clinical mammograms.

Two-point densities As we discussed in Sec. 8.4.2, two-point PDFs of the form $\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)]$ can be an important part of the stochastic description of objects in general, and they are particularly attractive for stationary random processes such as textures. For purposes of stochastic modeling, we can estimate the two-point PDF from the empirical co-occurrence statistics of one or a few images if we assume ergodicity. It was suggested by Julesz (1962) that textures with similar co-occurrence statistics would appear similar, though psychophysical studies have shown that higher-order statistics do have at least some effect on human texture perception (Diaconis and Freedman, 1981).

The use of co-occurrence statistics for synthesis of realistic textures should be distinguished from their use in texture discrimination or segmentation. In the latter application, the goal is to describe the texture pattern within a spatial region by a few features with good discriminatory power, and it is common to reduce pixel values in the region to a co-occurrence matrix and to derive the features from that matrix. There is no need to make any argument about ergodicity or stationarity in this application; if the features are useful in discriminating one region from another or classifying regions, that is justification enough.

Quasistationary textures Most of the discussion above has concentrated on textures as stationary random processes. If exact stationarity is not a good assumption, we may want to model a texture as quasistationary, and in this case the stochastic Wigner distribution function defined in Sec. 8.2.5 is a useful tool. In particular, if the quasistationary form (8.142) is valid, we can estimate the two factors $b(\mathbf{r}_0)$ and $A(\boldsymbol{\rho})$ separately from samples. If we want to generate sample textures with a stochastic Wigner distribution specified by (8.142), we can use a lumpy background with a spatially variable lump density (mean number of lumps per unit area) given by $b(\mathbf{r}_0)$. For more discussion on the statistics of lumpy backgrounds, see Sec. 11.3.10.

Sometimes the pattern we want to synthesize is stationary within prespecified boundaries. For example, we may want to simulate statistically independent sample functions of an abdominal section of the body in order to study image quality in computed tomography (CT). We can start with a good anatomical model, obtained perhaps by manual or automated segmentation of a single reference CT image, and we can identify specific organs such as liver and spleen within this image (Zubal *et al.*, 1994). Then any of the methods described above can be used to characterize the texture within each organ and to generate sample functions consistent with this characterization. These sample functions can then be placed within the specified organ boundaries, and the procedure can be repeated as many times as needed to get a large number of simulated abdomens. These simulations can be regarded as object representations rather than images since the organ boundaries will be sharp and the textures may contain very high spatial frequencies.

Random shapes In addition to simulating random textures within a region, we may wish to make the shape itself random. Simulating a shape usually means adopting some parameterized description of the shape and choosing the parameters. Some simple approaches to describing shapes mathematically were discussed briefly in Sec. 7.1.6. One approach, used for example by Cargill (1989) to describe the human liver, is to specify the distance R from some internal reference point to the boundary as a function of polar angles θ and ϕ . If the surface of the object is smooth, an expansion of $R(\theta, \phi)$ in spherical harmonics can be terminated with relatively few terms (~ 100 in Cargill's work), and the coefficients in this expansion are the desired parametric representation of the liver. This general approach is applicable to any 3D shape in which a reference point can be found for which $R(\theta, \phi)$ is unique; it is not necessary that the shape be convex, though convexity avoids the necessity of searching for a suitable reference point.

Another general approach, also mentioned briefly in Sec. 7.1.6, is to express the shape as a geometric transformation of a given reference shape. Affine or non-affine transformations can be used, and the parameters of the transformation are then the shape descriptors.

After establishing a parametric description of shape, the next step in shape simulation is to find the PDF on the parameters, for example by analyzing real shapes. One common approach is to compute a sample mean and sample covariance matrix on a set of measured parameters and, in effect, to assume that the PDF is multivariate normal with this mean and covariance. If there are many parameters, it can be advantageous to use principal components analysis or PCA (see Sec. 8.4.1) and retain only components corresponding to a few of the eigenvectors of the sample covariance with the largest eigenvalues. The eigenvectors themselves

are sets of shape parameters, and the shapes associated with them are often called *eigenshapes*. It must be kept in mind, however, that these eigenshapes are characteristics of both the particular shape description used and the experimental data set from which the parameters were derived.

However the PDF on the shape parameters is formulated, samples drawn from it can be used to synthesize new shapes consistent with the estimated PDF, and these random shapes can then be used in image-quality studies and many other investigations. For an example of these procedures, see Duta *et al.* (1999), and for general mathematical treatments of statistical shape analysis, see Small (1996), Dryden and Mardia (1998) and Kendall *et al.* (1999).

8.4.5 Signals and backgrounds

In many imaging situations, we do not have equal interest in all parts of the scene. In aerial reconnaissance, for example, we are relatively uninterested in trees and bushes, but we would be extraordinarily interested in a military vehicle that might be hiding in the bushes. Similarly, in an abdominal MRI scan, we have little interest in the myriad features of normal anatomy, but we are much more interested in a small nodule that might turn out to be malignant. As a very general term, we can call an object of interest, that may or may not be present in a given scene, a *signal*. The remainder of the scene can be called *background* or (especially in the radar literature) *clutter*. In Chap. 13 we shall discuss in detail methods of detecting signals, or distinguishing between different signals, but here we introduce the topic by discussing stochastic models for objects with and without signals.

Additive signals Perhaps surprisingly, it entails no loss of generality to decompose an object into a simple sum of signal and background components:

$$f(\mathbf{r}) = f_s(\mathbf{r}) + f_b(\mathbf{r}). \quad (8.306)$$

Once we have defined the portion of the object that we regard as signal and denoted it as $f_s(\mathbf{r})$, then the background $f_b(\mathbf{r})$ is just *defined* as $f(\mathbf{r}) - f_s(\mathbf{r})$.

This does not say that $f_b(\mathbf{r})$ is the same as $f(\mathbf{r})$ would be in the absence of the signal, though in fact it may be. In nuclear medicine for example, a tumor is often manifest by an increased uptake of some tumor-seeking radiopharmaceutical, so it is natural to simply add the tumor distribution $f_s(\mathbf{r})$ to the distribution $f_b(\mathbf{r})$ in normal tissue. If both $f_s(\mathbf{r})$ and $f_b(\mathbf{r})$ are sample functions of random processes, then it may be reasonable to take the two processes as statistically independent.

In optical imaging, on the other hand, objects are opaque, so a signal of interest may obscure the background behind it. For purposes of describing the response of an imaging system, the object $f(\mathbf{r})$ is either $f_b(\mathbf{r})$ or $f_s(\mathbf{r})$, not their sum. Nevertheless, we can still use an additive model if the statistical dependence of the two processes is taken into account.

Nonrandom signals The simplest model for a signal on a background is one where the signal function is completely specified and the only randomness is whether or not it is present. This model is often called SKE (signal known exactly). As we shall see in Chap. 13, it is an excellent starting point for discussing signal detection and image quality.

If we adopt the SKE model and assume that the signal is just added to the background rather than obscuring it, then the signal and background are statistically independent. With or without a signal, the PDF on $f(\mathbf{r})$ is fully determined by the PDF on $f_b(\mathbf{r})$ since that is the only random process in the problem. In the absence of a signal, we can write the univariate density on $f(\mathbf{r})$ as

$$\text{pr}[f(\mathbf{r})|\text{signal absent}] = \text{pr}_b[f_b(\mathbf{r})]. \quad (8.307)$$

We have added the subscript b to indicate that $\text{pr}_b[f_b(\mathbf{r})]$ is specifically the PDF on the background; the notation is redundant here since the same information is conveyed by the subscript on $f_b(\mathbf{r})$, but its usefulness will become apparent in a moment.

Because of the assumed statistical independence, the form of the PDF for $f_b(\mathbf{r})$ is still the same with a signal present, but to relate it to the PDF on $f(\mathbf{r})$ we must rewrite (8.306) as

$$f_b(\mathbf{r}) = f(\mathbf{r}) - f_s(\mathbf{r}). \quad (8.308)$$

We then have

$$\text{pr}[f(\mathbf{r})|\text{signal present}] = \text{pr}_b[f(\mathbf{r}) - f_s(\mathbf{r})]. \quad (8.309)$$

Now we see the need for the subscript: the 1D PDF $\text{pr}_b[f_b(\mathbf{r})]$ is merely shifted along the axis by the presence of a nonrandom signal (see Fig. 8.9), and the functional form is unchanged.

Fig. 8.9 Effect on the univariate PDF of adding a nonrandom signal to a random background.

This discussion has specifically dealt with univariate densities at a single point, but it is easy to extend it to an arbitrary number of points or to general Hilbert-space vectors representing object, signal and background. Abstractly, we can write

$$\text{pr}(\mathbf{f}|\text{signal absent}) = \text{pr}_b(\mathbf{f}_b); \tag{8.310}$$

$$\text{pr}(\mathbf{f}|\text{signal present}) = \text{pr}_b(\mathbf{f} - \mathbf{f}_s). \tag{8.311}$$

These densities can be interpreted as PDFs on coefficient vectors like $\boldsymbol{\alpha}$ or as multi-point densities. In fact, (8.308) and (8.309) follow from (8.310) and (8.311) just by regarding $f(\mathbf{r})$ as a component of \mathbf{f} (and similarly for \mathbf{f}_b and \mathbf{f}_s) and taking marginals on both sides of (8.310) and (8.311). Whatever space we are working in, addition of a nonrandom signal merely shifts the background PDF.

Parametric signal models Sometimes a signal is not known exactly but can be described by a function with a small number of unknown parameters. For example, in nuclear medicine a tumor might be well modeled as a sphere with random location, size and uptake of a radiopharmaceutical. Similarly, in astronomy a pulsar could be modeled as a time-varying point source, where the random parameters are its coordinates in the sky and the amplitude and period of the pulsation.

In these cases we do not need an infinite-dimensional PDF like $\text{pr}(\mathbf{f}_s)$ to describe the signal; if the signal is fully specified by L parameters $\{\theta_{s\ell}, \ell = 1, \dots, L\}$, all we need is the L -variate PDF $\text{pr}(\{\theta_{s\ell}\})$. The signal parameters can also be arranged into an $L \times 1$ vector $\boldsymbol{\theta}_s$, so we need the PDF $\text{pr}(\boldsymbol{\theta}_s)$ in order to describe the signal fully.

With a signal described parametrically, the object PDF is given by

$$\text{pr}(\mathbf{f}|\text{signal present}) = \int_{\infty} d^L\theta \text{pr}(\mathbf{f}|\text{signal present}, \boldsymbol{\theta}_s) \text{pr}(\boldsymbol{\theta}_s). \tag{8.312}$$

The conditional density $\text{pr}(\mathbf{f}|\text{signal present}, \boldsymbol{\theta}_s)$ is just the density for an SKE problem; if we condition on a set of parameters that completely specify the signal, then the signal *is* known exactly. If the signal and background are statistically independent, then this conditional density is given by (8.311), and we have

$$\text{pr}(\mathbf{f}|\text{signal present}) = \int_{\infty} d^L\theta_s \text{pr}_b[\mathbf{f} - \mathbf{f}_s(\boldsymbol{\theta}_s)] \text{pr}(\boldsymbol{\theta}_s). \tag{8.313}$$

The object PDF is now a weighted average of shifted background PDFs.

Obscuring signals If point \mathbf{r} lies within the signal and the signal obscures the background, then $f_b(\mathbf{r})$ can take on only the value zero at this point. Since $f(\mathbf{r})$ is then identical to $f_s(\mathbf{r})$, the univariate density on $f(\mathbf{r})$ for a nonrandom signal is given by

$$\text{pr}[f(\mathbf{r})|\text{signal present at } \mathbf{r}] = \delta[f(\mathbf{r}) - f_s(\mathbf{r})]. \tag{8.314}$$

If the signal is absent, or if it is present in the object but not at point \mathbf{r} , then (8.307) still holds.

Multipoint densities can be formulated similarly. For example, if a nonrandom signal is present at \mathbf{r}_1 but not at \mathbf{r}_2 , the two-point conditional PDF is

$$\text{pr}[f(\mathbf{r}_1), f(\mathbf{r}_2)|\text{signal present at } \mathbf{r}_1, \text{ absent at } \mathbf{r}_2] = \delta[f(\mathbf{r}_1) - f_s(\mathbf{r}_1)] \text{pr}_b[f(\mathbf{r}_2)]. \tag{8.315}$$

The univariate marginals of (8.315) are consistent with (8.314) and (8.307).

The PDFs specified by (8.314) and (8.315) can be difficult to work with, especially when we extend the discussion to random signals. It is often preferable to work in terms of the expansion coefficients $\{\alpha_n\}$. Consider a nonrandom, obscuring signal with support \mathbf{S}_s ; that is, the signal obscures the background for all points \mathbf{r} in the region \mathbf{S}_s . For an orthonormal basis, the coefficient α_n is given by

$$\alpha_n = \int_{\mathbf{S}_f} d^q r \psi_n^*(\mathbf{r}) f(\mathbf{r}), \quad (8.316)$$

where \mathbf{S}_f is the overall support of the object. When a signal is present, this integral can be written as

$$\alpha_n = \int_{\mathbf{S}_s} d^q r \psi_n^*(\mathbf{r}) f_s(\mathbf{r}) + \int_{\mathbf{S}_{sc}} d^q r \psi_n^*(\mathbf{r}) f_b(\mathbf{r}), \quad (8.317)$$

where \mathbf{S}_{sc} is the complement of \mathbf{S}_s , *i.e.*, the set of points in \mathbf{S}_f but not in \mathbf{S}_s .

We can think of the first integral in (8.317) as the n^{th} component of an infinite vector α_s describing the signal in the basis $\{\psi_n\}$; since the signal is nonrandom, α_s is nonrandom. The second integral would be the n^{th} expansion coefficient for the background except that we have excluded the region \mathbf{S}_s from the range of integration. Nevertheless, we can think of that integral as the n^{th} component of a random vector which we can denote as α_b , and we can write, without approximation,

$$\alpha = \alpha_s + \alpha_b, \quad (\text{signal present}). \quad (8.318)$$

If the signal is absent, then the support of the background is the same as the object support, and we can write

$$\alpha = \alpha_b, \quad (\text{signal absent}), \quad (8.319)$$

where α_b is now computed via integration over all of \mathbf{S}_f .

Because of the different regions of integration, the statistics of α_b will, in general, depend on whether or not the signal is present. There is, however, one interesting situation in which we might assume that α_b is independent of the signal. Suppose we have a spatially compact signal but a spatially extended basis function, such as a Fourier basis function (see Sec. 7.1.2). In that case, deletion of a small region may not change the value of the integral very much, so it might be a good approximation to say that α_b is the same with and without the obscuring signal. If that assumption is valid, then we are back to an additive model with a signal-independent background, at least in this basis. If, on the other hand, deletion of the signal support does change the integral significantly, we can still use the additive form (8.318), but we have to use a different PDF on α_b for signal present and signal absent.

8.5 STOCHASTIC MODELS FOR IMAGES

Having just discussed various stochastic models for objects, we turn now to images. In keeping with our emphasis on digital imaging, we consider only CD systems here, and for simplicity we assume they are linear. Our objective will be to characterize an ensemble of such images by its mean vector and covariance matrix and, where possible, a multivariate probability density function.

8.5.1 Linear systems

In the absence of noise, we defined a linear imaging system as one for which the image was a linear functional of the object; with noise, a linear imaging system can be defined as one for which the *average* image, obtained after many repeated images of the same object, is a linear functional of the object. If we denote this mean image by $\bar{\mathbf{g}}(\mathbf{f})$, then for any linear system we can write

$$\bar{\mathbf{g}}(\mathbf{f}) = \mathcal{H}\mathbf{f}, \quad (8.320)$$

where \mathcal{H} is a linear operator acting on the object \mathbf{f} .

Specifically for the case of digital imaging of an object function, we know from Sec. 7.3.1 that the most general way to write the linear mapping is

$$\bar{g}_m(\mathbf{f}) = \int_{\mathbf{S}_f} d^q r h_m(\mathbf{r}) f(\mathbf{r}), \quad m = 1, \dots, M. \quad (8.321)$$

Except for the overbar and the explicit argument \mathbf{f} , this equation is identical to (7.225). We emphasize that the average implied by this overbar is for repeated images of a single object.

To get an expression for the actual random image, we can define an $M \times 1$ noise vector \mathbf{n} by

$$\mathbf{n} \equiv \mathbf{g} - \bar{\mathbf{g}}(\mathbf{f}) = \mathbf{g} - \mathcal{H}\mathbf{f}. \quad (8.322)$$

Thus, we have

$$\mathbf{g} = \mathcal{H}\mathbf{f} + \mathbf{n}. \quad (8.323)$$

This is the fundamental equation describing noisy, digital imaging of real objects. Now we must understand the statistical properties of \mathbf{g} , both for a particular object \mathbf{f} and when a random ensemble of objects is considered.

8.5.2 Conditional statistics for a single object

Conditional density If each component of \mathbf{g} is a continuous random variable, we can denote the conditional probability density function (for a particular object) by $\text{pr}(\mathbf{g}|\mathbf{f})$. If each component of \mathbf{g} can take on only discrete values, we should use the conditional probability $\text{Pr}(\mathbf{g}|\mathbf{f})$, but to avoid considering these two cases in parallel, we shall use the lower-case $\text{pr}(\mathbf{g}|\mathbf{f})$ in both cases, understanding it as a probability density function or probability as needed. Specific forms for $\text{pr}(\mathbf{g}|\mathbf{f})$ will be given later, especially in Chaps. 11 and 12. As we shall see there, independent Poisson models are usually valid when photon-counting detectors are used, and multivariate normal models are valid with most other detectors.

Even without specific models for the detector statistics, we can make some general statements about $\text{pr}(\mathbf{g}|\mathbf{f})$. For one thing, we know that \mathbf{f} affects the data only through the system operator \mathcal{H} , so

$$\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}(\mathbf{g}|\mathcal{H}\mathbf{f}) = \text{pr}(\mathbf{g}|\mathcal{H}\mathbf{f}_{meas}). \quad (8.324)$$

Thus only the measurement component of the object affects the statistics of the image.

Furthermore, for a given \mathbf{f} , $\mathcal{H}\mathbf{f}$ is not a random variable, so

$$\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}_{\mathbf{n}}(\mathbf{g} - \mathcal{H}\mathbf{f}|\mathcal{H}\mathbf{f}), \quad (8.325)$$

where $\text{pr}_{\mathbf{n}}(\mathbf{n}|\bar{\mathbf{g}})$ is the PDF on the noise vector¹⁴ given some mean value for the detector output. If this density is independent of $\bar{\mathbf{g}}$, then we say that the noise is *object-independent* and write

$$\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}_{\mathbf{n}}(\mathbf{g} - \mathcal{H}\mathbf{f}). \quad (8.326)$$

In this case, therefore, the conditional density on \mathbf{g} is just a displaced version of the density on the noise. As we shall see in more detail in later chapters, this object-independent model is often valid for electronic and other excess noise in detectors.

A related approximation is that the noise is object-dependent but *signal-independent*. When we divide an object into signal and background, as in (8.306), it may turn out that the signal is weak compared to the background, and sometimes we can write $\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}(\mathbf{g}|\mathbf{f}_b + \mathbf{f}_s) \approx \text{pr}(\mathbf{g}|\mathbf{f}_b)$. This may be a good approximation with photon-counting detectors in low-contrast situations where all components of $\mathcal{H}\mathbf{f}$ are approximately equal.

Another assumption that is often justified in practice is that the components of \mathbf{n} are statistically independent for a fixed object. With discrete arrays of photodiodes, for example, the electronic noise in one element is often statistically independent of noise in all other elements, and we shall see in Chap. 11 that photon-counting detectors viewing a Poisson source almost always yield statistically independent measurements. When this assumption is valid, we have

$$\text{pr}(\mathbf{g}|\mathbf{f}) = \prod_{m=1}^M \text{pr}(g_m|\mathbf{f}). \quad (8.327)$$

Conditional mean and covariance We can also make some general statements about conditional means and covariances. We know already that the conditional mean of \mathbf{g} is

$$\text{E}\{\mathbf{g}|\mathbf{f}\} \equiv \bar{\mathbf{g}} = \mathcal{H}\mathbf{f}, \quad (8.328)$$

from which it follows at once that

$$\text{E}\{\mathbf{n}|\mathbf{f}\} = 0. \quad (8.329)$$

Thus we can always regard the noise vector as zero-mean.

Since we are conditioning on \mathbf{f} and hence $\mathcal{H}\mathbf{f}$ is not a random variable, the conditional covariance of \mathbf{g} is the same as the covariance of \mathbf{n} ; notationally, we write

$$\mathbf{K}_{\mathbf{g}|\mathbf{f}} = \mathbf{K}_{\mathbf{n}}, \quad (8.330)$$

but we must allow for the possibility that $\mathbf{K}_{\mathbf{n}}$ depends on \mathbf{f} (in the Poisson case, for example).

8.5.3 Effects of object randomness

Next we examine the image statistics in the case where the object is random. In frequentist terms, we can consider a large number of images, each with a different object drawn from some ensemble. Our knowledge of the object statistics is given by a stochastic model such as those considered in Sec. 8.4.

¹⁴Recall that we add subscripts to PDFs only when the random variable is not obvious from the argument.

Overall density Formally, we can write the overall probability density as

$$\text{pr}(\mathbf{g}) = \int_{\mathcal{U}} d\mathbf{f} \text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}). \quad (8.331)$$

In principle, this integral runs over the entire infinite-dimensional object space, but from (8.324) we know that only the measurement subspace contributes. The dimensionality of this subspace is R , the rank of the operator \mathcal{H} , so really only R components are important. If we expand \mathbf{f}_{meas} in some suitable basis for measurement space as in (7.251), with an $R \times 1$ coefficient vector $\boldsymbol{\alpha}$, then the integral can be written as

$$\text{pr}(\mathbf{g}) = \int_{\infty} d^R\alpha \text{pr}(\mathbf{g}|\boldsymbol{\alpha}) \text{pr}(\boldsymbol{\alpha}). \quad (8.332)$$

Depending on the choice of basis for measurement space, there is some matrix \mathbf{H}_0 that exactly maps the coefficients $\boldsymbol{\alpha}$ to $\mathcal{H}\mathbf{f}$ (see Sec. 7.4.3), so we can write

$$\text{pr}(\mathbf{g}) = \int_{\infty} d^R\alpha \text{pr}(\mathbf{g}|\mathbf{H}_0\boldsymbol{\alpha}) \text{pr}(\boldsymbol{\alpha}). \quad (8.333)$$

Derivation of the form of \mathbf{H}_0 for the specific case of expansion in natural pixels (Sec. 7.4.3) is an interesting exercise for the reader.

For object-independent noise as in (8.326), (8.333) takes the appealing form,

$$\text{pr}(\mathbf{g}) = \int_{\infty} d^R\alpha \text{pr}_{\mathbf{n}}(\mathbf{g} - \mathbf{H}_0\boldsymbol{\alpha}) \text{pr}(\boldsymbol{\alpha}). \quad (8.334)$$

This equation is not quite a convolution, but nevertheless it can be usefully transformed by Fourier methods. With characteristic functions as defined in (8.27) and some algebra similar to that used in obtaining (8.43), we can show that

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \psi_{\mathbf{n}}(\boldsymbol{\xi}) \psi_{\boldsymbol{\alpha}}(\mathbf{H}_0^t \boldsymbol{\xi}). \quad (8.335)$$

Increasing the noise level decreases the width of $\psi_{\mathbf{n}}(\boldsymbol{\xi})$ in this Fourier domain, and increasing the degree of object randomness decreases the width of $\psi_{\boldsymbol{\alpha}}(\mathbf{H}_0^t \boldsymbol{\xi})$; either measure decreases the width of $\psi_{\mathbf{g}}(\boldsymbol{\xi})$ and hence increases the spread of $\text{pr}(\mathbf{g})$.

For Poisson noise (8.334) and (8.335) are not valid; instead, (8.334) must be written as¹⁵

$$\text{Pr}(\mathbf{g}) = \int_{\infty} d^R\alpha \text{Pr}(\mathbf{g}|\mathbf{H}_0\boldsymbol{\alpha}) \text{pr}(\boldsymbol{\alpha}). \quad (8.336)$$

Note that we have written $\text{Pr}(\mathbf{g})$ instead of $\text{pr}(\mathbf{g})$ since Poisson random variables are discrete. The probability (not density) $\text{Pr}(\mathbf{g}|\mathbf{H}_0\boldsymbol{\alpha})$ is just a product of univariate Poisson probabilities, where the mean of g_m is $[\mathbf{H}_0\boldsymbol{\alpha}]_m$.

The transformation of the characteristic function in the Poisson case was derived by Clarkson *et al.* (2002). They show that (8.336) is equivalent to

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \psi_{\boldsymbol{\alpha}}[\mathbf{H}_0^t \boldsymbol{\Gamma}(\boldsymbol{\xi})], \quad (8.337)$$

¹⁵We could also have written $\text{Pr}(\mathbf{g}|\mathbf{H}_0\boldsymbol{\alpha})$ in (8.336) as $\text{Pr}(\mathbf{g}|\boldsymbol{\alpha})$ since $\mathbf{H}_0\boldsymbol{\alpha}$ is fully determined by $\boldsymbol{\alpha}$, but the former version is more useful when we want to write the probability as a product of Poissons; the probability for g_m is specified by a single component of $\mathbf{H}_0\boldsymbol{\alpha}$, but all components of $\boldsymbol{\alpha}$ may be required because of the matrix multiplication.

where $\mathbf{\Gamma}$ is an operator that acts independently on each component of its vector operand; it is defined such that

$$[\mathbf{\Gamma}(\boldsymbol{\xi})]_m = \frac{-1 + \exp(-2\pi i \xi_m)}{-2\pi i}. \quad (8.338)$$

Clarkson *et al.* (2002) show also that this transformation law applies when \mathbf{H}_0 is replaced by a CD operator \mathcal{H} and the full infinite-dimensional vector \mathbf{f} is used in place of the finite-dimensional $\boldsymbol{\alpha}$. In that case the characteristic *function* for \mathbf{g} is related to the characteristic *functional* for \mathbf{f} by

$$\psi_{\mathbf{g}}(\boldsymbol{\xi}) = \Psi_{\mathbf{f}}[\mathcal{H}^\dagger \mathbf{\Gamma}(\boldsymbol{\xi})]. \quad (8.339)$$

Overall mean We shall use the notation of (8.331), recognizing that the integral will be realized by expanding the measurement component of \mathbf{f} in some basis and integrating over the coefficients. With this convention, we can write the overall mean image as

$$\mathbf{E}(\mathbf{g}) = \int_{\infty} d^M g \mathbf{g} \text{pr}(\mathbf{g}) = \int_{\infty} d^M g \mathbf{g} \int_{\mathcal{U}} d\mathbf{f} \text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f}). \quad (8.340)$$

Shuffling the integrals, we see that

$$\mathbf{E}(\mathbf{g}) = \int_{\mathcal{U}} d\mathbf{f} \text{pr}(\mathbf{f}) \int_{\infty} d^M g \mathbf{g} \text{pr}(\mathbf{g}|\mathbf{f}). \quad (8.341)$$

The inner integral is the average of \mathbf{g} with respect to the conditional density, which is precisely what we called $\bar{\mathbf{g}}(\mathbf{f})$ previously, so

$$\mathbf{E}(\mathbf{g}) = \int_{\mathcal{U}} d\mathbf{f} \text{pr}(\mathbf{f}) \bar{\mathbf{g}}(\mathbf{f}). \quad (8.342)$$

Another notation that means the same thing is

$$\langle \mathbf{g} \rangle = \langle \langle \mathbf{g} \rangle_{\mathbf{n}|\mathbf{f}} \rangle_{\mathbf{f}}. \quad (8.343)$$

Yet another notation denotes this overall average as $\bar{\bar{\mathbf{g}}}$, with the double overbar indicating that we have averaged over both the measurement noise and the object variability. This double average can also be seen directly in (8.340) when we recall that $\text{pr}(\mathbf{g}|\mathbf{f}) \text{pr}(\mathbf{f})$ is also the joint density, $\text{pr}(\mathbf{g}, \mathbf{f})$.

Overall covariance When both measurement noise and object variability are taken into account, the covariance matrix on \mathbf{g} is defined (for real \mathbf{g}) by

$$\mathbf{K}_{\mathbf{g}} = \langle \langle [\mathbf{g} - \bar{\mathbf{g}}] [\mathbf{g} - \bar{\mathbf{g}}]^t \rangle_{\mathbf{n}|\mathbf{f}} \rangle_{\mathbf{f}}. \quad (8.344)$$

Adding and subtracting $\bar{\mathbf{g}}(\mathbf{f})$ in each factor gives

$$\mathbf{K}_{\mathbf{g}} = \langle \langle [\mathbf{g} - \bar{\mathbf{g}}(\mathbf{f}) + \bar{\mathbf{g}}(\mathbf{f}) - \bar{\mathbf{g}}] [\mathbf{g} - \bar{\mathbf{g}}(\mathbf{f}) + \bar{\mathbf{g}}(\mathbf{f}) - \bar{\mathbf{g}}]^t \rangle_{\mathbf{n}|\mathbf{f}} \rangle_{\mathbf{f}}. \quad (8.345)$$

Noting that $\bar{\mathbf{g}}(\mathbf{f}) - \bar{\mathbf{g}}$ does not involve \mathbf{n} (since it has been averaged out) and that $\langle [\mathbf{g} - \bar{\mathbf{g}}(\mathbf{f})] \rangle_{\mathbf{n}|\mathbf{f}} = 0$, we see that

$$\mathbf{K}_{\mathbf{g}} = \langle \langle [\mathbf{g} - \bar{\mathbf{g}}(\mathbf{f})][\mathbf{g} - \bar{\mathbf{g}}(\mathbf{f})]^t \rangle_{\mathbf{n}|\mathbf{f}} \rangle_{\mathbf{f}} + \langle [\bar{\mathbf{g}}(\mathbf{f}) - \bar{\mathbf{g}}] [\bar{\mathbf{g}}(\mathbf{f}) - \bar{\mathbf{g}}]^t \rangle_{\mathbf{f}}. \quad (8.346)$$

The first term in this expression is just the noise covariance matrix \mathbf{K}_n averaged over \mathbf{f} (though this average is superfluous in the case of object-independent noise); we can denote this term as $\overline{\mathbf{K}}_n$. The second term has nothing to do with \mathbf{n} but rather reflects the object variability as seen in the mean image; we can denote this term as $\mathbf{K}_{\overline{\mathbf{g}}}$. With this notation, we have

$$\mathbf{K}_g = \overline{\mathbf{K}}_n + \mathbf{K}_{\overline{\mathbf{g}}}. \quad (8.347)$$

This division of the overall covariance into two terms, one representing the average noise covariance and the other representing the variation in the conditional mean, is exact and does not require any assumptions about the form of either $\text{pr}(\mathbf{g}|\mathbf{f})$ or $\text{pr}(\mathbf{f})$. In particular, it does not require that the noise be object-independent, and it does not require that either the noise or the object be Gaussian.

Other expressions for the object-variability term There are several alternative ways of expressing $\mathbf{K}_{\overline{\mathbf{g}}}$. First, since the object $f(\mathbf{r})$ is a sample function of a random process, we can use the autocovariance operator \mathcal{K}_f , *i.e.*, the integral operator with kernel $K_f(\mathbf{r}, \mathbf{r}')$. Since $\overline{\mathbf{g}}$ is a linear transformation of \mathbf{f} by (8.320), it follows that [*cf.* (8.50) and (8.145)]

$$\mathbf{K}_{\overline{\mathbf{g}}} = \mathcal{H} \mathcal{K}_f \mathcal{H}^\dagger. \quad (8.348)$$

Similarly, if we know that $\mathbf{f}_{meas} = \mathbf{H}_0 \boldsymbol{\alpha}$ as in (8.333), and if we know the covariance matrix \mathbf{K}_α , then we have

$$\mathbf{K}_{\overline{\mathbf{g}}} = \mathbf{H}_0 \mathbf{K}_\alpha \mathbf{H}_0^t. \quad (8.349)$$

Finally, if we have some approximate object representation as in (7.301) and a system matrix \mathbf{H} as defined in (7.304), and we know a covariance matrix for the coefficients $\boldsymbol{\theta}$, then we can approximate $\mathbf{K}_{\overline{\mathbf{g}}}$ by

$$\mathbf{K}_{\overline{\mathbf{g}}} \approx \mathbf{H} \mathbf{K}_\theta \mathbf{H}^t. \quad (8.350)$$

This approximation will be accurate if the image error defined in (7.329) is small for all objects in the ensemble (and, of course, if \mathbf{K}_θ is accurate).

Sample averages We have written formal expressions for the overall mean and covariance as if we know the densities needed to perform the averages. In practice, we will usually know the conditional density $\text{pr}(\mathbf{g}|\mathbf{f})$, since it follows from the physics of the measurement process; as we have noted, this conditional density will usually be Gaussian or Poisson. The average over objects is much more problematical in practice. In Sec. 8.4 we discussed a variety of statistical models for objects, but we saw that there were many circumstances where we could generate samples of \mathbf{f} but could not develop an analytical expression for $\text{pr}(\mathbf{f})$. In these circumstances we have no choice but to approximate the analytical averages with sample averages; more details on how this is done in practice will be forthcoming in Chap. 14.

8.5.4 Signals and backgrounds in image space

In Sec. 8.4.5, we divided the object into signal and background parts as in (8.306), which we can also write as

$$\mathbf{f} = \mathbf{f}_s + \mathbf{f}_b. \quad (8.351)$$

Now we shall look at how this division affects the image statistics.

Conditional statistics The conditional mean, for a fixed object, is still given by (8.328), but because of the assumed linearity of the operator, we can write separately that

$$\bar{\mathbf{g}}_s = \mathcal{H}\mathbf{f}_s, \quad \bar{\mathbf{g}}_b = \mathcal{H}\mathbf{f}_b, \quad (8.352)$$

The conditional covariance is still given by (8.330), but for signal-dependent noise we have to assume in general that the noise covariance matrix depends on both the signal and the background. In many problems, however, we can assume that the signal is weak compared to the background, so \mathbf{K}_n is approximately independent of \mathbf{f}_s .

The conditional density is still given by (8.325), which we can now write as

$$\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}_n(\mathbf{g} - \mathcal{H}\mathbf{f}_s - \mathcal{H}\mathbf{f}_b|\mathcal{H}\mathbf{f}) \quad (8.353)$$

or, for object-independent noise,

$$\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}_n(\mathbf{g} - \mathcal{H}\mathbf{f}_s - \mathcal{H}\mathbf{f}_b). \quad (8.354)$$

For noise that is object-dependent but signal-independent, this expression would become $\text{pr}(\mathbf{g}|\mathbf{f}) = \text{pr}_n(\mathbf{g} - \mathcal{H}\mathbf{f}_s - \mathcal{H}\mathbf{f}_b|\mathcal{H}\mathbf{f}_b)$.

Random background When the background \mathbf{f}_b is random but the signal is not, then the overall probability density function in (8.331) becomes

$$\text{pr}(\mathbf{g}) = \int_{\mathcal{U}} d\mathbf{f}_b \text{pr}(\mathbf{g}|\mathbf{f}_b, \mathbf{f}_s) \text{pr}(\mathbf{f}_b) \quad (8.355)$$

or, for object-independent noise,

$$\text{pr}(\mathbf{g}) = \int_{\mathcal{U}} d\mathbf{f}_b \text{pr}_n(\mathbf{g} - \mathcal{H}\mathbf{f}_b - \mathcal{H}\mathbf{f}_s) \text{pr}(\mathbf{f}_b). \quad (8.356)$$

For a nonrandom signal, the overall covariance matrix is almost unchanged from before; from (8.347) and (8.348), we have

$$\mathbf{K}_g = \bar{\mathbf{K}}_n + \mathcal{H}\mathcal{K}_{\mathbf{f}_b}\mathcal{H}^\dagger. \quad (8.357)$$

Essentially the only change here is the subscript on \mathcal{K} .

Random signals If both signal and background are random but they are statistically independent, the overall density on the data is given by [cf. (8.355)]

$$\text{pr}(\mathbf{g}) = \int_{\mathcal{U}} d\mathbf{f}_s \int_{\mathcal{U}} d\mathbf{f}_b \text{pr}(\mathbf{g}|\mathbf{f}_b, \mathbf{f}_s) \text{pr}(\mathbf{f}_b) \text{pr}(\mathbf{f}_s). \quad (8.358)$$

The overall covariance matrix in this case is given by

$$\mathbf{K}_g = \bar{\mathbf{K}}_n + \mathcal{H}\mathcal{K}_{\mathbf{f}_s}\mathcal{H}^\dagger + \mathcal{H}\mathcal{K}_{\mathbf{f}_b}\mathcal{H}^\dagger. \quad (8.359)$$

If \mathbf{f}_s and \mathbf{f}_b are not statistically independent, we can write $\text{pr}(\mathbf{f}_b)\text{pr}(\mathbf{f}_s) = \text{pr}(\mathbf{f}_b|\mathbf{f}_s)\text{pr}(\mathbf{f}_s)$ and do a nested average as in (8.344); the result will be that $\mathcal{K}_{\mathbf{f}_b}$ acquires an overbar indicating that it is to be averaged over signals.

9

Diffraction Theory and Imaging

In Chapter 7 we looked at various ways of describing imaging systems as mathematical operators. Now we begin to connect these operators with physical phenomena and specific imaging systems. In particular, in this chapter we consider the broad category of imaging via wave propagation. The waves in question can be light waves, other electromagnetic waves such as microwaves, sound waves as in medical ultrasound, or even matter waves as in electron microscopy.

To analyze such systems, we need a thorough understanding of wave propagation and diffraction theory, and much of this chapter is devoted to those topics. The story begins with first principles, which for electromagnetic waves is Maxwell's equations. In Sec. 9.1 we use Maxwell's equations to derive the general time-dependent wave equation, and then we specialize to the case of monochromatic or single-frequency waves. Two important special solutions of the wave equation are plane waves and spherical waves, both discussed in Sec. 9.2.

In Sec. 9.3 we develop an important tool called Green's functions for solving the wave equations. Green's functions will prove to be familiar from Chap. 7 since they are the point response functions if we think of the wave equation as a linear system.

Waves passing through a finite aperture or radiating from a finite source propagate in complicated ways, giving rise to beautiful and highly useful patterns. In Secs. 9.4 and 9.5 we develop the essential mathematical techniques needed to calculate these patterns. These techniques are referred to collectively as diffraction theory, though they could equally well be called radiation theory. As we shall see, they also fit nicely into the theory of linear shift-invariant systems developed in Chap. 7.

In Sec. 9.6 we start to apply diffraction theory to imaging. We introduce a mathematical description for an ideal lens and then analyze how it forms an image of a monochromatic point object. Then deviations from ideal behavior, called aberrations, are discussed from a diffraction-theory viewpoint.

The imaging of extended planar objects is discussed in Sec. 9.7. Included in Sec. 9.7 is an introduction to the concept of coherence, needed when the radiation source is random. This development builds on the discussion of random processes in Chap. 8.

The treatment of diffraction and imaging in Secs. 9.4–9.7 is essentially two-dimensional; objects are described as planar apertures or transparencies, and the resulting fields are computed on planes. In Sec. 9.8, however, we extend the discussion to volume objects and fields computed at general points in a 3D space.

9.1 WAVE EQUATIONS

In this section we derive the basic equations that describe wave propagation. The treatment here is for electromagnetic waves, but the resulting theory is valid, with minor modifications, for acoustic waves as well. The key difference is that an electromagnetic wave consists of vector fields (such as the electric and magnetic fields), while an acoustic wave consists of more complicated fields (the stress and strain) called tensors. In practice, however, we usually reduce both the electromagnetic and acoustic wave equations to an equation describing a scalar field, and at that point the mathematical distinction between electromagnetics and acoustics largely disappears. Moreover, the scalar theory is also applicable to electron imaging when the electrons are regarded as waves (Reimer, 1985).

9.1.1 Maxwell's equations

A vector field is a vector, each component of which is a function of spatial position and time. Spatial position is given by a 3D vector which we shall denote by the boldface gothic \mathbf{r} . Later in this chapter, we shall also deal with 2D position vectors, which will be denoted by \mathbf{r} . In Cartesian coordinates,

$$\mathbf{r} = (x, y, z), \quad \mathbf{r} = (x, y). \quad (9.1)$$

A 3D vector field has three Cartesian components, each a function of \mathbf{r} and time t . Electromagnetic waves are described by four such vector fields: (1) the electric field $\mathbf{e}(\mathbf{r}, t)$, (2) the electric flux density or displacement $\mathbf{d}(\mathbf{r}, t)$, (3) the magnetic field $\mathbf{h}(\mathbf{r}, t)$ and (4) the magnetic flux density $\mathbf{b}(\mathbf{r}, t)$. These fields are produced by a current density (current per unit area) $\mathbf{j}(\mathbf{r}, t)$ and a charge density (charge per unit volume) $q(\mathbf{r}, t)$. This notation is nonstandard in that it uses lower-case letters where most books use capitals, and in the use of q for charge density instead of the usual ρ , which we want to reserve for spatial frequency. A potential confusion is that q is often used for charge, but here it is charge per unit volume.

The field quantities obey Maxwell's equations, a set of four coupled first-order partial differential equations. In the International System of Units (SI), Maxwell's equations are given by

$$\nabla \times \mathbf{e}(\mathbf{r}, t) = -\frac{\partial}{\partial t} \mathbf{b}(\mathbf{r}, t), \quad (9.2a)$$

$$\nabla \times \mathbf{h}(\mathbf{r}, t) = \mathbf{j}(\mathbf{r}, t) + \frac{\partial}{\partial t} \mathbf{d}(\mathbf{r}, t), \quad (9.2b)$$

$$\nabla \cdot \mathbf{d}(\mathbf{r}, t) = q(\mathbf{r}, t), \quad (9.2c)$$

$$\nabla \cdot \mathbf{b}(\mathbf{r}, t) = 0. \quad (9.2d)$$

In these equations, $\nabla \cdot$ and $\nabla \times$ are the divergence and curl operators, respectively. They can be expressed in terms of the vector operator ∇ , specified in Cartesian coordinates as $(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z})$. The divergence of a vector field such as $\mathbf{b}(\mathbf{r}, t)$ is a scalar field obtained formally by performing a 3D scalar or dot product between ∇ and $\mathbf{b}(\mathbf{r}, t)$, so that

$$\nabla \cdot \mathbf{b}(\mathbf{r}, t) = \frac{\partial b_x(\mathbf{r}, t)}{\partial x} + \frac{\partial b_y(\mathbf{r}, t)}{\partial y} + \frac{\partial b_z(\mathbf{r}, t)}{\partial z}. \quad (9.3)$$

The curl is computed similarly except that a vector cross product is used. The curl of a vector field is thus another vector field, with components given by

$$[\nabla \times \mathbf{b}(\mathbf{r}, t)]_i = \frac{\partial b_j(\mathbf{r}, t)}{\partial x_k} - \frac{\partial b_k(\mathbf{r}, t)}{\partial x_j}, \quad (9.4)$$

where (i, j, k) is a cyclic permutation of $(1, 2, 3)$.

We shall often consider free space where there are no material media, no currents and no charges. In free space, $q(\mathbf{r}, t) = 0$, $\mathbf{j}(\mathbf{r}, t) = 0$, and the following relations connect $\mathbf{d}(\mathbf{r}, t)$ to $\mathbf{e}(\mathbf{r}, t)$ and $\mathbf{b}(\mathbf{r}, t)$ to $\mathbf{h}(\mathbf{r}, t)$:

$$\mathbf{d}(\mathbf{r}, t) = \epsilon_0 \mathbf{e}(\mathbf{r}, t), \quad \mathbf{b}(\mathbf{r}, t) = \mu_0 \mathbf{h}(\mathbf{r}, t), \quad (9.5)$$

where ϵ_0 and μ_0 are the permittivity and permeability, respectively, of free space. These equations are called *constitutive relations*. More complicated constitutive relations, to be discussed in Sec. 9.1.3, apply in material media.

In free space, Maxwell's equations can be written entirely in terms of $\mathbf{e}(\mathbf{r}, t)$ and $\mathbf{h}(\mathbf{r}, t)$:

$$\nabla \times \mathbf{e}(\mathbf{r}, t) = -\mu_0 \frac{\partial}{\partial t} \mathbf{h}(\mathbf{r}, t), \quad (9.6a)$$

$$\nabla \times \mathbf{h}(\mathbf{r}, t) = \epsilon_0 \frac{\partial}{\partial t} \mathbf{e}(\mathbf{r}, t), \quad (9.6b)$$

$$\nabla \cdot \mathbf{e}(\mathbf{r}, t) = 0, \quad (9.6c)$$

$$\nabla \cdot \mathbf{h}(\mathbf{r}, t) = 0. \quad (9.6d)$$

9.1.2 Maxwell's equations in the Fourier domain

By straightforward Fourier analysis, $\mathbf{e}(\mathbf{r}, t)$ can be represented as

$$\mathbf{e}(\mathbf{r}, t) = \int_{-\infty}^{\infty} d^3\sigma \int_{-\infty}^{\infty} d\nu \mathbf{E}(\boldsymbol{\sigma}, \nu) \exp[2\pi i(\boldsymbol{\sigma} \cdot \mathbf{r} - \nu t)], \quad (9.7)$$

with the inverse relation

$$\mathbf{E}(\boldsymbol{\sigma}, \nu) = \int_{-\infty}^{\infty} d^3\mathbf{r} \int_{-\infty}^{\infty} dt \mathbf{e}(\mathbf{r}, t) \exp[-2\pi i(\boldsymbol{\sigma} \cdot \mathbf{r} - \nu t)]. \quad (9.8)$$

Note that we use $\boldsymbol{\sigma}$ for the 3D spatial-frequency vector here, reserving $\boldsymbol{\rho}$ for the 2D frequency later on.

We shall refer to $\mathbf{E}(\boldsymbol{\sigma}, \nu)$ as the 4D Fourier transform of $\mathbf{e}(\mathbf{r}, t)$ even though it does not conform to the sign conventions for Fourier transforms introduced in Chap. 3. By those conventions, $\mathbf{E}(\boldsymbol{\sigma}, \nu)$ is a 3D spatial Fourier transform and a 1D *inverse* Fourier transform of $\mathbf{e}(\mathbf{r}, t)$. The convention employed in (9.7) and (9.8) has the advantage that a component with positive ν represents a wave travelling in the $+\boldsymbol{\sigma}$ direction. With the understanding that the usual Fourier sign convention is reversed for temporal transforms, we write

$$\mathbf{E}(\boldsymbol{\sigma}, \nu) = \mathcal{F}_4\{\mathbf{e}(\mathbf{r}, t)\}. \quad (9.9)$$

The Fourier transform of a vector is another vector, obtained by transforming each Cartesian component of the first. In other words, $E_x\{\boldsymbol{\sigma}, \nu\} = \mathcal{F}_4\{e_x(\mathbf{r}, t)\}$, and similarly for y and z components. Note also that the vectors being transformed are 3D but the transform operations are 4D; the argument of the 3D vector field $\mathbf{e}(\mathbf{r}, t)$ can be regarded as a 4D vector with components (x, y, z, t) .

From (3.234) we can establish that

$$\mathcal{F}_4\left\{\frac{\partial}{\partial t}\mathbf{e}(\mathbf{r}, t)\right\} = -2\pi i\nu\mathbf{E}(\boldsymbol{\sigma}, \nu), \quad (9.10)$$

$$\mathcal{F}_4\{\nabla \cdot \mathbf{e}(\mathbf{r}, t)\} = 2\pi i\boldsymbol{\sigma} \cdot \mathbf{E}(\boldsymbol{\sigma}, \nu), \quad (9.11)$$

$$\mathcal{F}_4\{\nabla \times \mathbf{e}(\mathbf{r}, t)\} = 2\pi i\boldsymbol{\sigma} \times \mathbf{E}(\boldsymbol{\sigma}, \nu). \quad (9.12)$$

With similar Fourier representations for the other fields, Maxwell's equations can be transformed into

$$\boldsymbol{\sigma} \times \mathbf{E}(\boldsymbol{\sigma}, \nu) = \nu\mathbf{B}(\boldsymbol{\sigma}, \nu), \quad (9.13a)$$

$$2\pi i\boldsymbol{\sigma} \times \mathbf{H}(\boldsymbol{\sigma}, \nu) = \mathbf{J}(\boldsymbol{\sigma}, \nu) - 2\pi i\nu\mathbf{D}(\boldsymbol{\sigma}, \nu), \quad (9.13b)$$

$$2\pi i\boldsymbol{\sigma} \cdot \mathbf{D}(\boldsymbol{\sigma}, \nu) = Q(\boldsymbol{\sigma}, \nu), \quad (9.13c)$$

$$\boldsymbol{\sigma} \cdot \mathbf{B}(\boldsymbol{\sigma}, \nu) = 0. \quad (9.13d)$$

Fourier transformation has converted the coupled differential equations into coupled algebraic equations.

Note that it is not legal to set \mathbf{J} and Q to zero and then claim that equations (9.13) are valid in free space. Equations (9.6) are valid in any region of space where \mathbf{j} and q are zero since the differential operators in (9.6) are *local*, relating fields at a point to sources at the *same* point, but Fourier transformation is not local. The Fourier transforms \mathbf{J} and Q would be zero for all $\boldsymbol{\sigma}$ and ν only if \mathbf{j} and q were zero *everywhere*, which is a physically uninteresting case.

SVD of Maxwell's equations In Chap. 7, one of our primary tools for describing linear systems was singular-value decomposition or SVD. The value of SVD is that it reduces complicated linear operators to simple multiplications. Since Maxwell's equations are linear, they should also be amenable to SVD analysis.

In fact, equations (9.13) can be regarded as Maxwell's equations in SVD form. We saw in Sec. 2.4.5 that the vector derivatives that occur in Maxwell's equations can all be expressed in terms of convolutions with corresponding derivatives of delta functions. We also know from Sec. 7.2.3 that Fourier analysis is equivalent to SVD for convolution operators, so the multiplicative forms in (9.13) should not be surprising. A differential equation with constant coefficients is a linear, shift-invariant system.

9.1.3 Material media

Equations (9.6a-d) or (9.13a-d) will form the basis for our discussion of electromagnetic waves, but before proceeding we take a look at how they must be modified if the wave is in a material medium rather than free space. The main thing we have to re-examine is the constitutive relations, (9.5). The electric field and electric displacement in a material medium are related by

$$\mathbf{d}(\mathbf{r}, t) = \epsilon_0 \mathbf{e}(\mathbf{r}, t) + \mathbf{p}(\mathbf{r}, t), \quad (9.14)$$

where $\mathbf{p}(\mathbf{r}, t)$ is the *polarization* of the medium, defined as the electric dipole moment per unit volume averaged over a volume large compared to an atom. A useful physical picture of polarization is that it results from distortion of a charge distribution. A symmetric distribution of charge for which $q(\mathbf{r}, t) = q(-\mathbf{r}, t)$ has no dipole moment and hence no polarization. As an example, an isolated atom in any stationary state (any definite energy level) has no dipole moment because the electronic charge cloud is symmetrically disposed about the nucleus, so a collection of such atoms has no polarization.

Except for certain materials called *ferroelectrics*, there is no permanent polarization; $\mathbf{p}(\mathbf{r}, t)$ is induced by the applied electric field. For example, an electric field exerts a force on the electron cloud around an atom, distorting it and creating a polarization. If the electric field is strong, the polarization can be a nonlinear function of the electric field, but for weak fields the distortion is proportional to the force, so $\mathbf{p}(\mathbf{r}, t)$ is a linear function of $\mathbf{e}(\mathbf{r}, t)$. Except for a few places where we mention nonlinear optics, we shall assume linear media in this sense throughout this book.

The most general linear model would allow $\mathbf{p}(\mathbf{r}, t)$ to be influenced by $\mathbf{e}(\mathbf{r}', t')$ for all \mathbf{r}' and for all $t' \leq t$. The latter restriction is imposed since the response (polarization) at time t has no way of anticipating the stimulus (electric field) at a later time; the response must be causal (see Sec. 7.2.3). Since any Cartesian component of the vector $\mathbf{p}(\mathbf{r}, t)$ can, in general, be affected by any component of $\mathbf{e}(\mathbf{r}, t)$, the most general linear relation between $\mathbf{p}(\mathbf{r}, t)$ and the electric field that induces it has the form

$$\mathbf{p}(\mathbf{r}, t) = \int_{\infty} d^3 \mathbf{r}' \int_{-\infty}^t dt' \mathbf{M}(\mathbf{r}, t; \mathbf{r}', t') \mathbf{e}(\mathbf{r}', t'), \quad (9.15)$$

where $\mathbf{M}(\mathbf{r}, t; \mathbf{r}', t')$ is a 3×3 response matrix, each element of which is a function of two spatial variables, \mathbf{r} and \mathbf{r}' , and two temporal variables, t and t' . If the medium is isotropic, the polarization must be parallel to the electric field by symmetry; there is no preferred direction in the problem except that of the electric field. The mathematical statement of isotropy is that \mathbf{M} is some function $m(\mathbf{r}, t; \mathbf{r}', t')$ times the 3×3 unit matrix. With this form, each Cartesian component of the polarization is affected only by the corresponding component of the electric field.

Two additional assumptions will simplify the formulation further. First, since polarization is the result of the force exerted by an electric field on a charge distribution, we assume that it is local, which means that the polarization at some point \mathbf{r} is influenced only by the field at that same point \mathbf{r} . In addition, if the properties of the medium are not themselves time-dependent, the system is temporally shift-invariant (see Sec. 7.2.3). We express these assumptions mathematically by writing $m(\mathbf{r}, t; \mathbf{r}', t') = \delta(\mathbf{r} - \mathbf{r}') w(\mathbf{r}, t - t')$. To ensure causality, we assume that

$w(\mathbf{r}, t - t') = 0$ if $t < t'$. With these assumptions, (9.15) becomes

$$\mathbf{p}(\mathbf{r}, t) = \int_{-\infty}^{\infty} dt' w(\mathbf{r}, t - t') \mathbf{e}(\mathbf{r}, t'), \quad (9.16)$$

which is now in the form of a 1D temporal convolution for each spatial position and each Cartesian component. It is necessary to retain the temporal convolution if we wish to consider electric fields with arbitrary temporal dependence.

If the medium is homogeneous, so that its response is independent of position, we can write

$$w(\mathbf{r}, t) = w(t) = \mathcal{F}_1^{-1}\{W(\nu)\}. \quad (9.17)$$

With this assumption, a 1D temporal Fourier transform of (9.16) followed by a 3D spatial Fourier transform yields

$$\mathbf{P}(\boldsymbol{\sigma}, \nu) = W(\nu) \mathbf{E}(\boldsymbol{\sigma}, \nu), \quad (9.18)$$

where $\mathbf{P}(\boldsymbol{\sigma}, \nu) = \mathcal{F}_4\{\mathbf{p}(\mathbf{r}, t)\}$ and $W(\nu) = \mathcal{F}_1\{w(t)\}$.

If we also assume that $\mathbf{E}(\boldsymbol{\sigma}, \nu)$ is concentrated in a narrow band of frequencies centered around $\nu = \nu_0$, it may sometimes be valid to assume that $\mathbf{P}(\boldsymbol{\sigma}, \nu) \approx W(\nu_0) \mathbf{E}(\boldsymbol{\sigma}, \nu)$ for frequencies in this band. In these circumstances, it is customary to define $W(\nu_0) = \epsilon_0 \chi(\nu_0)$, where $\chi(\nu)$ is the *frequency-dependent susceptibility*. With this definition we have

$$\mathbf{P}(\boldsymbol{\sigma}, \nu) \approx \epsilon_0 \chi(\nu_0) \mathbf{E}(\boldsymbol{\sigma}, \nu), \quad \mathbf{p}(\mathbf{r}, t) \approx \epsilon_0 \chi(\nu_0) \mathbf{e}(\mathbf{r}, t). \quad (9.19)$$

Plugging this result into (9.14), we find

$$\mathbf{d}(\mathbf{r}, t) = \epsilon_0 [1 + \chi(\nu_0)] \mathbf{e}(\mathbf{r}, t) \equiv \epsilon(\nu_0) \mathbf{e}(\mathbf{r}, t). \quad (9.20)$$

Thus, if the long string of assumptions made in this section is valid, all we have to do to use the constitutive relation $\mathbf{d} = \epsilon_0 \mathbf{e}$ in a material medium is to replace ϵ_0 with $\epsilon(\nu_0)$. It is worth recounting the assumptions that go into this result, however. We must assume that the medium is linear, isotropic and homogeneous, that its response is local (which means that $\mathbf{p}(\mathbf{r}, t)$ is determined by $\mathbf{e}(\mathbf{r}, t)$ at that same \mathbf{r}), that $\mathbf{e}(\mathbf{r}, t)$ is narrowband or *quasimonochromatic* in the sense that its temporal Fourier transform spans a narrow range of frequencies, and that the response of the medium is approximately independent of the temporal frequency over this range. If all of these assumptions hold, we can use (9.20), but it is incumbent on us to check them in particular problems.

One might think that we would have to go through a similar discussion to find a generalization of the magnetic constitutive relation, $\mathbf{b}(\mathbf{r}, t) = \mu_0 \mathbf{h}(\mathbf{r}, t)$, but in optical problems we have a great simplification. Unlike electric dipoles, magnetic dipoles do not respond at optical frequencies, so magnetization (magnetic dipole moment per unit volume) is independent of the applied field. Thus we can use the free-space magnetic constitutive relation with impunity in a material medium.

The punchline of this section is that we can often get away with (9.6) simply by replacing ϵ_0 with $\epsilon(\nu_0)$. Media for which this approximation is valid will be called *nondispersive*, meaning that $\epsilon(\nu)$ does not vary much over the relevant temporal bandwidth. To simplify the notation we shall use ϵ for $\epsilon(\nu_0)$, but the requirements for narrowband radiation and nondispersive media should be kept in mind.

9.1.4 Time-dependent wave equations

Though Maxwell's equations are a complete description of electromagnetic waves, it is more convenient to work with wave equations, which are second-order partial differential equations.

Consider a region of space where there are no material media, but where there may be charges and currents to generate the field. In this region, the constitutive relations of (9.5) hold. The wave equation for the electric field in this region is obtained by taking the curl of (9.2a) and using the other Maxwell's equations, the constitutive relations and the following identity from vector calculus:

$$\nabla \times (\nabla \times \mathbf{e}) = \nabla(\nabla \cdot \mathbf{e}) - \nabla^2 \mathbf{e}, \quad (9.21)$$

where ∇^2 is the Laplacian operator $\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$. The result of these manipulations is

$$\left(\nabla^2 - \mu_0 \epsilon_0 \frac{\partial^2}{\partial t^2} \right) \mathbf{e}(\mathbf{r}, t) = \mu_0 \frac{\partial}{\partial t} \mathbf{j}(\mathbf{r}, t) + \frac{1}{\epsilon_0} \nabla q(\mathbf{r}, t). \quad (9.22)$$

The advantage of using a second-order equation is now apparent: (9.22) is an equation for $\mathbf{e}(\mathbf{r}, t)$ alone, uncoupled from the other field quantities. If $\mathbf{j}(\mathbf{r}, t)$ and $q(\mathbf{r}, t)$ are specified, we can solve directly for $\mathbf{e}(\mathbf{r}, t)$ (and we shall do so in Sec. 9.3.4).

Note also that (9.22) is really three equations, one for each of the three Cartesian components of $\mathbf{e}(\mathbf{r}, t)$, but these equations are uncoupled as well. We can solve for $e_x(\mathbf{r}, t)$ knowing only the x component of the right-hand side of (9.22) and without having to solve for the y and z components of $\mathbf{e}(\mathbf{r}, t)$.

Similar wave equations can be obtained for other field quantities of interest. For example, the wave equation for $\mathbf{h}(\mathbf{r}, t)$ has exactly the same differential operator on the left-hand side as in (9.22), but with a different driving term on the right. No matter what field quantity we consider, we arrive at the *time-dependent inhomogeneous scalar wave equation*, the general form of which is (Jackson, 1998; Arfken and Weber, 1995)

$$\left(\nabla^2 - \frac{1}{c_m^2} \frac{\partial^2}{\partial t^2} \right) u(\mathbf{r}, t) = s(\mathbf{r}, t), \quad (9.23)$$

where $u(\mathbf{r}, t)$ is some scalar field and $s(\mathbf{r}, t)$ is a corresponding scalar source term related in some way to charges and currents. The field $u(\mathbf{r}, t)$ may, for example, be a Cartesian component of the electric or magnetic field, or it may be the scalar potential or a Cartesian component of the vector potential. Each choice for $u(\mathbf{r}, t)$ has associated with it an appropriate $s(\mathbf{r}, t)$, the form of which can be derived from Maxwell's equations. If $s(\mathbf{r}, t) = 0$, (9.23) reduces to the *homogeneous time-dependent wave equation*.

The constant c_m in (9.23) has dimensions of speed, and we shall see in Sec. 9.2 that it can be interpreted as the speed of wave propagation in the medium (hence the subscript). Different media and different kinds of waves require different choices for c_m . For electromagnetic waves in vacuum, $c_m^2 = (\mu_0 \epsilon_0)^{-1} = c^2$, where c is the speed of light. In a material satisfying the assumptions of Sec. 9.1.3, $c_m^2 = 1/\mu_0 \epsilon \equiv c^2/n^2$, where n is the index of refraction of the medium. For homogeneous media, c_m is a constant, but in general it can be a function of position and time.

The scalar wave equation (9.23) applies to other kinds of waves as well. For

example, with proper choice of c_m , $u(\mathbf{r}, t)$ and $s(\mathbf{r}, t)$, it applies to acoustic waves. For the remainder of this chapter, we shall work directly with (9.23) and not worry about the physical interpretation of $u(\mathbf{r}, t)$ and $s(\mathbf{r}, t)$.

The Fourier transform of the time-dependent scalar wave equation is

$$-4\pi^2 \left(\sigma^2 - \frac{\nu^2}{c_m^2} \right) U(\boldsymbol{\sigma}, \nu) = S(\boldsymbol{\sigma}, \nu), \quad (9.24)$$

where $U(\boldsymbol{\sigma}, \nu)$ and $S(\boldsymbol{\sigma}, \nu)$ denote 4D Fourier transforms of $u(\mathbf{r}, t)$ and $s(\mathbf{r}, t)$, respectively. Once again, Fourier transformation has converted a partial differential equation to an algebraic one.

9.1.5 Time-independent wave equations

An important special case of the scalar wave equation arises when the source oscillates at a single frequency, so we can write

$$s(\mathbf{r}, t) = s(\mathbf{r}) \exp(-2\pi i \nu_0 t). \quad (9.25)$$

Of course, $s(\mathbf{r}, t)$ must be real, so the real part of the complex exponential is understood (see Sec. 7.1.1). Because of the linearity of the wave equation, we can use complex notation for source and field and separate real and imaginary parts at the end of the calculation. We allow $s(\mathbf{r})$ to be complex, so the magnitude and phase of the oscillation can vary arbitrarily with position.

The Fourier representation of the source in (9.25) is

$$S(\boldsymbol{\sigma}, \nu) = S(\boldsymbol{\sigma}) \delta(\nu - \nu_0). \quad (9.26)$$

A source that satisfies (9.25), and hence (9.26), is said to be *monochromatic* (the light has a single color). Inserting (9.26) into (9.24) yields

$$-4\pi^2 \left(\sigma^2 - \frac{\nu^2}{c_m^2} \right) U(\boldsymbol{\sigma}, \nu) = S(\boldsymbol{\sigma}) \delta(\nu - \nu_0), \quad (9.27)$$

which can be satisfied only if

$$U(\boldsymbol{\sigma}, \nu) = U(\boldsymbol{\sigma}) \delta(\nu - \nu_0), \quad (9.28)$$

or, in the space domain,

$$u(\mathbf{r}, t) = u(\mathbf{r}) \exp(-2\pi i \nu_0 t). \quad (9.29)$$

In other words, the field must have the same monochromatic time dependence as the source, though possibly with a phase shift since $u(\mathbf{r})$ can be complex. Had we chosen some other time dependence for the source, other than the complex exponential, the time dependence of the field would not have been the same as that of the source. The wave equation describes a temporal linear shift-invariant system, and the complex exponential $\exp(-2\pi i \nu_0 t)$ is an eigenfunction of it.

With a monochromatic source, the Fourier transform of the wave amplitude must satisfy

$$-4\pi^2 \left(\sigma^2 - \frac{\nu_0^2}{c_m^2} \right) U(\boldsymbol{\sigma}) = S(\boldsymbol{\sigma}). \quad (9.30)$$

Transforming back to the space domain yields

$$(\nabla^2 + k^2) u(\mathbf{r}) = s(\mathbf{r}), \quad (9.31)$$

where $k = 2\pi\nu_0/c_m$. This equation is known as the *time-independent scalar wave equation* or the *Helmholtz equation*. If $s(\mathbf{r}) = 0$, (9.31) is called the *homogeneous Helmholtz equation*.

Poisson and Laplace equations If the source is independent of time ($\nu_0 = 0$), then $k = 0$ and the Helmholtz equation reduces to the *Poisson equation*, given by

$$\nabla^2 u(\mathbf{r}) = s(\mathbf{r}). \quad (9.32)$$

The homogeneous Poisson equation is called the *Laplace equation*. The Poisson and Laplace equations are fundamental in electrostatics and magnetostatics.

9.2 PLANE WAVES AND SPHERICAL WAVES

In later sections we shall determine the general forms of solutions to the time-dependent and time-independent wave equations, but first we examine two important special solutions, plane waves and spherical waves, in order to assemble some notation, terminology and mathematical tools that will be needed later. We consider here only homogeneous, source-free media.

9.2.1 Plane waves

A monochromatic plane wave of wavevector \mathbf{k} and frequency ν_0 has the form

$$u(\mathbf{r}, t) \propto \exp(i\mathbf{k} \cdot \mathbf{r} - 2\pi i\nu_0 t). \quad (9.33)$$

In the direction parallel to \mathbf{k} , this function is periodic with period $2\pi/k$ (where $k = |\mathbf{k}|$), so we can define a period or wavelength by $\lambda = 2\pi/k$.

The 3D wavevector \mathbf{k} can be expressed in terms of its Cartesian components by $\mathbf{k} = (k_x, k_y, k_z)$, but it is convenient to use the 3D spatial frequency $\boldsymbol{\sigma}$ and define

$$\mathbf{k} = 2\pi\boldsymbol{\sigma} = (2\pi\xi, 2\pi\eta, 2\pi\zeta), \quad (9.34)$$

where $\xi = k_x/2\pi$, etc. In order for this plane wave to be a solution of the homogeneous wave equation, (9.23) with $s(\mathbf{r}, t) = 0$, we require

$$\begin{aligned} & \left(\nabla^2 - \frac{1}{c_m^2} \frac{\partial^2}{\partial t^2} \right) \exp[2\pi i(\boldsymbol{\sigma} \cdot \mathbf{r} - \nu_0 t)] \\ &= -4\pi^2 \left(\xi^2 + \eta^2 + \zeta^2 - \frac{\nu_0^2}{c_m^2} \right) \exp[2\pi i(\boldsymbol{\sigma} \cdot \mathbf{r} - \nu_0 t)] = 0, \end{aligned} \quad (9.35)$$

or

$$\sigma^2 = \xi^2 + \eta^2 + \zeta^2 = \frac{\nu_0^2}{c_m^2}. \quad (9.36)$$

Since $\boldsymbol{\sigma} = 2\pi k$ and $k = 2\pi/\lambda$, we can also write

$$\xi^2 + \eta^2 + \zeta^2 = \frac{1}{\lambda^2}. \quad (9.37)$$

It also follows that the frequency and wavevector must be related by

$$k = \frac{2\pi\nu_0}{c_m}. \quad (9.38)$$

An important conclusion from (9.37) is that the three components of $\boldsymbol{\sigma}$ are not independent. If, for example, ξ and η are given (and it is known that we are discussing a simple plane wave of wavelength λ), ζ can be found from (9.37) as

$$\zeta = \pm \sqrt{\frac{1}{\lambda^2} - \xi^2 - \eta^2}. \quad (9.39)$$

The only ambiguity is the sign, but if we are dealing with waves propagating generally in the $+z$ direction, we must take the $+$ sign.

Speed of propagation An instructive way to write a monochromatic plane wave is

$$u(\mathbf{r}, t) = \exp[ik(\hat{\boldsymbol{\kappa}} \cdot \mathbf{r} - c_m t)], \quad (9.40)$$

where $\hat{\boldsymbol{\kappa}}$ is a unit vector in the direction of \mathbf{k} (*i.e.*, $\mathbf{k} = k\hat{\boldsymbol{\kappa}}$) and we have used (9.38). This form shows immediately that c_m can indeed be interpreted as the speed of propagation in the medium; the wave has a constant value on the plane $\hat{\boldsymbol{\kappa}} \cdot \mathbf{r} = c_m t$, and this plane moves in direction $\hat{\boldsymbol{\kappa}}$ with speed c_m .

Other mathematical descriptions of plane waves The spatial-frequency components ξ , η and ζ can be related back to the direction of propagation of the plane wave. If α , β and γ denote the direction cosines of $\boldsymbol{\sigma}$ (or equivalently, of \mathbf{k} or $\hat{\boldsymbol{\kappa}}$) with respect to the x , y and z axes, respectively, we have

$$k_x = 2\pi\alpha/\lambda, \quad k_y = 2\pi\beta/\lambda, \quad k_z = 2\pi\gamma/\lambda, \quad (9.41)$$

$$\xi = \alpha/\lambda, \quad \eta = \beta/\lambda, \quad \zeta = \gamma/\lambda. \quad (9.42)$$

The direction cosines obey the constraint

$$\alpha^2 + \beta^2 + \gamma^2 = 1, \quad (9.43)$$

which is equivalent to (9.37).

In the paraxial approximation, when $\boldsymbol{\sigma}$ is nearly parallel to the z axis and α and β are both near zero, it is convenient to work with angles measured from the z axis. Suppose the projection of $\boldsymbol{\sigma}$ onto the x - z plane makes an angle θ_x with the z axis and the projection onto the y - z plane makes an angle θ_y with the z axis. Then,

$$\sin \theta_x = \frac{\xi}{\sqrt{\xi^2 + \zeta^2}}, \quad \sin \theta_y = \frac{\eta}{\sqrt{\eta^2 + \zeta^2}}, \quad (9.44)$$

but if these angles are small, then $\gamma \approx 1$, $\zeta \approx 1/\lambda$, and

$$\sin \theta_x \approx \theta_x \approx \xi\lambda, \quad \sin \theta_y \approx \theta_y \approx \eta\lambda. \quad (9.45)$$

Thus, paraxially, ξ and η can be interpreted as angles divided by wavelength, *i.e.*, $\xi = \theta_x/\lambda$, $\eta = \theta_y/\lambda$.

In summary, we can specify a plane wave by giving any of the following pairs of numbers: (k_x, k_y) , (ξ, η) , (α, β) or (θ_x, θ_y) . The missing third component can always be determined by a constraint equation such as (9.37) or (9.43), which must be satisfied if the plane wave is to be a solution to the wave equation.

9.2.2 Spherical waves

A monochromatic spherical wave has the form

$$u(\mathbf{r}, t) = \frac{1}{|\mathbf{r} - \mathbf{r}_0|} \exp(ik|\mathbf{r} - \mathbf{r}_0| - 2\pi i\nu_0 t). \quad (9.46)$$

By inspection, this function is spherically symmetric about the point \mathbf{r}_0 , and it has a monochromatic time dependence with frequency ν_0 . At this stage, k is just a constant, but we shall demonstrate that it must be given by (9.38).

To show that (9.46) is a solution to the wave equation, we need to take its Laplacian. For this purpose, we make a change of variables,

$$\mathbf{R} \equiv \mathbf{r} - \mathbf{r}_0. \quad (9.47)$$

In spherical coordinates centered on \mathbf{r}_0 , the 3D vector \mathbf{R} has components (R, θ_R, ϕ_R) , but $u(\mathbf{r}, t)$ is independent of the angles. Therefore the Laplacian is given by

$$\nabla^2 \left[\frac{e^{ikR}}{R} \right] = \frac{1}{R} \frac{\partial^2}{\partial R^2} \left[R \frac{e^{ikR}}{R} \right] = -k^2 \frac{e^{ikR}}{R}, \quad (9.48)$$

provided $R \neq 0$, or $\mathbf{r} \neq \mathbf{r}_0$. The behavior at the point $\mathbf{r} = \mathbf{r}_0$ will be discussed in Sec. 9.3.

From (9.48) and (9.23), we see that the spherical wave of (9.46) satisfies the homogeneous wave equation provided $k = 2\pi\nu_0/c_m$. Exactly this condition was encountered in (9.38) for plane waves, and in fact it is a general condition. We can decompose an arbitrary solution of the homogeneous wave equation into monochromatic plane waves or spherical waves, and for each component we can define a wavelength λ and an associated $k = 2\pi/\lambda$. For propagation in a source-free homogeneous medium, we must always have $k = 2\pi\nu_0/c_m$. If sources are present, however, the condition can be violated since the source imposes its own spatial and temporal dependence, which may not be constrained by $k = 2\pi\nu_0/c_m$.

9.3 GREEN'S FUNCTIONS

Each of the three inhomogeneous wave equations, (9.23), (9.31) and (9.32), has the form $\mathcal{L}\mathbf{u} = \mathbf{s}$, where \mathcal{L} is a linear differential operator, \mathbf{u} is an unknown scalar field¹ and \mathbf{s} is the source that generates it. In this section we develop methods to solve such equations.

The basic approach is one we exploited in Chap. 7. We first consider a point source and compute the field produced by it, and then we invoke linear superposition to compute the field due to an arbitrary source. In the imaging literature, the field produced by a point source would be called a point response function (or point spread function in the shift-invariant case), but in electromagnetism it is more commonly called a *Green's function*.² As we shall see, the same Green's function

¹We use boldface for the source and field here since we want to think of them as vectors in a Hilbert space. In the remainder of the chapter, the convention of using non-boldface characters for operators will be followed.

²Modern books often drop the possessive and say *Green function* for consistency with *Bessel function*. We make no claim to modernity or consistency.

will allow us to solve problems where there is no source in the region of interest but the field on the boundary of the region is specified.

9.3.1 Differential equations for the Green's functions

We begin with the time-dependent scalar wave equation, (9.23). The equation for the Green's function is obtained simply by replacing the general source $s(\mathbf{r}, t)$ with a point source. The point is an impulse in both space and time, so it is a 4D delta function, $\delta(\mathbf{r} - \mathbf{r}') \delta(t - t')$, which is a source that is zero except at position \mathbf{r}' and time t' . The Green's function $p(\mathbf{r}, t; \mathbf{r}', t')$ is the field at space-time point (\mathbf{r}, t) due to the impulsive source at (\mathbf{r}', t') . The notation $p(\cdot)$ suggests that a Green's function is really a point response function.

In a homogeneous medium, the Green's function must satisfy the time-dependent wave equation with the impulsive source term:

$$\left[\nabla^2 - \frac{1}{c_m^2} \frac{\partial^2}{\partial t^2} \right] p(\mathbf{r}, t; \mathbf{r}', t') = \delta(\mathbf{r} - \mathbf{r}') \delta(t - t'). \quad (9.49)$$

In free space, c_m can be replaced by the vacuum speed of light c , but we shall retain the subscript for generality. Since $c_m = c/n$, the medium is homogeneous if the refractive index is independent of position.

Similarly, the Green's function for the Helmholtz equation must satisfy

$$(\nabla^2 + k^2) p(\mathbf{r}; \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}'), \quad (9.50)$$

where $k = 2\pi\nu_0/c_m = 2\pi n\nu_0/c$.

9.3.2 Time-dependent Green's function

To solve any differential equation, we must specify boundary conditions. The effect of physical boundaries will be taken up in Sec. 9.4, but here we seek solutions to (9.49) and (9.50) in a homogeneous medium without boundaries. The solutions for the Green's functions must be causal and decay as the observation point recedes to an infinite distance from the source, but otherwise there are no boundary conditions.

The absence of boundaries makes the problem shift-invariant. For the time-dependent wave equation, this means that $p(\mathbf{r}, t; \mathbf{r}', t')$ is a function only of $\mathbf{r} - \mathbf{r}'$ and $t - t'$. A useful change of variables is thus

$$\mathbf{R} = \mathbf{r} - \mathbf{r}', \quad \tau = t - t', \quad (9.51)$$

so we can write³

$$p(\mathbf{r}, t; \mathbf{r}', t') = p(\mathbf{R}, \tau). \quad (9.52)$$

Similarly, for the Helmholtz equation, we can write $p(\mathbf{r}; \mathbf{r}') = p(\mathbf{R})$.

Explicit forms for the Green's functions can be obtained in the Fourier domain. The 4D Fourier transform of (9.49) is

$$-4\pi^2 \left(\sigma^2 - \frac{\nu^2}{c_m^2} \right) P(\boldsymbol{\sigma}, \nu) = 1, \quad (9.53)$$

³Do not confuse $p(\mathbf{R}, \tau)$ with the polarization, which we denoted as $\mathbf{p}(\mathbf{r}, t)$ in Sec. 9.1.3. We shall have no further use for polarization in this chapter.

where $P(\boldsymbol{\sigma}, \nu)$ is the 4D Fourier transform of $p(\mathbf{R}, \tau)$. From (9.53) we get

$$P(\boldsymbol{\sigma}, \nu) = -\frac{1}{4\pi^2} \frac{1}{\left(\sigma^2 - \frac{\nu^2}{c_m^2}\right)}. \quad (9.54)$$

The inverse 4D Fourier transform of $P(\boldsymbol{\sigma}, \nu)$ consists of a 3D spatial part and a 1D temporal part. The spatial part has rotational symmetry, so it is given by (3.250). The temporal part is straightforward, but we must remember the sign convention used in this chapter: the temporal inverse transform has a minus sign in the exponent of the Fourier kernel. We thus have

$$\begin{aligned} p(\mathbf{R}, \tau) &= 4\pi \int_0^\infty \sigma^2 d\sigma \operatorname{sinc}(2\sigma R) \int_{-\infty}^\infty d\nu \exp(-2\pi i\nu\tau) P(\boldsymbol{\sigma}, \nu) \\ &= \frac{c_m^2}{\pi} \int_0^\infty \sigma^2 d\sigma \operatorname{sinc}(2\sigma R) \int_{-\infty}^\infty d\nu \frac{\exp(-2\pi i\nu\tau)}{(\nu + c_m\sigma)(\nu - c_m\sigma)}, \end{aligned} \quad (9.55)$$

where $R = |\mathbf{R}|$. The integral over ν can be performed by contour integration in the complex- ν plane if we can interpret the singularities on the real axis at $\nu = \pm c\sigma$. As discussed in App. B (Sec. B.3.8), the options are to deform the contour slightly so that it passes over the pole (or, equivalently, displace the pole downward), deform the contour so it passes under the pole, or take the Cauchy principal value. We cannot decide among these three options purely mathematically; instead, we must choose the one that makes physical sense. In particular, in order for the system to be causal, we must impose the condition

$$p(\mathbf{R}, \tau) = 0 \quad \text{if } \tau < 0. \quad (9.56)$$

Fig. 9.1 Illustration of the contours needed for calculation of the Green's function for the time-dependent wave equation.

This condition will be satisfied if we indent the contour above the singularities as shown in Fig. 9.1. To see why this contour implies (9.56), note that, for $\tau < 0$, $\exp(-2\pi i\nu\tau)$ vanishes on an infinite semicircle in the upper half-plane, so the contour can be closed by this semicircle without changing the value of the integral. The poles will then lie outside the contour, and (9.56) follows from the Cauchy integral formula. For $\tau > 0$, the contour must be closed by a semicircle in the lower half-plane, so both poles are enclosed and Cauchy's formula yields

$$\begin{aligned}
 p(\mathbf{R}, \tau) &= 2c_m \int_0^\infty \sigma d\sigma \operatorname{sinc}(2\sigma R) \sin(2\pi c_m \tau \sigma) \\
 &= -\frac{c_m}{8\pi R} \int_{-\infty}^\infty d\sigma [\exp(2\pi i \sigma R) - \exp(-2\pi i \sigma R)] [\exp(2\pi i \sigma c_m \tau) - \exp(-2\pi i \sigma c_m \tau)].
 \end{aligned}
 \tag{9.57}$$

When we multiply it out, the integrand contains four terms of the form $\exp[2\pi i \sigma(\pm R \pm c_m \tau)]$. By (3.151), a function of this form integrates to $\delta(\pm R \pm c_m \tau)$, but we must recall that both R and τ are positive, so the delta function is nonzero only if we take opposite signs. Also, $\delta(R - c_m \tau) = \delta(-R + c_m \tau) = c_m^{-1} \delta(\tau - R/c_m)$, so

$$p(\mathbf{R}, \tau) = -\frac{1}{4\pi R} \delta\left(\tau - \frac{R}{c_m}\right),
 \tag{9.58}$$

or, with the original variables,

$$p(\mathbf{r}, t; \mathbf{r}', t') = -\frac{1}{4\pi|\mathbf{r} - \mathbf{r}'|} \delta\left(t - t' - \frac{|\mathbf{r} - \mathbf{r}'|}{c_m}\right).
 \tag{9.59}$$

Note that the delta function here is *one-dimensional*; it describes a function that is zero unless $R = c_m \tau$, which is the equation for a sphere of radius $c\tau$ in 3D space. The Green's function $p(\mathbf{r}, t; \mathbf{r}', t')$ is a spherical shell of field, zero except on the sphere of radius $c\tau$ (see Fig. 9.2). The sphere expands outwards at the speed of light in the medium, c_m , so a disturbance originating at some point \mathbf{r}' reaches another point \mathbf{r} in a time given exactly by $|\mathbf{r} - \mathbf{r}'|/c_m$.

Fig. 9.2 (a) Plot of the Green's function for the time-dependent wave equation as a function of time. (b) Plot of the Green's function for the time-dependent wave equation in the x - y plane.

The Green's function diminishes in amplitude as $1/R$, which is a consequence of conservation of energy. As discussed in Sec. 10.1, the energy flux (power per unit area) is proportional to field squared, and the Green's function is the field produced by a point source. Thus the flux varies as $1/R^2$ while the total area of a sphere of radius R varies as R^2 , so the total energy passing through any sphere surrounding the point source is independent of R .

9.3.3 Green's functions for the Helmholtz and Poisson equations

In the absence of physical boundaries, the Helmholtz equation is spatially shift-invariant, so its Green's function can be written as $p(\mathbf{r}, \mathbf{r}') = p(\mathbf{R})$, where again $\mathbf{R} = \mathbf{r} - \mathbf{r}'$. This Green's function can be computed by a Fourier method similar to the one used above, except that there is no temporal transform. The 3D Fourier transform of (9.50) yields

$$P(\boldsymbol{\sigma}) = \frac{1}{-4\pi^2\boldsymbol{\sigma}^2 + k^2} \quad (9.60)$$

and the inverse transform is given by (3.250) as

$$p(\mathbf{R}) = 4\pi \int_0^\infty \sigma^2 d\sigma \operatorname{sinc}(2\sigma R) \frac{1}{-4\pi^2\sigma^2 + k^2}. \quad (9.61)$$

Again we have poles on the real axis, and again we must appeal to causality for guidance in dealing with them. Depending on which poles are enclosed, contour integration of (9.61) yields terms proportional to $\exp(\pm ikR)$. Either sign would be mathematically acceptable, but we must recall that $p(\mathbf{R})$ is a field and has associated with it a time dependence given by (9.29). Since k was defined as $2\pi\nu_0/c_m$, $\exp(\pm ikR) \exp(-2\pi i\nu_0 t) = \exp[ik(\pm R - c_m t)]$. This exponential represents a *spherical wave*; it is constant on a sphere of radius $R = \pm c_m t$ about the source. Causality dictates that we take the plus sign so that the spherical wave will be expanding outward from the source instead of converging inward toward it. We can ensure that only this sign occurs by proper choice of the contour of integration in (9.61).

Thus the causal Green's function for the Helmholtz equation in a homogeneous medium is given by

$$p(\mathbf{R}) = -\frac{1}{4\pi} \frac{\exp(ikR)}{R}. \quad (9.62)$$

This function, illustrated in Fig. 9.3, satisfies

$$[\nabla^2 + k^2] \frac{\exp(ikR)}{R} = -4\pi \delta(\mathbf{R}). \quad (9.63)$$

This result is consistent with the discussion of spherical waves in Sec. 9.2.2, where we showed that $\exp(ikR)/R$ is a solution of the homogeneous wave equation except at the point $\mathbf{r} = 0$; if $\mathbf{R} \neq 0$, $\delta(\mathbf{R}) = 0$ and (9.63) is the homogeneous⁴ Helmholtz equation.

The Helmholtz equation reduces to the Poisson equation as $k \rightarrow 0$, so the Green's function for the Poisson equation is simply $-1/(4\pi R)$, which satisfies

$$\nabla^2 \frac{1}{R} = -4\pi \delta(\mathbf{R}). \quad (9.64)$$

⁴Do not confuse the two meanings of the word *homogeneous*. In the context of linear differential equations, it means that there is no source term (a term independent of the unknown function), but in physics it refers to a medium with all properties independent of position.

Fig. 9.3 (a) Plot of the Green's function for the Helmholtz equation as a function of radius. (b) Contour plot of the Green's function for the Helmholtz equation in the x - y plane.

9.3.4 Defined-source problems

We now know the Green's functions for the three wave equations in a homogeneous medium. In each case, the Green's function is the field produced by a unit point source. For any other *specified* source distribution, the total field can be obtained by linear superposition. For example, for the time-dependent wave equation, we have

$$\begin{aligned}
 u(\mathbf{r}, t) &= \int_{-\infty}^{\infty} dt' \int_{\infty} d^3\mathbf{r}' p(\mathbf{r}, t; \mathbf{r}', t') s(\mathbf{r}', t') \\
 &= -\frac{1}{4\pi} \int_{-\infty}^t dt' \int_{\infty} d^3\mathbf{r}' \frac{1}{|\mathbf{r} - \mathbf{r}'|} \delta\left(t - t' - \frac{|\mathbf{r} - \mathbf{r}'|}{c_m}\right) s(\mathbf{r}', t'). \quad (9.65)
 \end{aligned}$$

We can verify that this field is indeed a solution of the time-dependent wave equation by operating on both sides of the equation with the operator $\nabla^2 - \frac{1}{c_m^2} \frac{\partial^2}{\partial t^2}$, taking the operator under the integrals on the right, and using (9.49).

An instructive alternative form of (9.65) is obtained by using the 1D delta function to perform the 1D integral over t' . The result is

$$u(\mathbf{r}, t) = -\frac{1}{4\pi} \int_{\infty} d^3\mathbf{r}' \frac{1}{|\mathbf{r} - \mathbf{r}'|} s\left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c_m}\right). \quad (9.66)$$

This form shows that the field at (\mathbf{r}, t) is influenced by the source at point \mathbf{r}' at an earlier time $t - |\mathbf{r} - \mathbf{r}'|/c_m$, called the *retarded time*. The time delay accounts for the finite speed of propagation of the wave from the source point \mathbf{r}' to the observation point \mathbf{r} .

Optical path Since we know from Sec. 9.1.4 that $c_m = c/n$, where n is the index of refraction, the retarded time can be written as $t - n|\mathbf{r} - \mathbf{r}'|/c$. The effect of the medium is that the actual physical distance $|\mathbf{r} - \mathbf{r}'|$ between source and observation point is replaced by the distance times the index of refraction. Index-weighted distances, called *optical path lengths*, play a key role in optics, especially in the geometrical-optics approximation. So far, we have treated the index as a constant, so the difference between actual path length and optical path length is just a constant, but in many formulations of optics n is allowed to be a general function of

position. Indeed, most of classical optics is derived from *Fermat's principle*, which asserts that light follows a path that minimizes the optical path length, or equivalently the propagation time from source to observation point. We shall have more to say about optical path length in Sec. 9.7.4.

Helmholtz equation The time-independent solution of the Helmholtz equation can be found in several ways. Linear superposition gives at once

$$u(\mathbf{r}) = -\frac{1}{4\pi} \int_{\infty} d^3\mathbf{r}' \frac{\exp(ik|\mathbf{r} - \mathbf{r}'|)}{|\mathbf{r} - \mathbf{r}'|} s(\mathbf{r}') = -\frac{1}{4\pi} \int_{\infty} d^3\mathbf{r}' \frac{\exp(ikR)}{R} s(\mathbf{r}'). \quad (9.67)$$

We can verify that this field is a solution of the Helmholtz equation by operating on both sides with $(\nabla^2 + k^2)$ and using (9.63).

An alternative derivation of (9.67) uses (9.66), which is general enough to allow any time dependence, including the monochromatic $\exp(-2\pi i\nu_0 t)$ of (9.25). Evaluating this function at the retarded time, as required by (9.66), yields

$$\exp\left[-2\pi i\nu_0 \left(t - \frac{|\mathbf{r} - \mathbf{r}'|}{c_m}\right)\right] = \exp(-2\pi i\nu_0 t) \exp(ik|\mathbf{r} - \mathbf{r}'|). \quad (9.68)$$

Plugging this result into (9.66), we find $u(\mathbf{r}, t) = u(\mathbf{r}) \exp(-2\pi i\nu_0 t)$, with $u(\mathbf{r})$ given by (9.67). The factor $\exp(ikR)$ in the Helmholtz Green's function thus arises from retardation of the source time dependence for a monochromatic source. The $1/R$ factor is again a consequence of conservation of energy.

The field produced by a static source can be obtained from (9.67) simply by setting $k = 0$ [or $\exp(ikR) = 1$].

Relation to operator theory We can restate the key results of this section in operator form. We have already noted that the inhomogeneous wave equations have the form $\mathcal{L}\mathbf{u} = \mathbf{s}$, where \mathcal{L} is the appropriate linear differential operator. We can also define an integral operator \mathcal{G} whose kernel is the Green's function, and we recall from Chap. 1 [see (1.64)] that the delta function is the kernel of the unit operator \mathcal{I} in the domain of \mathcal{L} . Thus (9.49) and (9.50) state that $\mathcal{L}\mathcal{G} = \mathcal{I}$, and hence \mathcal{G} is a right inverse of \mathcal{L} [see (1.37)]. With this right inverse, the solution of the original equation for a specified source is $\mathbf{u} = \mathcal{G}\mathbf{s}$, which is the abstract form of (9.65) or (9.67).

9.3.5 Boundary-value problems

The problems treated in Sec. 9.3.4 require knowledge of the source throughout space; in practice we seldom have such complete knowledge. A more common scenario is that we do not know the details of the source but can describe the field it produces on some surface. The objective is then to calculate the field at points not on this surface. Problems of this type, called *boundary-value problems*, are the subject of this section.

Types of boundary conditions Possible boundary conditions are *Dirichlet* conditions, in which the field is specified on the surface, *Neumann* conditions, in which the normal derivative of the field is specified, and *Cauchy* conditions in which both

the field and its normal derivative are specified. Each type can be *homogeneous*,⁵ where the specified quantity is zero, or *inhomogeneous*, where it is nonzero. For example, with homogeneous Dirichlet boundary conditions, the field must be zero over the surface.

The surfaces themselves can be either *open* or *closed*. This distinction is intuitive for purely spatial surfaces — a closed surface is one that completely surrounds a finite volume, dividing space uniquely into interior and exterior points such that there is no path connecting an interior point to an exterior one. In discussing the time-dependent wave equation, however, we shall encounter surfaces in 4D where one of the coordinates is time. The situation is best illustrated in 2D, in the x - t plane. The lines $x = \text{const}$ for all t or $t = \text{const}$ for all x would be open surfaces. Similarly, in 4D, a spatial *volume* at one time is an *open* boundary. To construct a closed surface in the x - t plane, we could consider two open surfaces such as the x axis at time t_1 and the x axis at time t_2 and connect them at $x = \pm\infty$.

The type of equation determines what boundary conditions can be used in its solution. Second-order partial differential equations can be classified as *hyperbolic*, *elliptic* or *parabolic* equations. We do not need to go into the reasons for these designations, but we note that the time-dependent scalar wave equation is hyperbolic while the Helmholtz and Poisson equations are elliptic. An example of a parabolic equation, which we shall not discuss here, is the diffusion equation.

For elliptic equations, such as the Helmholtz equation, there exists a unique, stable solution for Dirichlet or Neumann boundary conditions⁶ on a closed surface (Morse and Feshbach, 1953, Chap. 6). Since either Dirichlet or Neumann conditions alone lead to a solution, Cauchy conditions in general are an overspecification. If we were to place independent requirements on both the field and its normal derivative, without requiring that they were consistent with each other, there would be no solution compatible with both conditions and with the differential equation. Of course, any real physical problem leads to *some* values of the field and its derivative on the surface, and if we could specify those actual physical values, a solution would exist, but we usually cannot do so.

The situation is different with a hyperbolic equation such as the time-dependent wave equation. In that case, a unique, stable solution is determined by Cauchy boundary conditions on an open surface (Morse and Feshbach, 1953). To illustrate this statement, consider the homogeneous time-dependent wave equation in one spatial dimension,

$$\left(\frac{\partial^2}{\partial x^2} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) u(x, t) = 0, \quad (9.69)$$

which might describe the free vibrations of a string. If the string has infinite length, a suitable open boundary is the line $t = 0$ between $x = -\infty$ and $x = \infty$. Cauchy boundary conditions on this boundary, *i.e.*, specification of the displacement and velocity of the string at all points for $t = 0$, are sufficient to determine the motion for all later times. On the other hand, if we were to specify displacement and velocity over only a portion of the string, say $a < x < b$, we would not be able to determine the motion at all points at all later times. In fact, we could not even

⁵This is yet another meaning of *homogeneous*; see footnote 4.

⁶For Neumann conditions, there is an additional constraint that the integral of the gradient over the surface must vanish; see Morse and Feshbach (1953), p. 698.

determine the motion in $a < x < b$ at all later times since disturbances outside that region could propagate into it later. Thus Cauchy boundary conditions are sufficient on an infinite open surface, but not on a finite one.⁷ Similarly, for the time-dependent wave equation in three spatial dimensions, a spatial volume at one time is an open boundary as noted above. Specification of the field and its time derivative at $t = 0$ at all points in the volume leads to a unique, stable solution for all points at any later time. Another possible open surface is the plane $z = 0$ for all t . Specification of the field and its z derivative on this plane for all x, y and t are acceptable boundary conditions for the time-dependent wave equation. A finite region of the plane $z = 0$ does not suffice in general.

In summary, unique, stable solutions to the Helmholtz and Poisson equations are obtained by specifying either the field or its normal derivative (but not both) on a closed surface. Unique, stable solutions to the time-dependent wave equation result from specifying both the field and its normal derivative on a spatio-temporal open surface, an example of which is the entire spatial volume for one time.

Green's theorem To incorporate boundary conditions into the solution of the Helmholtz equation, we use *Green's theorem*, an important theorem from vector calculus which states that

$$\int_{\mathcal{V}} d^3\mathbf{r} [\psi(\mathbf{r}) \nabla^2 \phi(\mathbf{r}) - \phi(\mathbf{r}) \nabla^2 \psi(\mathbf{r})] = \int_{\mathcal{S}} da \left[\psi(\mathbf{r}) \frac{\partial}{\partial n} \phi(\mathbf{r}) - \phi(\mathbf{r}) \frac{\partial}{\partial n} \psi(\mathbf{r}) \right], \tag{9.70}$$

where $\psi(\mathbf{r})$ and $\phi(\mathbf{r})$ are scalar fields, \mathcal{S} is a closed surface enclosing volume \mathcal{V} , da is an area element on \mathcal{S} , and the notation $\frac{\partial}{\partial n}$ means

$$\frac{\partial \psi(\mathbf{r})}{\partial n} = \hat{\mathbf{n}} \cdot \nabla \psi(\mathbf{r}_0) \Big|_{\mathcal{S}}, \tag{9.71}$$

where $\hat{\mathbf{n}}$ is the outward unit normal to \mathcal{S} . For example, if \mathcal{S} includes the plane $z = 0$ and \mathcal{V} is the right half-space, then $\partial \psi(\mathbf{r}) / \partial n = -\partial \psi(\mathbf{r}) / \partial z$ on that plane, the minus sign arising since the outward normal points in the $-z$ direction.

To apply Green's theorem to the problem at hand, change the variable of integration in (9.70) from \mathbf{r} to \mathbf{r}_0 and let $\phi(\mathbf{r}_0)$ be the field $u(\mathbf{r}_0)$ and $\psi(\mathbf{r}_0)$ be the Green's function $p(\mathbf{r}, \mathbf{r}_0)$. The differential operators ∇ and $\frac{\partial}{\partial n}$ now imply differentiation with respect to \mathbf{r}_0 and will accordingly be denoted ∇_0 and $\frac{\partial}{\partial n_0}$, respectively.

The Green's function must satisfy (9.50), which in the present notation becomes

$$(\nabla_0^2 + k^2) p(\mathbf{r}, \mathbf{r}_0) = \delta(\mathbf{r} - \mathbf{r}_0), \quad \mathbf{r} \text{ and } \mathbf{r}_0 \text{ in } \mathcal{V}. \tag{9.72}$$

The Green's function is the field at \mathbf{r}_0 produced by a point source at \mathbf{r} plus other sources outside \mathcal{V} needed to satisfy the boundary conditions. Suppose, for example, that the field on the boundary is produced by a point source at \mathbf{r}_1 outside \mathcal{V} . By analogy to (9.50), one might think that we would have to include a term $\delta(\mathbf{r}_0 - \mathbf{r}_1)$ on the right-hand side of (9.72), but we do not need such a term since

⁷A precise statement of the requirements on the boundary uses the concept of *characteristics*, discussed in Morse and Feshbach (1953) or Sokolnikoff and Redheffer (1958), for example. For the 1D wave equation, the characteristics are two families of curves, $x + ct = \text{constant}$ and $x - ct = \text{constant}$. Specification of Cauchy conditions on an open surface determines the solution uniquely in a region bounded by those characteristics that intersect the open surface.

$\delta(\mathbf{r}_0 - \mathbf{r}_1)$ is identically zero if \mathbf{r}_0 is inside \mathcal{V} and \mathbf{r}_1 is outside. Of course, sources outside \mathcal{V} can produce fields inside, so the Green's function is no longer given by (9.62). In fact, it is no longer shift invariant since the absolute position of \mathbf{r} and \mathbf{r}_0 with respect to the boundary is important.

Inserting (9.72) into (9.70) and using the Helmholtz equation (9.31) and the sifting property of the delta function, we find

$$u(\mathbf{r}) = \int_{\mathcal{V}} d^3\mathbf{r}_0 p(\mathbf{r}, \mathbf{r}_0) s(\mathbf{r}_0) + \int_{\mathcal{S}} da \left[u(\mathbf{r}_0) \frac{\partial p(\mathbf{r}, \mathbf{r}_0)}{\partial n_0} - p(\mathbf{r}, \mathbf{r}_0) \frac{\partial u(\mathbf{r}_0)}{\partial n_0} \right]. \quad (9.73)$$

Comparing this result to (9.67), we see that the volume integral has been modified since it now includes only sources inside \mathcal{V} , but the new surface integral accounts for sources outside \mathcal{V} through their effect on the boundary conditions.

Equation (9.73) will be our primary tool for calculating fields in a closed volume when we are given knowledge of the fields on the boundary and the sources (if any) inside the volume. In the next section we shall apply this tool to diffraction by an aperture.

9.4 DIFFRACTION BY A PLANAR APERTURE

A common situation in optics and imaging involves an open aperture in an otherwise opaque screen, as shown in Fig. 9.4. It is customary to take the screen as the plane $z = 0$. The standard diffraction problem is to assume some wave incident on the screen from the left and to calculate the resulting field for all points to the right of the screen. Thus the volume \mathcal{V} in Green's theorem is the right half-space. In order to bound this volume with a closed surface \mathcal{S} , we can construct a hemisphere of radius R_a centered on the aperture and let $R_a \rightarrow \infty$. Equation (9.73) provides a way of determining the field in \mathcal{V} if we know the sources in \mathcal{V} and the boundary conditions on the surface. Here we shall assume that there are no sources in \mathcal{V} , so only the surface integral in (9.73) is needed. In Sec. 9.4.1, we argue that the infinite hemispherical surface is irrelevant, so the only important part of \mathcal{S} is the plane $z = 0$. In Sec. 9.4.2, we discuss an approximate way of expressing the field on this plane, and in Sec. 9.4.3 we derive an explicit formula for the field at an arbitrary point in \mathcal{V} .

Fig. 9.4 Geometry for diffraction by a planar aperture.

9.4.1 Surface at infinity

For the time-dependent wave equation, we can dispense with the infinite hemisphere. If the field incident on the aperture is turned on at some starting time t_s , rather than existing from $t = -\infty$, then there is no way the boundary condition on the infinite hemisphere can influence the field a finite distance from the aperture at a finite time, and the hemisphere can be safely ignored.

This argument can also be applied, to a good approximation, to a monochromatic source. Strictly speaking, such a source has a time dependence of $\exp(-2\pi i\nu_0 t)$ for all t , but if the source is switched on at a finite time, the field has a time dependence given by $\exp(-2\pi i\nu_0 t) \text{step}(t - t_s)$. If $t - t_s$ is finite but sufficiently large that all transient effects from the step function have died out, then the field at a finite distance from the aperture is described adequately by the Helmholtz equation, but the surface at infinity plays no role since the disturbance has not had time to get there.

Next we shall compute how long one must wait for this approximation to be valid. From (9.66), we know that the field at (\mathbf{r}, t) is influenced by the source at point \mathbf{r}' at the earlier time $t - |\mathbf{r} - \mathbf{r}'|/c$. If R_{max} is the maximum distance between the observation point \mathbf{r} and any point on the screen where the field or its derivative is nonzero, then all we have to do is make $t - t_s > R_{max}/c$, and there will be no way to discern when the field was switched on. At later times, the field will be described by the Helmholtz equation, yet the surface at infinity will make no contribution.

Another approach, which we shall not describe here, is to write down formally the effect of the infinite hemisphere on the field at a point in \mathcal{V} and to show that it consists of two integrals which cancel one another as $R_a \rightarrow \infty$ as a result of the *Sommerfeld radiation condition*; for details on this approach, see Goodman (1968).

9.4.2 Kirchhoff boundary conditions

Having disposed of the surface at infinity, we turn next to the plane $z = 0^+$. To describe the field in this plane, we introduce the *Kirchhoff boundary condition* or *Kirchhoff approximation*, which assumes that the field in the clear aperture is exactly what it would be if there were no screen. This is a reasonable approximation if the opening is large compared to a wavelength, but we should expect it to break down for small apertures. For large apertures it is also reasonable to assume that the field is zero for any point just to the right of the opaque screen.

For a monochromatic source, all fields have the same time dependence $\exp(-2\pi i\nu_0 t)$, so the Kirchhoff boundary condition can be expressed in terms of the time-independent field amplitude. We refer to the field that would exist in the plane $z = 0$ in the absence of the screen as the incident wave and denote it by $u_{inc}(\mathbf{r})$. The Kirchhoff boundary condition states that the actual field in the plane $z = 0$ is given by

$$u(\mathbf{r})|_{z=0} = \begin{cases} u_{inc}(\mathbf{r}) & \text{if } \mathbf{r} \text{ lies in the clear aperture} \\ 0 & \text{if } \mathbf{r} \text{ is behind the opaque screen,} \end{cases} \quad (9.74)$$

where \mathbf{r} is the 2D vector obtained from \mathbf{r} by setting the z component to zero.

9.4.3 Application of Green's theorem

Using the scalar Kirchhoff boundary condition in (9.73) and assuming there are no sources in \mathcal{V} , we find

$$u(\mathbf{r}) = \int_{ap} d^2r_0 \left[u_{inc}(\mathbf{r}_0) \frac{\partial p(\mathbf{r}, \mathbf{r}_0)}{\partial n_0} - p(\mathbf{r}, \mathbf{r}_0) \frac{\partial u_{inc}(\mathbf{r}_0)}{\partial n_0} \right], \quad (9.75)$$

where the integral is over the clear aperture only.

Several forms of diffraction theory follow from (9.75) depending on what one assumes for the Green's function, $p(\mathbf{r}, \mathbf{r}_0)$ (see Goodman, 1968). We shall not explore all of these options here, but restrict ourselves to the generally accepted *Rayleigh-Sommerfeld diffraction theory*. Rayleigh and Sommerfeld recognized that specifying both $u(\mathbf{r}_0)$ and $\partial u(\mathbf{r}_0)/\partial n_0$ independently on the boundary (Cauchy boundary conditions) would be an overspecification for the Helmholtz equation. To avoid this difficulty, they suggested choosing the Green's function $p(\mathbf{r}, \mathbf{r}_0)$ to be zero on the aperture plane so that $\partial u_{inc}/\partial n_0$ is not needed.

We can construct a Green's function that satisfies this condition by recalling that we are free to add sources in the defining equation for the Green's function, (9.72), so long as they lie outside \mathcal{V} . To make $p(\mathbf{r}, \mathbf{r}_0)$ vanish when \mathbf{r}_0 lies on the plane $z_0 = 0$, we add a *negative* point source at the point $\mathbf{r}_m = (x, y, -z)$ which is the mirror image of \mathbf{r} in the aperture plane. Thus $p(\mathbf{r}, \mathbf{r}_0)$ is the field at \mathbf{r}_0 due to a positive point source at \mathbf{r} and a negative one at \mathbf{r}_m . Explicitly,

$$p(\mathbf{r}, \mathbf{r}_0) = -\frac{1}{4\pi} \left[\frac{\exp(ikR)}{R} - \frac{\exp(ikR_m)}{R_m} \right], \quad (9.76)$$

where

$$R = \sqrt{|\mathbf{r} - \mathbf{r}_0|^2 + (z - z_0)^2}, \quad R_m = \sqrt{|\mathbf{r} - \mathbf{r}_0|^2 + (-z - z_0)^2}, \quad (9.77)$$

and

$$|\mathbf{r} - \mathbf{r}_0|^2 = (x - x_0)^2 + (y - y_0)^2. \quad (9.78)$$

Note that $R_m = R$ if $z_0 = 0$.

Even though the Green's function is zero on the aperture plane, its normal derivative is not. Differentiation of (9.76) with respect to z_0 yields

$$\frac{\partial p(\mathbf{r}, \mathbf{r}_0)}{\partial n_0} = -\frac{\partial p(\mathbf{r}, \mathbf{r}_0)}{\partial z_0} \Big|_{z_0=0} = -\frac{1}{2\pi} \left(ik - \frac{1}{R} \right) \frac{\exp(ikR)}{R} \cos \theta, \quad (9.79)$$

where θ is the angle between $\mathbf{r} - \mathbf{r}_0$ and the z axis, so that

$$\cos \theta = \frac{z}{\sqrt{|\mathbf{r} - \mathbf{r}_0|^2 + z^2}}. \quad (9.80)$$

Collecting results, we have a general expression for the diffracted field in \mathcal{V} :

$$u(\mathbf{r}) = -\frac{1}{2\pi} \int_{ap} d^2r_0 u_{inc}(\mathbf{r}_0) \left(ik - \frac{1}{R} \right) \cos \theta \frac{\exp(ikR)}{R}. \quad (9.81)$$

Note that the z component of \mathbf{r}_0 is zero, so a point in the aperture is specified equally by the 2D vector \mathbf{r}_0 or the 3D vector \mathbf{r}_0 .

9.4.4 Diffraction as a 2D linear filter

Equation (9.81) can be evaluated for the field at any (x, y, z) , so $u(\mathbf{r})$ is a 3D function. If we evaluate it for all (x, y) on a plane of fixed z , however, it is a 2D function which we can denote by $u_z(\mathbf{r})$. Using a similar 2D notation for u_{inc} , we can rewrite (9.81) as

$$u_z(\mathbf{r}) = u(\mathbf{r}) = -\frac{1}{2\pi} \int_{\infty} d^2r_0 u_{inc}(\mathbf{r}_0) t_{ap}(\mathbf{r}_0) \left(ik - \frac{1}{R} \right) \cos \theta \frac{\exp(ikR)}{R}, \quad (9.82)$$

where $t_{ap}(\mathbf{r})$ is the *amplitude transmittance* of the aperture, defined by [cf. (9.74)]

$$t_{ap}(\mathbf{r}) \equiv \begin{cases} 1 & \text{if } \mathbf{r} \text{ lies in the clear aperture} \\ 0 & \text{if } \mathbf{r} \text{ is behind the opaque screen.} \end{cases} \quad (9.83)$$

Since R and $\cos \theta$ are both functions of $\mathbf{r} - \mathbf{r}_0$, as shown by (9.77) and (9.80), respectively, we recognize (9.82) as a 2D convolution. Thus we can write symbolically

$$u_z(\mathbf{r}) = [u_{inc}(\mathbf{r}) t_{ap}(\mathbf{r})] * p_z(\mathbf{r}), \quad (9.84)$$

where $p_z(\mathbf{r})$ is the 2D point spread function⁸ (PSF) for propagation, given by

$$p_z(\mathbf{r}) = -\frac{1}{2\pi} \left(ik - \frac{1}{\sqrt{r^2 + z^2}} \right) \frac{z}{\sqrt{r^2 + z^2}} \frac{\exp(ik\sqrt{r^2 + z^2})}{\sqrt{r^2 + z^2}}, \quad (9.85)$$

with $r = |\mathbf{r}|$. As a 2D mapping from the aperture plane to a parallel plane a distance z away, diffraction is a shift-invariant operation. If u_{inc} , t_{ap} and the observation point are all shifted together parallel to the aperture plane, nothing is changed.

Since the product $u_{inc}(\mathbf{r}) t_{ap}(\mathbf{r})$ is the input to the convolution, it will be useful to write

$$u_{inc}(\mathbf{r}) t_{ap}(\mathbf{r}) = u_0(\mathbf{r}), \quad (9.86)$$

where $u_0(\mathbf{r})$ is to be interpreted as the incident field as modified by the aperture.

As an exercise, the reader can show that $p_z(\mathbf{r}) \rightarrow \delta(\mathbf{r})$ as $z \rightarrow 0$, so $u_z(\mathbf{r}) \rightarrow u_0(\mathbf{r})$, as it should.

9.4.5 Some useful approximations

As it stands, (9.85) is a rather complicated expression from which it is difficult to get any insight. Several approximations are possible, all based on expanding various pieces of $p_z(\mathbf{r})$ in powers of $1/z$ and retaining only the leading terms.

Radiation and paraxial approximations Consider first the factor $ik - (r^2 + z^2)^{-\frac{1}{2}}$ in (9.85). If z is large, we can neglect $(r^2 + z^2)^{-\frac{1}{2}}$ compared to ik . Since $k = 2\pi\nu_0/c = 2\pi/\lambda$, where λ is the wavelength of the radiation, this approximation is valid when $z \gg \lambda$, which it almost always is in optical diffraction problems. This approximation is called the *radiation approximation*.⁹ It shows that the radiation

⁸Do not confuse the 2D PSF $p_z(\mathbf{r})$ with the Green's function $p(\mathbf{r}, \mathbf{r}_0)$; by (9.79) the former is the z derivative of the latter.

⁹The radiation approximation is a bit tricky since we are neglecting a real term compared to a pure imaginary one. It can be stated more precisely by noting that $ik - (r^2 + z^2)^{-\frac{1}{2}}$ approaches a complex number with magnitude k and phase $\pi/2$ as $z \rightarrow \infty$.

field falls off asymptotically as $1/z$, as required by conservation of energy, but near the aperture it can have a more complicated dependence on z .

With the radiation approximation, (9.82) becomes

$$u_z(\mathbf{r}) = \frac{1}{i\lambda} \int_{\infty} d^2r_0 u_0(\mathbf{r}_0) \cos\theta \frac{\exp(ikR)}{R} \quad (9.87)$$

and (9.85) becomes

$$p_z(\mathbf{r}) = \frac{1}{i\lambda} \frac{z}{\sqrt{r^2 + z^2}} \frac{\exp(ik\sqrt{r^2 + z^2})}{\sqrt{r^2 + z^2}}, \quad (9.88)$$

where we have used $k = 2\pi/\lambda$.

Equation (9.87) is a formal statement of *Huygens' Principle*, enunciated by the Dutch mathematician, astronomer and physicist Christiaan Huygens (1629–1695). Huygens is acknowledged as the founder of the wave theory of light and was one of the first to produce practical lenses, including a nearly perfect achromatic eyepiece. He is even credited in some books (Matteucci, 1970) with the invention of the internal combustion engine. (He proposed gunpowder as the fuel.) Huygens' principle says that every point on a wavefront acts as a source of a secondary spherical wave called a *Huygens' wavelet*. As Huygens knew, the wavelet has a 90° phase shift (relative to the incident wave), and this phase shift is seen in (9.87) as the factor of $1/i$. In (9.87), there is also an angular factor of $\cos\theta$, apparently unknown to Huygens. Since $\cos\theta$ is also the angular dependence of dipole radiation, (9.87) states that the wavefront is equivalent to a fictitious layer of dipoles radiating 90° out of phase with the wave.

The next approximation to consider is the *paraxial approximation*, which is useful if we consider only points that are close to the z -axis (which is assumed to run through the clear aperture). With this approximation, $\cos\theta \approx 1$. With the radiation and paraxial approximations together, (9.85) becomes

$$p_z(\mathbf{r}) \approx \frac{1}{i\lambda z} \exp(ik\sqrt{r^2 + z^2}). \quad (9.89)$$

Note that we have not yet approximated $(r^2 + z^2)^{\frac{1}{2}}$ in the exponent. Since k is potentially a very large number, of order 10^5 cm^{-1} at optical wavelengths, we must be very careful in making approximations in the exponent. We shall pursue this point below.

With (9.89), the field in plane z is given by

$$u_z(\mathbf{r}) \approx \frac{1}{i\lambda z} \int_{\infty} d^2r_0 u_0(\mathbf{r}_0) \exp(ik\sqrt{|\mathbf{r} - \mathbf{r}_0|^2 + z^2}). \quad (9.90)$$

The exponential factor, illustrated in Fig. 9.5, represents a spherical wave (the Huygens' wavelet) emanating from the point \mathbf{r}_0 in the plane $z = 0$ and observed at point \mathbf{r} in plane z .

Fig. 9.5 Illustration of the function $\exp(ik\sqrt{|\mathbf{r} - \mathbf{r}_0|^2 + z^2})$.

9.4.6 Fresnel diffraction

Next we investigate approximations to the exponential factor in (9.90). A binomial expansion for $z > |\mathbf{r} - \mathbf{r}_0|$ gives

$$R = \sqrt{|\mathbf{r} - \mathbf{r}_0|^2 + z^2} = z + \frac{|\mathbf{r} - \mathbf{r}_0|^2}{2z} - \frac{|\mathbf{r} - \mathbf{r}_0|^4}{8z^3} + \dots, \quad (9.91)$$

so we can write the exponential as

$$\exp\left(ik\sqrt{|\mathbf{r} - \mathbf{r}_0|^2 + z^2}\right) = \exp(ikz) \exp\left(ik\frac{|\mathbf{r} - \mathbf{r}_0|^2}{2z}\right) \exp\left(-ik\frac{|\mathbf{r} - \mathbf{r}_0|^4}{8z^3}\right) \dots \quad (9.92)$$

One of the *terms* in (9.91) can be neglected only if the corresponding *factor* in (9.92) is approximately unity. It does not suffice if a term in (9.91) is small relative to the previous term; it must be small compared to, say, $\pi/4$ in an absolute sense. The quartic term is negligible if

$$\frac{k|\mathbf{r} - \mathbf{r}_0|^4}{8z^3} \ll \frac{\pi}{4} \quad \text{or} \quad |\mathbf{r} - \mathbf{r}_0|^4 \ll \lambda z^3. \quad (9.93)$$

If z is large enough for this condition to hold, then the quartic term and all higher terms in (9.91) can be neglected, and (9.90) becomes

$$u_z(\mathbf{r}) \approx \frac{\exp(ikz)}{i\lambda z} \int_{\infty} d^2r_0 u_0(\mathbf{r}_0) \exp\left(i\pi\frac{|\mathbf{r} - \mathbf{r}_0|^2}{\lambda z}\right) = u_0(\mathbf{r}) * p_z(\mathbf{r}), \quad (9.94)$$

where now the 2D PSF is given by

$$p_z(\mathbf{r}) \approx \frac{\exp(ikz)}{i\lambda z} \exp\left(i\pi\frac{r^2}{\lambda z}\right). \quad (9.95)$$

In this form, called the *Fresnel approximation*, the PSF is a constant (independent of \mathbf{r}) times the quadratic phase factor $\exp(i\pi r^2/\lambda z)$. Once again, this factor represents a spherical wave as observed on a plane, but now the spherical wavefronts are approximated by paraboloids. To see the full space-time behavior of the waves, it must be recalled that there is an associated time dependence $\exp(-2\pi i\nu_0 t)$. Figure 9.6 displays the behavior of $\exp(i\pi r^2/\lambda z - 2\pi i\nu_0 t)$ as a function of r , z and t .

Fig. 9.6 (a) The real part of the time-dependent quadratic phase factor $\exp(i\pi \frac{r^2}{\lambda z} - 2\pi i\nu_0 t)$ as a function of r for different t . (b) The same function plotted as a function of r for different z .

As discussed in Sec. 4.3, a quadratic phase factor is also called a *chirp*, and convolution with a chirp is the same as computing a Fresnel transform. Within the Fresnel approximation, $u_z(\mathbf{r})$ is the Fresnel transform of $u_0(\mathbf{r})$, with the parameter β in (4.122) given by $1/\lambda z$. The properties of Fresnel transforms and chirps given in Sec. 4.3 are very useful in diffraction problems.

In particular, the Fourier implementation of the Fresnel transform discussed in Sec. 4.3 can be used to derive an alternative form for the Fresnel diffraction formula. All we have to do is to extend the 1D argument that led up to (4.138) to 2D. To this end, note that

$$|\mathbf{r} - \mathbf{r}_0|^2 = r^2 + r_0^2 - 2\mathbf{r} \cdot \mathbf{r}_0. \tag{9.96}$$

Substituting this form into (9.94), we find

$$u_z(\mathbf{r}) = \frac{\exp(ikz)}{i\lambda z} \exp\left(i\pi \frac{r^2}{\lambda z}\right) \int_{\infty} d^2r_0 u_0(\mathbf{r}_0) \exp\left(i\pi \frac{r_0^2}{\lambda z}\right) \exp\left(-2\pi i \frac{\mathbf{r} \cdot \mathbf{r}_0}{\lambda z}\right). \tag{9.97}$$

This integral can be recognized as the 2D Fourier transform of the product $u_0(\mathbf{r}_0) \exp(i\pi r_0^2/\lambda z)$, but the role of the spatial-frequency vector is played by $\mathbf{r}/\lambda z$. We can thus write

$$u_z(\mathbf{r}) = \frac{\exp(ikz)}{i\lambda z} \exp\left(i\pi \frac{r^2}{\lambda z}\right) \mathcal{F}_2 \left\{ u_0(\mathbf{r}_0) \exp\left(i\pi \frac{r_0^2}{\lambda z}\right) \right\}_{\boldsymbol{\rho}=\mathbf{r}/\lambda z}. \tag{9.98}$$

In spite of the transform, this equation relates the input $u_0(\mathbf{r})$ to the output $u_z(\mathbf{r})$ in the space domain; the substitution $\boldsymbol{\rho} = \mathbf{r}/\lambda z$ gets us back from the frequency domain to the space domain, and the Fourier transform is just a convenient way of performing the spatial convolution with the quadratic phase factor (9.95). The resulting expression, (9.98), is mathematically equivalent to (9.94) and is thus an equally valid formula for Fresnel diffraction.

9.4.7 Fraunhofer diffraction

The next approximation takes advantage of the limited support of $t_{ap}(\mathbf{r})$. Suppose the clear aperture fits into a circle of radius a , so that $r_0 < a$ for all \mathbf{r}_0 in the range of integration in (9.97). Then, if $z \gg a^2/\lambda$, we can approximate $\exp(i\pi r_0^2/\lambda z)$ by unity inside the Fourier transform in (9.98), and we have

$$u_z(\mathbf{r}) \approx \frac{\exp(ikz)}{i\lambda z} \exp\left(i\pi \frac{r^2}{\lambda z}\right) \mathcal{F}_2\{u_0(\mathbf{r}_0)\}_{\boldsymbol{\rho}=\mathbf{r}/\lambda z}, \quad z \gg a^2/\lambda. \quad (9.99)$$

Under this *Fraunhofer approximation*, $u_z(\mathbf{r})$ has a factor proportional to the Fourier transform of $u_0(\mathbf{r})$, rescaled by the substitution $\boldsymbol{\rho} = \mathbf{r}/\lambda z$. There is also a factor $\exp(i\pi r^2/\lambda z)$, which is not a constant since it depends on position in the observation plane. This factor can be interpreted as a spherical wave emanating from a point on the z axis, so (9.99) shows that, for z sufficiently large, $u_z(\mathbf{r})$ approaches a simple spherical wave modulated by the rescaled Fourier transform of $u_0(\mathbf{r})$. The region where $z \gg a^2/\lambda$ is called the *Fraunhofer zone* or the *far field*.

Irradiance in the Fraunhofer pattern Colloquially, the term *diffraction pattern* refers to the optical power per unit area incident on a surface, which is called the *irradiance* and denoted $I(\mathbf{r})$. It will be shown in Chap. 10 that, under certain broad assumptions, the irradiance is proportional to $|u(\mathbf{r})|^2$, with the constant of proportionality dependent on the physical interpretation of $u(\mathbf{r})$. In this chapter we dispense with the constants and set $I(\mathbf{r}) = |u(\mathbf{r})|^2$. When the field is random, we shall define the *mean irradiance* $\bar{I}(\mathbf{r})$ as the statistical expectation $\langle |u(\mathbf{r})|^2 \rangle$.

When we compute the irradiance, the leading factor of $\exp(i\pi r^2/\lambda z)$ in (9.99) disappears, and we have

$$|u_z(\mathbf{r})|^2 \approx \frac{1}{\lambda^2 z^2} \left| \int_{\infty} d^2 r_0 \exp(-2\pi i \mathbf{r} \cdot \mathbf{r}_0 / \lambda z) u_0(\mathbf{r}_0) \right|^2 = \frac{1}{\lambda^2 z^2} \left| U_0\left(\frac{\mathbf{r}}{\lambda z}\right) \right|^2, \quad (9.100)$$

where $U_0(\boldsymbol{\rho})$ is the 2D Fourier transform of $u_0(\mathbf{r})$. In the Fraunhofer approximation, therefore, the diffraction pattern is proportional to the squared modulus of the Fourier transform of the input field. If $u_{inc}(\mathbf{r})$ is a plane wave normally incident on the aperture plane, then $u_0(\mathbf{r})$ is proportional to $t_{ap}(\mathbf{r})$, and we can say that the Fraunhofer pattern is the squared modulus of the Fourier transform of the aperture transmittance.

Fraunhofer diffraction without the paraxial approximation The expressions (9.99) and (9.100) were obtained by first applying the paraxial approximation (or considering observation points near the axis), then taking advantage of the limited support of $t_{ap}(\mathbf{r})$. We can get another useful expression by leaving out the paraxial approximation. We expand R not in powers of $1/z$ as in (9.91) but in powers of $1/|\mathbf{r}|$, obtaining

$$R = |\mathbf{r} - \mathbf{r}_0| = \sqrt{|\mathbf{r}|^2 - 2\mathbf{r} \cdot \mathbf{r}_0 + |\mathbf{r}_0|^2} = |\mathbf{r}| - \frac{\mathbf{r}_0 \cdot \mathbf{r}}{|\mathbf{r}|} + \frac{|\mathbf{r}_0|^2}{2|\mathbf{r}|} + \dots \quad (9.101)$$

If the aperture restricts $|\mathbf{r}_0|$ to sufficiently small values that $k|\mathbf{r}_0|^2 \ll |\mathbf{r}|$, then only the first two terms in this series must be retained, and (9.81) becomes

$$u(\mathbf{r}) = \frac{1}{i\lambda} \cos \theta \frac{\exp(ik|\mathbf{r}|)}{|\mathbf{r}|} \int_{\infty} d^2 r_0 u_0(\mathbf{r}_0) \exp\left[-ik \frac{\mathbf{r}_0 \cdot \mathbf{r}}{|\mathbf{r}|}\right]. \quad (9.102)$$

Note that $\cos \theta$ is independent of \mathbf{r}_0 in this approximation.

Since $\mathbf{r}_0 = (\mathbf{r}_0, 0)$ and $\mathbf{r} = (\mathbf{r}, z)$, the 3D scalar product $\mathbf{r}_0 \cdot \mathbf{r}$ is the same as the 2D one, $\mathbf{r}_0 \cdot \mathbf{r}$. Thus we can write the integral in (9.102) as a 2D Fourier transform,

$$u(\mathbf{r}) = \frac{1}{i\lambda} \cos \theta \frac{\exp(ik|\mathbf{r}|)}{|\mathbf{r}|} \int_{\infty} d^2 r_0 u_0(\mathbf{r}_0) \exp(-2\pi i \mathbf{r}_0 \cdot \boldsymbol{\rho}) = \frac{1}{i\lambda} \cos \theta \frac{\exp(ik|\mathbf{r}|)}{|\mathbf{r}|} U_0(\boldsymbol{\rho}), \quad (9.103)$$

where the 2D spatial frequency vector is now given by

$$\boldsymbol{\rho} = \frac{\mathbf{r}}{\lambda|\mathbf{r}|}. \quad (9.104)$$

The two expressions for $\boldsymbol{\rho}$, $\mathbf{r}/\lambda z$ in (9.99) and $\mathbf{r}/\lambda|\mathbf{r}|$ in (9.104), agree if $\cos \theta \approx 1$, but the latter is more general.

As in (9.99), there is a factor in (9.103) representing a spherical wave, only now it is an exact spherical wave centered on the origin, not just the Fresnel approximation to such a wave. In both of these equations, however, the interesting factor is the Fourier integral. The amplitude of the field at an observation point is determined by a single component in the 2D Fourier transform of the field in the plane $z = 0$, so Fraunhofer diffraction gives us a way of probing the Fourier domain. Note that the components of the 2D vector $\mathbf{r}/|\mathbf{r}|$ in (9.104) are direction cosines of the unit vector pointing from the center of the aperture to the observation point, so this direction serves to pick out the Fourier component of interest. Figure 9.7 provides a graphical way of understanding this result.

Fig. 9.7 Illustration showing why the Fraunhofer diffraction pattern picks out a single spatial frequency. The Green's function can be interpreted as a spherical wave centered on the observation point, and this spherical wave acts as a weighting function for points in the aperture in the diffraction integral. If the Fraunhofer condition is satisfied, this spherical wave is approximately a plane wave over the aperture.

9.5 DIFFRACTION IN THE FREQUENCY DOMAIN

As we saw in Sec. 9.4.7, Fraunhofer diffraction singles out a particular Fourier component of the field and maps it to a point in the Fraunhofer region, but the role of Fourier analysis in diffraction theory is not limited to the Fraunhofer approximation. Fourier transforms arise naturally in all propagation and diffraction problems because free space (or any homogeneous medium) is a linear shift-invariant system,

and plane waves (or Fourier kernels) are eigenfunctions of such systems. When we write a field in terms of its Fourier transform, we are expanding it in the eigenfunction basis, so useful new insights and mathematical formulas can be expected.

In Sec. 9.5.1, we essentially start over and rederive diffraction theory from a Fourier viewpoint. The Fresnel and Fraunhofer approximations are revisited from this new viewpoint in Sec. 9.5.2. In Sec. 9.5.3 we illustrate the usefulness of this formalism by considering beam propagation. Finally, in Sec. 9.5.4 we apply the concept of angular spectrum to obtain the laws governing reflection and refraction of light from an interface between two different material media.

9.5.1 Angular spectrum

As in Sec. 9.4, consider diffraction from a planar aperture in the plane $z = 0$ and assume that the field $u_0(\mathbf{r})$ in this plane can be specified by the Kirchhoff boundary condition. This field can be represented in terms of its 2D Fourier transform $U_0(\boldsymbol{\rho})$ as

$$u_0(\mathbf{r}) = \int_{\infty} d^2\rho U_0(\boldsymbol{\rho}) \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) = \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\eta U_0(\xi, \eta) \exp[2\pi i(\xi x + \eta y)]. \quad (9.105)$$

We can interpret $\exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r})$ as a general plane wave (with the time dependence suppressed) evaluated on the plane $z = 0$, that is,

$$\exp[2\pi i(\xi x + \eta y)] = \exp[2\pi i(\xi x + \eta y + \zeta z)] \Big|_{z=0}, \quad (9.106)$$

or, in vector form,

$$\exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) = \exp(2\pi i \boldsymbol{\sigma} \cdot \mathbf{r}) \Big|_{z=0}, \quad (9.107)$$

The integral in (9.105) expresses the wave on $z = 0$ as a superposition of plane waves travelling in different directions. This superposition is known as the *angular spectrum* of the wave. Each plane wave will continue to propagate in the same direction, without coupling to any other plane wave, so all we have to do to get an expression for the field at an arbitrary z is to put back the dependence of the plane wave on z . We can do so since the missing z component of $\boldsymbol{\sigma}$ is determined by (9.39). Taking the $+$ sign in (9.39) since the incident wave propagates in the $+z$ direction, we can construct a solution valid for all z as follows:

$$\begin{aligned} u_z(\mathbf{r}) &= \int_{\infty} d^2\rho U_0(\boldsymbol{\rho}) \exp \left[2\pi i \left(\boldsymbol{\rho} \cdot \mathbf{r} + z \sqrt{\frac{1}{\lambda^2} - \rho^2} \right) \right] \\ &= \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\eta U_0(\xi, \eta) \exp \left[2\pi i \left(\xi x + \eta y + z \sqrt{\frac{1}{\lambda^2} - \xi^2 - \eta^2} \right) \right]. \end{aligned} \quad (9.108)$$

This form agrees with the boundary condition (9.105) if $z = 0$, and it satisfies the homogeneous wave equation by construction. Since the Dirichlet boundary condition uniquely determines a solution in \mathcal{V} , (9.108) must be that solution.

Transfer function Comparing (9.105) and (9.108), we see that the 2D transform of the field in plane z has the form

$$U_z(\boldsymbol{\rho}) = U_0(\boldsymbol{\rho}) P_z(\boldsymbol{\rho}), \quad (9.109)$$

where $P_z(\boldsymbol{\rho})$ is the 2D transfer function for propagation from the plane $z = 0$ to a parallel plane a distance z away. It is given by

$$P_z(\boldsymbol{\rho}) = \exp\left(2\pi iz\sqrt{\frac{1}{\lambda^2} - \rho^2}\right) = \exp\left(2\pi iz\sqrt{\frac{1}{\lambda^2} - \xi^2 - \eta^2}\right). \quad (9.110)$$

Note that $P_z(\boldsymbol{\rho}) \rightarrow 1$ as $z \rightarrow 0$, which corresponds to the statement that $p_z(\mathbf{r}) \rightarrow \delta(\mathbf{r})$.

Another way to derive the transfer function is to Fourier-transform the point spread function. Before any approximations, $p_z(\mathbf{r})$ is given by (9.85), so

$$P_z(\boldsymbol{\rho}) = \mathcal{F}_2\{p_z(\mathbf{r})\} = -\frac{1}{2\pi}\mathcal{F}_2\left\{\left(ik - \frac{1}{R}\right)\frac{\exp(ikR)}{R}\cos\theta\right\}, \quad (9.111)$$

where $R = \sqrt{r^2 + z^2}$, $\cos\theta = z/R$ and $k = 2\pi/\lambda$.

To evaluate the Fourier integral, recall that we obtained the form (9.85) for $p_z(\mathbf{r})$ in the first place by performing a derivative with respect to z in (9.79). Therefore we can write

$$p_z(\mathbf{r}) = -\frac{1}{2\pi}\frac{\partial}{\partial z}\left[\frac{\exp(ik\sqrt{r^2 + z^2})}{\sqrt{r^2 + z^2}}\right]. \quad (9.112)$$

The expression in brackets is a rotationally symmetric 2D function; taking its Fourier transform by means of (3.248), we find

$$P_z(\boldsymbol{\rho}) = -\frac{\partial}{\partial z}\int_0^\infty r dr J_0(2\pi\rho r)\left[\frac{\exp(ik\sqrt{r^2 + z^2})}{\sqrt{r^2 + z^2}}\right]. \quad (9.113)$$

A change of variables yields

$$P_z(\boldsymbol{\rho}) = -\frac{\partial}{\partial z}\int_z^\infty dt J_0\left(2\pi\rho\sqrt{t^2 - z^2}\right)e^{ikt}. \quad (9.114)$$

This integral is tabulated in a standard source (Gradshteyn and Ryzhik, 1980, p. 736), and we obtain

$$P_z(\boldsymbol{\rho}) = -i\frac{\partial}{\partial z}\frac{\exp(iz\sqrt{k^2 - 4\pi^2\rho^2})}{\sqrt{k^2 - 4\pi^2\rho^2}}, \quad (9.115)$$

from which differentiation and the substitution $k = 2\pi/\lambda$ gives (9.110) again.

Interpretation of the transfer function We see from (9.110) that the transfer function $P_z(\boldsymbol{\rho})$ is a pure phase factor for $\rho < 1/\lambda$. Hence the modulus of the transform is unchanged by propagation:

$$|P_z(\boldsymbol{\rho})| = |P_0(\boldsymbol{\rho})|, \quad \rho < \frac{1}{\lambda}. \quad (9.116)$$

As required by conservation of energy, no plane waves are either increased or decreased in amplitude as they propagate. All of the wondrous patterns of diffraction are produced by subtle changes of phase among the constituent plane waves in a field.

For $\rho > 1/\lambda$, on the other hand, the complex exponential becomes a real one, and

$$\exp\left(2\pi iz\sqrt{\frac{1}{\lambda^2} - \rho^2}\right) = \exp\left(-2\pi z\sqrt{\rho^2 - \frac{1}{\lambda^2}}\right), \quad \rho > \frac{1}{\lambda}. \quad (9.117)$$

Waves with $\rho > 1/\lambda$ decay exponentially as they propagate, so they contribute very little to the resulting field if z is more than a few wavelengths. For this reason they are called *evanescent waves*. This exponential decay does not violate conservation of energy since it can be shown that there is no energy flux associated with evanescent waves.

One might wonder whether evanescent waves can even exist. From (9.42), the condition $\rho > 1/\lambda$ implies that the direction cosines α or β have to exceed one, which is unphysical. On the other hand, if we are to represent an arbitrary wave $u_0(\mathbf{r})$ by a Fourier expansion like (9.105), the limits must run over the entire ξ - η plane, not just over a circle of radius $1/\lambda$. In fact, there are several physical ways in which one can create structures with very high spatial frequency in the plane $z = 0$. A simple way is to place a very fine grating with sub-wavelength spacing over the aperture. To correctly describe the field emerging from the aperture requires $\rho > 1/\lambda$ in (9.105), but (9.117) shows that these frequency components die off very quickly as z increases and may safely be ignored in most problems.

As soon as we make the paraxial approximation, we are implicitly ignoring evanescent waves. Paraxial waves propagate nearly parallel to the z axis and hence have $\rho \ll 1/\lambda$ by (9.105).

9.5.2 Fresnel and Fraunhofer approximations

Fresnel To derive the Fresnel approximation for $P_z(\boldsymbol{\rho})$, we assume $\rho \ll 1/\lambda$ and expand the exponent in (9.110). We find

$$P_z(\boldsymbol{\rho}) = \exp\left[2\pi iz\sqrt{\frac{1}{\lambda^2} - \rho^2}\right] \approx \exp(ikz) \exp(-i\pi\lambda z\rho^2). \quad (9.118)$$

This is the expected result since it follows from (3.263) that

$$\mathcal{F}_2^{-1}\{\exp(ikz) \exp(-i\pi\lambda z\rho^2)\} = \frac{\exp(ikz)}{i\lambda z} \exp(i\pi r^2/\lambda z), \quad (9.119)$$

in agreement with (9.95). Thus, in the Fresnel approximation, the angular spectrum propagates according to

$$U_z(\boldsymbol{\rho}) = U_0(\boldsymbol{\rho}) P_z(\boldsymbol{\rho}) \approx U_0(\boldsymbol{\rho}) \exp(ikz) \exp(-i\pi\lambda z\rho^2), \quad (9.120)$$

which is just the 2D Fourier transform of (9.94).

Fraunhofer The general angular-spectrum formula (9.108) expresses the field at a single point \mathbf{r} or (\mathbf{r}, z) as a superposition of Fourier components $U_0(\boldsymbol{\rho})$, but the Fraunhofer formula (9.104) shows that only a single frequency contributes, namely $\boldsymbol{\rho} = \mathbf{r}/\lambda z$. How do we get from an integral over plane-wave components to just one component?

To answer this question, we must recognize that a field $u_0(\mathbf{r})$ contained entirely within an aperture of radius a has a Fourier transform of width $\sim 1/a$ or greater by the Fourier uncertainty relation (5.10). If a is small, $U_0(\boldsymbol{\rho})$ is broad and slowly varying. In (9.108), this broad function is multiplied by the phase factor $\exp i\Phi(\boldsymbol{\rho}; \mathbf{r})$, where $\Phi(\boldsymbol{\rho}; \mathbf{r}) = 2\pi\boldsymbol{\rho} \cdot \mathbf{r} + 2\pi z\sqrt{\frac{1}{\lambda^2} - \rho^2}$. Regions of the frequency plane where $\Phi(\boldsymbol{\rho}; \mathbf{r})$ is a rapidly varying function of $\boldsymbol{\rho}$ do not make much contribution to the integral. Instead, the main contribution comes from the points of *stationary phase* $\boldsymbol{\rho} = \boldsymbol{\rho}_0$, defined by

$$\nabla_{\boldsymbol{\rho}}\Phi(\boldsymbol{\rho}; \mathbf{r}) = 0 \quad \text{at } \boldsymbol{\rho} = \boldsymbol{\rho}_0. \quad (9.121)$$

Straightforward differentiation shows that

$$\boldsymbol{\rho}_0 = \frac{1}{\lambda} \frac{\mathbf{r}}{\sqrt{r^2 + z^2}} = \frac{\mathbf{r}}{\lambda|\mathbf{r}|}. \quad (9.122)$$

If $U_0(\boldsymbol{\rho})$ is slowly varying in the vicinity of $\boldsymbol{\rho}_0$, (9.108) becomes

$$u_z(\mathbf{r}) = U_0\left(\frac{\mathbf{r}}{\lambda|\mathbf{r}|}\right) \int_{-\infty}^{\infty} d^2\rho \exp\left[2\pi i\left(\boldsymbol{\rho} \cdot \mathbf{r} + z\sqrt{\frac{1}{\lambda^2} - \rho^2}\right)\right]. \quad (9.123)$$

But the integral is now simply the inverse Fourier transform of the transfer function $P_z(\boldsymbol{\rho})$ defined in (9.110), so we have the simple and elegant formula,

$$u_z(\mathbf{r}) = U_0\left(\frac{\mathbf{r}}{\lambda|\mathbf{r}|}\right) p_z(\mathbf{r}), \quad (9.124)$$

where the point spread function $p_z(\mathbf{r})$ is given explicitly by (9.85). Thus the wave in the Fraunhofer region is the z -derivative of a spherical wave. The strength of this wave is determined by the Fourier transform of the wave in the aperture evaluated at the single frequency $\boldsymbol{\rho}_0$. This frequency has a simple interpretation; it corresponds to the plane wave with wave vector directed from the center of the aperture towards the observation point, which is just the plane-wave approximation to the spherical wave shown in Fig. 9.7.

9.5.3 Beams

To illustrate the use of the angular spectrum, we examine some optical fields that can be described as *beams* since they propagate predominantly in a single direction.

Gaussian beams Consider a mask with an amplitude transmittance given by

$$t_{mask}(\mathbf{r}) = \exp(-\pi r^2/a^2). \quad (9.125)$$

The constant a specifies the halfwidth of the transmittance function at the $e^{-\pi}$ points.

If this mask is illuminated with a normally incident plane wave of unit amplitude, the field emerging from the mask is also given by $t_{mask}(\mathbf{r})$, and the Fourier transform of that field is

$$U_0(\boldsymbol{\rho}) = a^2 \exp(-\pi a^2 \rho^2). \quad (9.126)$$

Within the Fresnel approximation, the Fourier transform of the field at plane z is given by (9.120) as

$$U_z(\boldsymbol{\rho}) = a^2 \exp(ikz) \exp(-i\pi\lambda z\rho^2 - \pi a^2\rho^2). \quad (9.127)$$

Fourier transforms of Gaussians and chirps were discussed in Sec. 3.4.5. To find the field $u_z(\mathbf{r})$ in the present problem, we require the inverse transform of a Gaussian times a chirp. The requisite formula is (3.263); the validity of that formula for complex β is justified simply by deleting the limit in the argument given in the vicinity of (3.181)–(3.185). With a little algebra, we find

$$u_z(\mathbf{r}) = \frac{a^2 \exp(ikz)}{a^2 + i\lambda z} \exp\left(-\pi \frac{r^2}{a^2 + i\lambda z}\right). \quad (9.128)$$

This form shows that the beam profile is unaltered so long as $a^2 \gg \lambda z$. Eventually, however, for sufficiently large z , it is necessary to consider the beam spread. The general behavior can be seen by rewriting (9.128) as

$$u_z(\mathbf{r}) = \frac{a^2 \exp(ikz)}{a^2 + i\lambda z} \exp\left(i\pi \frac{\lambda z r^2}{a^4 + \lambda^2 z^2}\right) \exp\left(-\pi \frac{a^2 r^2}{a^4 + \lambda^2 z^2}\right). \quad (9.129)$$

In plane z , the halfwidth of the beam (at the $e^{-\pi}$ point) is given by

$$a_z = \frac{1}{a} \sqrt{a^4 + \lambda^2 z^2}. \quad (9.130)$$

For small z , $a_z \approx a$, while for large z , $a_z \approx \lambda z/a$, as might be anticipated from the Fraunhofer formula (9.99).

The treatment above can be modified for the case where the Gaussian mask is illuminated by a converging spherical wave rather than a plane wave. For an interesting discussion of this case, see Gaskill (1978).

Exact Gaussian-like beams The discussion of Gaussian beams above was based on the Fresnel approximation. Without this approximation, a Gaussian beam does not satisfy the Helmholtz equation, as the reader can verify by direct differentiation. It is possible, however, to construct an exact solution to the Helmholtz equation that has many of the characteristics of Gaussian beams (Landesman and Barrett, 1988). This solution is most readily expressed in oblate spheroidal coordinates, one of the orthogonal coordinates systems in which the Helmholtz equation is separable. Solutions to the separated equations, called oblate spheroidal wavefunctions, have been known for many years; they are discussed in detail by Flammer (1957). Landesman's solution, on the other hand is fundamentally different in that it is not separable. In an appropriate paraxial limit (equivalent to taking a large), it reduces to the simple Gaussian beam, but it remains an exact solution for all values of the parameters.

Moreover, Landesman showed that the Gaussian-like exact solution was just one member of a complete family of solutions; the other members are analogs of Hermite-Gauss beams often used to model laser modes (Kogelnik and Li, 1966; Fox and Li, 1961).

From Gaussian beams to rays Geometric optics deals with thin pencils of light called rays. The theory of Gaussian beams just developed provides one way of conceptualizing rays.

Geometric optics ignores diffraction effects; to turn off diffraction, we can formally take the limit of very short wavelengths. Then (9.129) becomes

$$\lim_{\lambda \rightarrow 0} u_z(\mathbf{r}) = \exp\left(-\pi \frac{r^2}{a^2}\right). \quad (9.131)$$

Thus the form of the beam is independent of z in this limit, and we can identify the beam with a geometric ray.

Bessel beams Now suppose we have a mask with an amplitude transmittance given by

$$t_{Bessel}(\mathbf{r}) = J_0(2\pi\rho_0 r), \quad (9.132)$$

where ρ_0 is a positive real constant and $J_0(\cdot)$ is the zero-order Bessel function of the first kind. Note that this transmittance, unlike that of the Gaussian mask, can assume negative values. One way to implement such a mask would be to place thin glass plates over the negative regions and adjust the thickness so that the glass shifts the phase of the light by π relative to light that passes through the positive regions.

Again we assume that the mask is illuminated with a normally incident plane wave of unit amplitude, so the field $u_0(\mathbf{r})$ is also given by $t_{mask}(\mathbf{r})$. It can be verified from (3.248) that the Fourier transform of $u_0(\mathbf{r})$ is given by

$$U_0(\boldsymbol{\rho}) = \frac{1}{2\pi\rho_0} \delta(\rho - \rho_0). \quad (9.133)$$

Note that the delta function here is 1D; it vanishes except on a ring of radius ρ_0 in the 2D Fourier plane.

In angular-spectrum terms, the ring-delta function selects out plane waves that make a specific angle to the z axis. That is, the wavevectors \mathbf{k} form a cone around the z axis. We could have anticipated this interpretation simply by examining the integral by which we defined the J_0 Bessel function in Chap. 3; from (3.247) with a change of variables, we can write

$$J_0(2\pi\rho_0 r) = \frac{1}{2\pi} \int_0^{2\pi} d\theta_\rho e^{2\pi i \rho_0 r \cos \theta_\rho}. \quad (9.134)$$

If we let $\mathbf{r} = (r, 0)$ and $\boldsymbol{\rho} = (\rho_0, \theta_\rho)$ in polar coordinates, we see from (9.134) that $J_0(2\pi\rho_0 r)$ is a superposition of plane waves for which ρ_0 is constant and θ_ρ takes on all values in 2π .

To propagate the angular spectrum specified in (9.133), we use (9.109) and (9.110) and obtain

$$U_z(\boldsymbol{\rho}) = \frac{1}{2\pi\rho_0} \delta(\rho - \rho_0) \exp\left(2\pi i z \sqrt{\frac{1}{\lambda^2} - \rho^2}\right). \quad (9.135)$$

By (2.25), however, we can replace ρ with ρ_0 in any function that multiplies $\delta(\rho - \rho_0)$, so

$$U_z(\boldsymbol{\rho}) = \frac{1}{2\pi\rho_0} \delta(\rho - \rho_0) \exp\left(2\pi i z \sqrt{\frac{1}{\lambda^2} - \rho_0^2}\right) \equiv \frac{e^{i\phi}}{2\pi\rho_0} \delta(\rho - \rho_0). \quad (9.136)$$

In other words, except for the constant $e^{i\phi}$, $U_z(\boldsymbol{\rho})$ is identical to $U_0(\boldsymbol{\rho})$, and hence $u_z(\mathbf{r}) = \text{const} \cdot u_0(\mathbf{r})$. For this reason, the J_0 Bessel function is sometimes called a *diffraction-free beam*, in spite of the fact that diffraction theory is used to show that its form is unchanged by propagation. A more accurate statement is that it is an eigenfunction of free-space propagation.

More general diffraction-free beams Even the characterization of the Bessel beam as an eigenfunction might be surprising since we have previously noted that plane waves are the eigenfunctions of free space. We have seen that free-space propagation can be regarded as a 2D linear shift-invariant system, so the plane wave $\exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r})$ is an eigenfunction and the transfer function $P_z(\boldsymbol{\rho})$ is the eigenvalue. The key point, however, is that $P_z(\boldsymbol{\rho})$ depends solely on the magnitude of $\boldsymbol{\rho}$, so free space is a rotationally symmetric LSIV system. As we discussed in Sec. 7.2.9, such systems have infinite degeneracy. *All* plane waves making a specific angle to the z axis have the same eigenvalue (transfer function), and any linear combination of eigenfunctions with the same eigenvalue is another eigenfunction with that eigenvalue.

This observation allows us to synthesize more general beams that are also invariant with propagation. Since the eigenvalues are independent of θ_ρ , we can use any weighting function $A(\theta_\rho)$ that we choose. Hence, the most general form of a so-called diffraction-free beam is (Nieto-Vesperinas, 1991)

$$u_0(\mathbf{r}) = \int_0^{2\pi} d\theta_\rho A(\theta_\rho) e^{2\pi i \rho_0 r \cos \theta_\rho}. \quad (9.137)$$

The J_0 Bessel function corresponds to $A(\theta_\rho) = \frac{1}{2\pi}$.

Practical issues In the 1980s there was considerable interest in directed-energy applications of high-power lasers. The goal was to apply a large energy per unit area on a distant target, and diffraction spreading was the chief obstacle to achieving this goal. Diffraction-free beams were touted as a way of overcoming this obstacle, but it was immediately recognized that it was not possible to synthesize a true Bessel beam since that would require an optical system with an infinite aperture. Durnin (1987) investigated the diffraction patterns of beams of the form $J_0(2\pi\rho_0 r) \text{cyl}(r/R_a)$ and showed that they maintain a tightly concentrated central peak up to a critical distance determined by the aperture radius R_a .

It does not follow from this observation, however, that it is advantageous to place a Bessel mask over a given lens aperture. From (9.97), the irradiance on the optic axis is proportional to

$$|u_z(0)|^2 = \frac{1}{\lambda z^2} \left| \int_{ap} d^2 r_0 u_0(\mathbf{r}_0) \exp(i\pi r_0^2 / \lambda z) \right|^2, \quad (9.138)$$

where the integral is over an aperture of radius R_a . We know that $u_0(\mathbf{r}_0) = u_{inc} t_{ap}(\mathbf{r}_0)$, where u_{inc} is the amplitude of a plane wave normally incident on the aperture, and the amplitude transmittance in the aperture must satisfy $|t_{ap}(\mathbf{r}_0)| \leq 1$. Then the irradiance is maximized by choosing $t_{ap}(\mathbf{r}_0) = \exp(-i\pi r_0^2 / \lambda z)$. As we shall see in Sec. 9.6.1, this function describes a lens that focuses the beam on the target at distance z ; any other function in the aperture can only reduce the irradiance on target.

Bessel beams may be more useful in optical metrology than in directed-energy applications. In surveying, for example, it can be useful to have a fine pencil of light to define a line in space. A Gaussian laser beam may not allow sufficiently precise definition of the center of the pencil, and Durnin's results suggest that a Bessel beam could be advantageous. Even here, however, there are some interesting alternatives, which in fact were well known long before coinage of the term diffraction-free. One such is an axial prism called an *axicon*. This device is simply a conical piece of glass, and it also produces a fine pencil that maintains its form over a substantial distance.

9.5.4 Reflection and refraction of light

The law of reflection of light by a mirror was apparently known to Euclid, but the law of refraction when light passes from one medium to another is of more recent origin. This law is attributed to the Dutch mathematician Willebrord Snell van Royen (1591–1626), but his manuscript on the topic was apparently destroyed by fire; Descartes' *Dioptrique* (1637) is the first extant written account of the law of refraction (Herzberger, 1980).

In this section we shall see how the laws of reflection and refraction can be derived from the angular spectrum. Along the way, we shall acquire some insight into the connection between 2D spatial frequency and 3D direction of propagation.

Consider a plane wave of the form (9.33) incident on a planar interface between two different media, and assume for now that the interface is the plane $z = 0$. The normal to the interface and the incident \mathbf{k} vector define another plane, called the *plane of incidence*; we assume that the plane of incidence is the x - z plane, so that $k_y = 0$. As in Fig. 9.4, we can draw the z axis horizontal and the interface plane vertical, but now there is no physical aperture in this plane. Assume that the medium to the left of the interface plane is homogeneous and has refractive index n or, equivalently, speed of light $c_m = c/n$. Similarly, the homogeneous medium to the right of the plane is assumed to have refractive index n' and speed of light $c'_m = c/n'$.

The incident field in the plane $z = 0$ is described by the 2D function,

$$u_{inc}(\mathbf{r}, t) = A_{inc} \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r} - 2\pi i \nu_0 t), \quad (9.139)$$

where A_{inc} is a constant amplitude, $\boldsymbol{\rho} = (\xi, 0)$ in the chosen coordinate system, and we have included the time dependence for clarity. We see from (9.139) that $u_{inc}(\mathbf{r}, t)$ oscillates with frequency ν_0 and phase $2\pi \boldsymbol{\rho} \cdot \mathbf{r}$ at point \mathbf{r} . It is this temporal oscillation that determines the nature of the reflected and refracted waves emanating from the interface.

Snell's law Let us look first at the wave propagating to the right of the interface. We already know the form of the temporal oscillation at each point in the interface, so we can write

$$u_{tr}(\mathbf{r}, t) = A_{tr} \exp(2\pi i \boldsymbol{\rho} \cdot \mathbf{r} - 2\pi i \nu_0 t), \quad (9.140)$$

where the subscript tr stands for *transmitted*. Some additional considerations would be needed to determine the amplitude A_{tr} , but we won't need it in what follows. Comparison of (9.139) and (9.140) shows that the incident and transmitted waves have exactly the same dependence on \mathbf{r} and t in the interface plane, and

in particular, exactly the same spatial frequency ρ . It does not follow, however, that they describe identical waves in the two media; we need to be careful about converting 2D spatial frequency to 3D direction of propagation.

Since $\eta = 0$ in both (9.139) and (9.140), it follows from (9.41) and (9.42) that the y component of the transmitted wavevector \mathbf{k}_{tr} is zero. Another way to state this result is that \mathbf{k}_{tr} lies in the plane of incidence, but we must still determine its angle in this plane.

From (9.44) and (9.39) with $\eta = 0$, we can express the angle θ_{inc} between the incident \mathbf{k} vector and the z axis as¹⁰

$$\sin \theta_{inc} = \frac{\xi}{\sqrt{\xi^2 + \zeta^2}} = \lambda \xi. \quad (9.141)$$

The angle θ_{tr} between the z axis and \mathbf{k}_{tr} is given by a similar expression, but ζ and λ must be replaced by the values appropriate to the medium; by (9.36) and (9.39) we have

$$\zeta' = \sqrt{\frac{1}{\lambda'^2} - \xi^2} = \sqrt{\left(\frac{n'\nu_0}{c}\right)^2 - \xi^2}. \quad (9.142)$$

Thus

$$\sin \theta_{tr} = \frac{\xi}{\sqrt{\xi^2 + \zeta'^2}} = \lambda' \xi. \quad (9.143)$$

Since ξ is the same in (9.141) and (9.143), and since $\lambda n = \lambda' n'$, we see that

$$n \sin \theta_{inc} = n' \sin \theta_{tr}. \quad (9.144)$$

This is the usual scalar formulation of *Snell's law*.

Vector form of Snell's law Equation (9.144) is specific to the coordinate system in which the plane of incidence is the x - z plane and the interface is normal to the z axis. A simple vector form of Snell's law without any reference to specific coordinates is

$$n(\hat{\mathbf{k}}_{inc} \times \hat{\mathbf{n}}) = n'(\hat{\mathbf{k}}_{tr} \times \hat{\mathbf{n}}), \quad (9.145)$$

where $\hat{\mathbf{n}}$ is the unit vector normal to the interface and $\hat{\mathbf{k}}_{inc}$ and $\hat{\mathbf{k}}_{tr}$ are unit vectors parallel to the incident and transmitted wavevectors, respectively.

A useful alternative form of Snell's law can be found by constructing an orthonormal basis for the plane of incidence. The vectors $\hat{\mathbf{n}}$ and $\hat{\mathbf{k}}_{inc}$ are linearly independent (except in the case of normal incidence), so they form a basis for the plane of incidence, but they are not orthonormal. An orthonormal basis, obtained by applying Gram-Schmidt orthogonalization as outlined in Sec. A.4.3 of App. A, consists of $\hat{\mathbf{n}}$ plus an orthogonal unit vector defined by

$$\hat{\mathbf{n}}_{\perp} = \frac{\hat{\mathbf{k}}_{inc} - (\hat{\mathbf{k}}_{inc} \cdot \hat{\mathbf{n}})\hat{\mathbf{n}}}{\sqrt{1 - (\hat{\mathbf{k}}_{inc} \cdot \hat{\mathbf{n}})^2}}. \quad (9.146)$$

The subscript \perp indicates that $\hat{\mathbf{n}}_{\perp}$ is normal to $\hat{\mathbf{n}}$, which in turn is normal to the interface; hence $\hat{\mathbf{n}}_{\perp}$ lies in the interface plane, in fact along the intersection of the

¹⁰Note that θ_{inc} in this equation is the same as θ_x in (9.44); since we have chosen $k_y = 0$ there is no need to consider the projection of \mathbf{k} onto the x - z plane.

interface plane and the plane of incidence. The reader can verify that $\hat{\mathbf{n}} \cdot \hat{\mathbf{n}}_{\perp} = 0$ and $|\hat{\mathbf{n}}_{\perp}| = 1$.

In terms of these unit vectors, $\boldsymbol{\rho} = (2\pi)^{-1}(\mathbf{k}_{inc} \cdot \hat{\mathbf{n}}_{\perp})\hat{\mathbf{n}}_{\perp} = (2\pi)^{-1}(\mathbf{k}_{tr} \cdot \hat{\mathbf{n}}_{\perp})\hat{\mathbf{n}}_{\perp}$, and Snell's law is:

$$n(\hat{\boldsymbol{\kappa}}_{inc} \cdot \hat{\mathbf{n}}_{\perp}) = n'(\hat{\boldsymbol{\kappa}}_{tr} \cdot \hat{\mathbf{n}}_{\perp}). \quad (9.147)$$

The condition that both $\hat{\boldsymbol{\kappa}}_{inc}$ and $\hat{\boldsymbol{\kappa}}_{tr}$ lie in the plane of incidence is:

$$(\hat{\mathbf{n}}_{\perp} \times \hat{\mathbf{n}}) \cdot \hat{\boldsymbol{\kappa}}_{inc} = (\hat{\mathbf{n}}_{\perp} \times \hat{\mathbf{n}}) \cdot \hat{\boldsymbol{\kappa}}_{tr} = 0. \quad (9.148)$$

An explicit expression for $\hat{\boldsymbol{\kappa}}_{tr}$ that satisfies both of these conditions is

$$\hat{\boldsymbol{\kappa}}_{tr} = \frac{n}{n'}(\hat{\boldsymbol{\kappa}}_{inc} \cdot \hat{\mathbf{n}}_{\perp})\hat{\mathbf{n}}_{\perp} + \left[\sqrt{1 - \left(\frac{n}{n'}\right)^2 (\hat{\boldsymbol{\kappa}}_{inc} \cdot \hat{\mathbf{n}}_{\perp})^2} \right] \hat{\mathbf{n}}. \quad (9.149)$$

Reflected plane waves In the interface plane, the reflected wave has the same 2D structure as the incident and transmitted waves, namely (9.139) or (9.140). Once again, however, we have to figure out what this means in 3D terms.

We can use the vector form (9.149) for the reflected wave by making two simple modifications. First, since the incident and reflected waves propagate in the same medium, we must set $n' = n$. Second, we must account for the sign ambiguity seen in (9.39) when we convert from 2D spatial frequencies to 3D ones. For the reflected wave we must take the minus sign since the z component of \mathbf{k} or $\hat{\boldsymbol{\kappa}}$ is reversed. Thus, by comparison to (9.149), the unit vector in the direction of the reflected wavevector is given by

$$\begin{aligned} \hat{\boldsymbol{\kappa}}_{refl} &= (\hat{\boldsymbol{\kappa}}_{inc} \cdot \hat{\mathbf{n}}_{\perp})\hat{\mathbf{n}}_{\perp} - \left[\sqrt{1 - (\hat{\boldsymbol{\kappa}}_{inc} \cdot \hat{\mathbf{n}}_{\perp})^2} \right] \hat{\mathbf{n}} \\ &= (\hat{\boldsymbol{\kappa}}_{inc} \cdot \hat{\mathbf{n}}_{\perp})\hat{\mathbf{n}}_{\perp} - (\hat{\boldsymbol{\kappa}}_{inc} \cdot \hat{\mathbf{n}})\hat{\mathbf{n}}. \end{aligned} \quad (9.150)$$

This equation formalizes the usual law of mirror reflection: the angle of reflection equals the angle of incidence.

Reflection and refraction of beams The results obtained above also apply, at least approximately, to collimated beams rather than infinite plane waves. As in Sec. 9.5.3, we can consider a beam with, say, a Gaussian amplitude profile propagating in direction $\hat{\boldsymbol{\kappa}}_{inc}$. For simplicity, we take the Gaussian to be circularly symmetric on the aperture, which means that it is oval on a plane normal to $\hat{\boldsymbol{\kappa}}_{inc}$.

For this beam, the field in the interface plane is given by [cf. (9.139)]

$$u_{inc}(\mathbf{r}, t) = A_0 \exp(-\pi r^2/a^2) \exp(2\pi i \boldsymbol{\rho}_0 \cdot \mathbf{r} - 2\pi i \nu_0 t), \quad (9.151)$$

and this form applies also to the transmitted and reflected waves. The effect of the Gaussian is that the incident wave no longer consists of a single spatial frequency (or equivalently, a single wavevector). Instead, the 2D angular spectrum (with the time dependence deleted) is given via (3.237) and (3.262) as

$$U_{inc}(\boldsymbol{\rho}) = A_0 a^2 \exp(-\pi a^2 |\boldsymbol{\rho} - \boldsymbol{\rho}_0|^2). \quad (9.152)$$

If $a\rho_0 \gg 1$, then this spectrum is concentrated around the frequency $\boldsymbol{\rho}_0$ which corresponds to the average incident wavevector. Under this approximation, we can assume that all wavevectors undergo approximately the same refraction, and Snell's law applies to the beam as well as to a plane wave. The reader is invited to fill in the details.

Reflection and refraction of rays Though we derived the laws of refraction and reflection by considering first plane waves and then beams, we note that the wavelength does not appear explicitly in the final result. For example, (9.145) and (9.150) are written entirely in terms of unit vectors $\hat{\mathbf{k}}$ rather than wavevectors \mathbf{k} . That means that they are still valid as the wavelength goes to zero. We noted in Sec. 9.5.3 that Gaussian beams in free space behave as geometric rays in this limit. Now we see that geometric rays defined this way obey the same laws of reflection and refraction as plane waves.

9.6 IMAGING OF POINT OBJECTS

We have now laid most of the groundwork needed to analyze imaging systems based on wave propagation, but we must still introduce image-forming elements such as lenses. There are many ways of introducing these elements, including approaches based on Snell's law or Fermat's principle, but the approach taken here is to regard a lens as a device for transforming a wave field.

Several other physical entities are the functional equivalent of lenses, in the sense that they can form images or otherwise alter light beams in a manner analogous to lenses. Included in this category are convex and concave mirrors, holographic optical elements and diffractive optics. In this chapter, however, we shall consider only lenses *per se*.

9.6.1 Ideal thin lens

An *ideal lens* is one that produces an image point that is as compact as it can be according to the laws of physical optics. Hence an ideal lens is also called a *diffraction-limited* lens. Any imperfection in a lens that causes spreading of the light is referred to as an *aberration*.

It is often useful to consider an idealization called the *thin lens*. An operational definition of a thin lens is obtained by constructing two parallel planes as close to the physical lens as possible. In geometrical optics terms, the lens is thin if a ray incident on the first plane undergoes negligible lateral displacement as it goes through the lens to the second plane. In physical-optics terms, a light source to the left of the lens produces an irradiance pattern on the first plane, and the lens is thin if essentially the same irradiance pattern appears on the second plane, no matter what source is used. Since the irradiance is proportional to the squared modulus of the complex field, a thin lens can be defined as one that alters the phase of the field but not its modulus.

Amplitude transmittance In Sec. 9.4 we considered diffraction from an open aperture in the plane $z = 0$. We used the Kirchhoff boundary condition to express the wave in this aperture as the incident field multiplied by a zero-one function $t_{ap}(\mathbf{r})$, where \mathbf{r} is a 2D vector in the plane $z = 0$. We now introduce a similar notation to express the field emerging from a thin lens. We write

$$u_+(\mathbf{r}) = u_-(\mathbf{r}) t_{lens}(\mathbf{r}), \quad (9.153)$$

where $u_+(\mathbf{r})$ is the field just after the lens, $u_-(\mathbf{r})$ is the field incident on the lens, and $t_{lens}(\mathbf{r})$ is called the *amplitude transmittance* of the lens. Consistent with the

assumption of a thin lens, $u_+(\mathbf{r})$, $u_-(\mathbf{r})$ and $t_{lens}(\mathbf{r})$ are all assumed to be measured in the plane $z = 0$. We assume that the lens is centered on the z -axis, which is called the *optical axis*. If the lens is rotationally symmetric, then the optical axis is also an axis of symmetry; otherwise it is just a convenient line running through the lens.

Equation (9.153) is already an idealization since it assumes that $t_{lens}(\mathbf{r})$ is independent of the form of the incident wave, even though it is well known that the effect of a lens on an incident wave depends on the angle of incidence. We shall return to this point in Sec. 9.6.3.

Since we have defined a thin lens as one that alters only the phase of the incident field, leaving its modulus unchanged, we can write

$$t_{lens}(\mathbf{r}) = \exp[i\Phi_{lens}(\mathbf{r})] t_{ap}(\mathbf{r}), \quad (9.154)$$

where $t_{ap}(\mathbf{r})$ is unity inside the aperture of the lens and zero outside, and $\Phi_{lens}(\mathbf{r})$ is the phase shift induced at point \mathbf{r} by the lens. Within the lens aperture, $|u_+(\mathbf{r})| = |u_-(\mathbf{r})|$.

To elucidate the meaning of $t_{lens}(\mathbf{r})$, consider the incident field to be a unit-amplitude plane wave travelling parallel to the z axis. Then

$$u_-(\mathbf{r}) = \exp(ikz)|_{z=0} = 1, \quad (9.155)$$

where $k = 2\pi/\lambda$, with λ being the wavelength of the light. With (9.155), (9.153) becomes

$$u_+(\mathbf{r}) = t_{lens}(\mathbf{r}). \quad (9.156)$$

Thus $t_{lens}(\mathbf{r})$ is the field emerging from a lens when it is illuminated with a plane wave travelling parallel to the z axis.

Amplitude transmittance of an ideal lens An ideal thin lens will convert the incident plane wave into a spherical wave converging toward a point on the optical axis at a distance $z = f$, where f is the *focal length* of the lens. The wavefront is a portion of the *Gaussian sphere*, a sphere of radius f centered on the focal point. For an ideal lens, we thus have

$$t_{lens}(\mathbf{r}) = t_{ideal}(\mathbf{r}) = \exp(-ikR_f) t_{ap}(\mathbf{r}), \quad (9.157)$$

where $k = 2\pi/\lambda$, and R_f is the distance from point \mathbf{r} in the lens plane to the focal point, given by

$$R_f = \sqrt{r^2 + f^2}, \quad (9.158)$$

where $r = |\mathbf{r}|$. Note the minus sign in the exponent in (9.157). Since we use the convention that a wave $u(\mathbf{r})$ has associated with it a time dependence $\exp(-2\pi i\nu_0 t)$, the spatial factor $\exp(-ikR_f)$ represents a *converging* spherical wave. Thus a positive lens (one with a positive focal length) produces a converging spherical wave when illuminated with a plane wave. Conversely, a negative lens produces a diverging spherical wave. A negative lens is also described by (9.157) simply by allowing f to be negative.

Fresnel approximation In the Fresnel approximation, the spherical surface defined by (9.158) is approximated by a paraboloid, so we can write

$$t_{ideal}(\mathbf{r}) \approx \exp\left(-i\pi \frac{r^2}{\lambda f}\right) t_{ap}(\mathbf{r}), \quad (9.159)$$

where we have dropped a constant phase factor $\exp(-ikf)$. This factor affects only the overall phase of the field emerging from the lens, which is almost always irrelevant since it can be observed only by interferometric methods. We retain factors that influence the spatial variation of the phase, but we do not need to consider a constant overall phase.

Fig. 9.8 (a) Illustration of a plano-convex lens used for calculation of $t_{lens}(\mathbf{r})$. (b) Field at point \mathbf{r} on the output plane arises from points in a small neighborhood of point \mathbf{r} on the input plane.

Another way to understand (9.159) is to consider specifically a plano-convex lens as illustrated in Fig. 9.8a (Goodman, 1968). We assume that a plane wave is normally incident on the planar side, and we want to compute the field $u_+(\mathbf{r})$ as a function of radius r on a plane tangent to the convex surface as shown. To compute $u_+(\mathbf{r})$ rigorously by diffraction theory, we would have to integrate over the entire planar input surface, but if the lens is thin, the main contribution to $u_+(\mathbf{r})$ at point \mathbf{r} comes from a small neighborhood of the point \mathbf{r} on the input surface (see Fig. 9.8b). Light from each of these points undergoes very nearly the same phase shift in propagating through the lens and air gap, so the sum over all points in the neighborhood undergoes that phase shift. Thus, determining $t_{lens}(\mathbf{r})$ amounts to determining the phase shift *along a horizontal straight line* displaced from the axis by \mathbf{r} . We do not need to consider explicitly refraction at the interface since the lens is thin.

The phase shift on this line can be computed from the speeds of light in the two media and the thicknesses of the media. The speed of light in air is essentially c , the speed of light in vacuum, while the speed in glass is c/n , where n is the refractive index. The thickness of air along the line is $w_a = R_c(1 - \cos \theta)$ and the thickness of glass is $w_g = w_L - R_c(1 - \cos \theta)$, where R_c is the radius of curvature of the convex surface and w_L is the overall thickness of the lens (see Fig. 9.8a). The total time $\tau(r)$ required to traverse the horizontal line at radius r is

$$\tau(r) = \frac{w_a}{c} + \frac{nw_g}{c}. \quad (9.160)$$

In time $\tau(r)$, the light traversing the lens undergoes a phase retardation of

$$\Phi_{lens}(r) = -2\pi\nu_0\tau(r) = -\frac{2\pi}{\lambda}(w_a + nw_g), \quad (9.161)$$

where λ is the wavelength of the light in free space. We assume the angle θ (see Fig. 9.8) is small, so that

$$1 - \cos \theta \approx \frac{1}{2}\theta^2 \approx \frac{r^2}{2R_c^2}. \quad (9.162)$$

With this approximation, (9.161) becomes

$$\Phi_{lens}(r) = -\frac{2\pi}{\lambda} \left[\frac{r^2}{2R_c} + n \left(w_L - \frac{r^2}{2R_c} \right) \right] = \frac{\pi}{\lambda} (n-1) \frac{r^2}{R_c} + const. \quad (9.163)$$

An elementary result from geometrical optics (Longhurst, 1973) relates the radius of curvature to the focal length of a plano-convex lens by

$$\frac{1}{f} = \frac{n-1}{R_c}, \quad (9.164)$$

so (9.163) agrees with (9.159). A similar analysis applies to double-convex and other kinds of lenses.

9.6.2 Imaging a monochromatic point source

We derived (9.159) by assuming that the incident wave was a plane wave travelling parallel to the z axis. Now consider what happens when the incident wave is produced by a monochromatic point source on the optical axis at $z = -p$. The incident wave measured in the lens plane ($z = 0$) is the diverging spherical wave given by

$$u_-(\mathbf{r}) = A \frac{\exp ikR_p}{R_p}, \quad (9.165)$$

where A specifies the strength of the source and

$$R_p = \sqrt{r^2 + p^2} = p + \frac{r^2}{2p} + \dots \quad (9.166)$$

As in the discussion of the Fresnel approximation in Sec. 9.4.5, we retain the first two terms in this expansion in the exponent of (9.165), but only the first term in the denominator. From (9.153) and (9.159), we find

$$u_+(\mathbf{r}) = A \frac{\exp(ikp)}{p} \exp\left(i\pi \frac{r^2}{\lambda p}\right) \exp\left(-i\pi \frac{r^2}{\lambda f}\right) t_{ap}(\mathbf{r}). \quad (9.167)$$

But this equation can be rewritten as

$$u_+(\mathbf{r}) = const \cdot \exp\left(-i\pi \frac{r^2}{\lambda q}\right) t_{ap}(\mathbf{r}), \quad (9.168)$$

where q is given by the *imaging condition*,

$$\frac{1}{p} + \frac{1}{q} = \frac{1}{f}. \quad (9.169)$$

If $p > f$, then q is a positive number and $u_+(\mathbf{r})$ represents a converging spherical wave, with the spherical wavefronts centered on a point on the optical axis at $z = q$.

Similarly, if $p < f$, then q is negative and $u_+(\mathbf{r})$ represents a diverging spherical wave radiating from a point on the optical axis at $z = -|q|$. In familiar geometrical-optics terms, the image of the point source is always located at $z = q$, and the image is real if q is positive and virtual if q is negative (see Fig. 9.9). The case of an incident plane wave can be recovered by letting $p \rightarrow \infty$, in which case $q = f$.

Fig. 9.9 (a) Illustration of a simple lens producing a real image. The arcs are surfaces of constant phase, also called wavefronts, and the straight lines are constructed to be normal to the wavefronts. (b) The same lens producing a virtual image. (c) The same lens imaging a point at infinity.

Field distribution The above discussion is sufficient for determining the center of curvature of the spherical wavefront, also known as the *Gaussian image* of the point source. To determine the field distribution in this image, we must invoke diffraction theory. From (9.98), we can write the field in the image plane ($z = q$) as

$$u_{im}(\mathbf{r}) = \frac{\exp(ikq)}{i\lambda q} \exp\left(i\pi \frac{r^2}{\lambda q}\right) \left[\mathcal{F}_2 \left\{ \exp\left(i\pi \frac{r'^2}{\lambda q}\right) u_+(\mathbf{r}') \right\} \right]_{\rho=\mathbf{r}/\lambda q}. \quad (9.170)$$

Note that the quadratic phase factor inside the Fourier transform is exactly cancelled by its complex conjugate, which appears in (9.168). We thus find

$$u_{im}(\mathbf{r}) = A \frac{\exp[ik(p+q)]}{i\lambda pq} \exp\left(i\pi \frac{r^2}{\lambda q}\right) T_{ap}\left(\frac{\mathbf{r}}{\lambda q}\right), \quad (9.171)$$

where $T_{ap}(\boldsymbol{\rho})$ is the 2D Fourier transform of $t_{ap}(\mathbf{r})$.

We are often able to approximate the factor $\exp(i\pi r^2/\lambda q)$ in (9.171) by unity. For example, if $t_{ap}(\mathbf{r})$ is a clear aperture of diameter D , its Fourier transform $T_{ap}(\boldsymbol{\rho})$ has its first zero at $\rho = 1.22/D$ (see (3.260) and Fig. 3.5). Thus the spatial function $T_{ap}(\mathbf{r}/\lambda q)$ has its first zero at $r = 1.22\lambda q/D$. At this radius, the argument of $\exp(i\pi r^2/\lambda q)$ is $i\pi(1.22)^2\lambda q/D^2$, which can also be written as $i\pi(1.22)^2 F^2 \lambda/q$, where $F = q/D$ is called the *effective F-number* of the lens.¹¹ Typically, F is in the range 1–10 and λ/q is of order 10^{-4} or less, so it is an excellent approximation to set $\exp(i\pi r^2/\lambda q) \approx 1$ for values of r such that $T_{ap}(\mathbf{r}/\lambda q)$ is appreciable.

With this approximation, the field in the plane $z = q$ is given by a scaled version of the Fourier transform of the aperture function:

$$u_{im}(\mathbf{r}) = \frac{A}{\lambda qp} T_{ap}\left(\frac{\mathbf{r}}{\lambda q}\right), \quad (9.172)$$

where we have dropped constant phase factors (including a factor of i).

¹¹The F -number of a lens is usually defined as f/D , which is identical to q/D if $p = \infty$.

Off-axis points The point source considered above was on the optical axis; we now generalize the calculation to a point source at a position specified by 2D vector \mathbf{r}_0 in the plane $z = -p$. The field incident on the lens is given by a translated version of (9.165), which in the Fresnel approximation becomes

$$u_-(\mathbf{r}) = \frac{A}{p} \exp\left(i\pi \frac{|\mathbf{r} - \mathbf{r}_0|^2}{\lambda p}\right), \quad (9.173)$$

where we have again dropped an irrelevant constant phase factor. If the lens is ideal, the field emerging from it is

$$u_+(\mathbf{r}) = u_-(\mathbf{r}) t_{ideal}(\mathbf{r}) = \frac{A}{p} \exp\left(i\pi \frac{|\mathbf{r} - \mathbf{r}_0|^2}{\lambda p}\right) \exp\left(-i\pi \frac{r^2}{\lambda f}\right) t_{ap}(\mathbf{r}). \quad (9.174)$$

Expanding the exponent, we find

$$\begin{aligned} u_+(\mathbf{r}) &= \frac{A}{p} \exp\left[i\pi \frac{(r^2 + r_0^2 - 2\mathbf{r} \cdot \mathbf{r}_0)}{\lambda p}\right] \exp\left(-i\pi \frac{r^2}{\lambda f}\right) t_{ap}(\mathbf{r}) \\ &= \frac{A}{p} \exp\left[i\pi \frac{(r_0^2 - 2\mathbf{r} \cdot \mathbf{r}_0)}{\lambda p}\right] \exp\left(-i\pi \frac{r^2}{\lambda q}\right) t_{ap}(\mathbf{r}), \end{aligned} \quad (9.175)$$

where the last step made use of (9.169). The field in the image plane is obtained by use of (9.170). Again there is a cancellation of quadratic phase factors inside the Fourier transform, and again constant phase factors can be dropped. If the quadratic phase factors outside the transform can be approximated by unity, we are left with

$$\begin{aligned} u_{im}(\mathbf{r}) &= \frac{A}{\lambda q p} \left[\mathcal{F}_2 \left\{ \exp\left(-2\pi i \frac{\mathbf{r}' \cdot \mathbf{r}_0}{\lambda p}\right) t_{ap}(\mathbf{r}') \right\} \right]_{\boldsymbol{\rho}=\mathbf{r}/\lambda q} \\ &= \frac{A}{\lambda q p} T_{ap} \left(\frac{\mathbf{r}}{\lambda q} + \frac{\mathbf{r}_0}{\lambda p} \right). \end{aligned} \quad (9.176)$$

This result is most easily compared to (9.172) by rewriting it as

$$u_{im}(\mathbf{r}) = \frac{A}{\lambda q p} T_{ap} \left[\frac{1}{\lambda q} (\mathbf{r} - m\mathbf{r}_0) \right], \quad (9.177)$$

where m is the *lateral magnification*, given just as in geometrical optics by

$$m = -\frac{q}{p}. \quad (9.178)$$

Note that $m = -1$ if $p = q = 2f$.

9.6.3 Transmittance of an aberrated lens

So far we have considered only ideal thin lenses. Such lenses can be described fully by the transmittance of (9.157) or, in the Fresnel approximation, (9.159). In essence, these equations say that an ideal lens produces an ideal spherical wavefront, so the temporal phase of the wave is the same at all points on a spherical cap, *i.e.*, a spherical surface truncated by the lens aperture. An aberrated lens, on the other

hand, produces a wavefront that is not exactly spherical. The phase difference between the desired spherical wave and the actual wave emerging from the lens is called the wavefront error and is commonly denoted by $kW(\mathbf{r})$, where $k = 2\pi/\lambda$ as usual. Thus $W(\mathbf{r})$ has units of length and can be interpreted as the spatial distance, along a line parallel to the z axis, between the desired spherical wave and the actual wavefront at vector distance \mathbf{r} from the z axis (see Fig. 9.10). For the moment we assume that $W(\mathbf{r})$ is independent of the wave incident on the lens, but we shall soon remove this restriction.

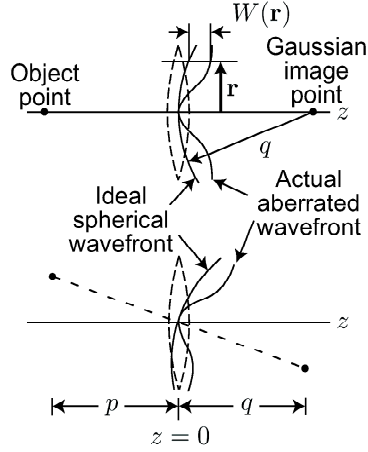

Fig. 9.10 Illustration of an aberrated wavefront.

If we express the phase transformation of the lens by (9.154), then

$$\Phi_{lens}(\mathbf{r}) = \Phi_{ideal}(\mathbf{r}) + kW(\mathbf{r}) \quad (9.179)$$

and

$$t_{lens}(\mathbf{r}) = \exp[i\Phi_{lens}(\mathbf{r})] t_{ap}(\mathbf{r}) = \exp[-ikR_f + ikW(\mathbf{r})] t_{ap}(\mathbf{r}). \quad (9.180)$$

Another way to express this same result is in terms of the *pupil function*. For a thin lens with the aperture stop at the lens, the pupil function is defined by

$$t_{pupil}(\mathbf{r}) = \exp[ikW(\mathbf{r})] t_{ap}(\mathbf{r}). \quad (9.181)$$

Hence

$$t_{lens}(\mathbf{r}) = \exp(-ikR_f) t_{pupil}(\mathbf{r}). \quad (9.182)$$

In the Fresnel approximation, we have (apart from a constant phase factor),

$$t_{lens}(\mathbf{r}) \approx \exp\left(-i\pi \frac{r^2}{\lambda f}\right) t_{pupil}(\mathbf{r}). \quad (9.183)$$

The pupil function thus describes the aberrations and the overall aperture of the lens, but not the phase transformation characteristic of an ideal lens.

The wavefront error can also depend on the nature of the wave incident on the lens. Suppose that wave is a spherical wave emanating from point \mathbf{r}_0 in the plane $z = -p$. In the lens plane ($z = 0$), this wave is expressed by

$$u_-(\mathbf{r}) = A \frac{\exp ikR_p}{R_p}, \quad (9.184)$$

where

$$R_p = \sqrt{|\mathbf{r} - \mathbf{r}_0|^2 + p^2} = p + \frac{|\mathbf{r} - \mathbf{r}_0|^2}{2p} + \dots \quad (9.185)$$

The wave emerging from the lens is

$$u_+(\mathbf{r}) = \frac{A}{R_p} \exp[ikR_p + i\Phi_{lens}(\mathbf{r}; \mathbf{r}_0)] t_{ap}(\mathbf{r}), \quad (9.186)$$

where the dependence of Φ_{lens} on the source location is now shown explicitly. We can again define a wavefront error, now denoted $kW(\mathbf{r}; \mathbf{r}_0)$, by

$$\Phi_{lens}(\mathbf{r}; \mathbf{r}_0) = \Phi_{ideal}(\mathbf{r}) + kW(\mathbf{r}; \mathbf{r}_0). \quad (9.187)$$

In the Fresnel approximation, this equation becomes

$$\Phi_{lens}(\mathbf{r}; \mathbf{r}_0) = -\pi \frac{r^2}{\lambda f} + kW(\mathbf{r}; \mathbf{r}_0). \quad (9.188)$$

Without making assumptions about the nature of the lens, this is as far as we can go.

9.6.4 Rotationally symmetric lenses

Almost all lenses used in practice are rotationally symmetric. We learned in Sec. 7.2.9 how to analyze rotationally symmetric linear systems; to apply that theory here, we need to define a suitable system. A convenient approach is to consider the mapping between the 2D field distribution in plane $z = -p$ and the 2D field distribution emerging from the lens. If we denote this mapping by the operator \mathcal{H} , we have two choices in defining its symmetry properties. As in Sec. 7.2.9, we could construct the operator $\mathcal{H}^\dagger \mathcal{H}$ and require that $\mathcal{H}^\dagger \mathcal{H} \mathcal{R}_\phi = \mathcal{R}_\phi \mathcal{H}^\dagger \mathcal{H}$, where \mathcal{R}_ϕ is the operator for rotation by angle ϕ about the z axis. Alternatively, since the range and domain of \mathcal{H} are both 2D function spaces, we can require that $\mathcal{H} \mathcal{R}_\phi = \mathcal{R}_\phi \mathcal{H}$. The latter condition is the stronger one, but it is satisfied for practical lenses if they are properly centered on the axis.

With this assumption, it follows from the discussion in Sec. 7.2.9 that the kernel of \mathcal{H} can be a function of the lengths of the vectors \mathbf{r} and \mathbf{r}_0 and of the angle $\theta - \theta_0$ between them, but it cannot depend on the absolute orientation of \mathbf{r} and \mathbf{r}_0 . Since the kernel is fully determined by $W(\mathbf{r}; \mathbf{r}_0)$, the same conclusion applies to that function too. Moreover, practical lenses also have mirror symmetry,¹² which implies that $W(\mathbf{r}; \mathbf{r}_0)$ must be an even function of $\theta - \theta_0$ (see Sec. 7.2.9).

Aberration expansion The conclusion from the discussion above is that $W(\mathbf{r}; \mathbf{r}_0)$ is a function of r , r_0 and $\theta - \theta_0$, and it is an even function of the angular difference if the lens has mirror symmetry. Of course, it must also be periodic with period 2π in the angular difference if it is to represent a physically realizable, single-valued function on the plane.

¹²It is possible to concoct systems with rotational symmetry but no mirror symmetry. An image rotator such as a Dove prism, for example, is rotationally symmetric but lacks mirror symmetry.

One way to express a function with these properties is through a power series of the form (Born and Wolf, 1999),

$$W(\mathbf{r}; \mathbf{r}_0) = \sum_{\alpha\beta\gamma} C_{\alpha\beta\gamma} r_0^{2\alpha} r^{2\beta} (\mathbf{r} \cdot \mathbf{r}_0)^\gamma. \quad (9.189)$$

The *order* of a term in this expansion is $\alpha + \beta + \gamma$. A more conventional way to express the same expansion is

$$W(\mathbf{r}; \mathbf{r}_0) = \sum_{lmn} w_{lmn} r_0^l r^m [\cos(\theta - \theta_0)]^n, \quad (9.190)$$

where $l = 2\alpha + \gamma$, $m = 2\beta + \gamma$ and $n = \gamma$. The coefficients in either expansion depend on p and the nature of the lens, but they are independent of \mathbf{r} and \mathbf{r}_0 . In addition, $W(\mathbf{r}; \mathbf{r}_0)$ may also depend on the wavelength of the light, but we consider only monochromatic sources here.

The zero-order term ($\alpha = \beta = \gamma = 0$) is uninteresting since it just signifies a constant phase. Of the three possible first-order terms, we need to consider only one. The term $\alpha = 1$, $\beta = \gamma = 0$, can be dismissed since it corresponds to a phase that depends on source location but is constant over the lens aperture. The term $\alpha = \beta = 0$, $\gamma = 1$ cannot occur if the lens surface is a second-order surface, such as a sphere or paraboloid, centered on the optic axis.

The remaining first-order term, $\alpha = \gamma = 0$, $\beta = 1$, corresponding to the coefficient w_{020} , will now be discussed. If only this term is present, (9.188) becomes

$$\Phi_{lens}(\mathbf{r}; \mathbf{r}_0) = -\pi \frac{r^2}{\lambda f} + k w_{020} r^2 = -\pi \frac{r^2}{\lambda f'}, \quad (9.191)$$

where (since $k = 2\pi/\lambda$)

$$\frac{1}{f'} = \frac{1}{f} - 2w_{020}. \quad (9.192)$$

This aberration thus causes the lens to behave as an ideal thin lens with a different focal length. The lens will form a sharp image but not at $z = q$, and the aberration is called *defocus*.

The possible second-order terms are listed below, with their common names and mathematical forms:

Field curvature or Petzval¹³ curvature: $w_{220} r_0^2 r^2$;

Distortion: $w_{311} r_0^3 r \cos(\theta - \theta_0) = w_{311} r_0^2 (\mathbf{r} \cdot \mathbf{r}_0)$;

Primary spherical aberration: $w_{040} r^4$;

Coma: $w_{131} r_0 r^3 \cos(\theta - \theta_0) = w_{131} r^2 (\mathbf{r} \cdot \mathbf{r}_0)$;

¹³Born and Wolf (1999) credit the Hungarian mathematician J. Petzval with the earliest investigation of deviations from the Gaussian image formulas. They comment that his manuscript was stolen by thieves, and that much of what we know about his work comes from semi-popular reports.

$$\text{Astigmatism: } w_{222}r_0^2r^2[\cos(\theta - \theta_0)]^2 = w_{222}(\mathbf{r} \cdot \mathbf{r}_0)^2.$$

These second-order terms are known variously as *primary aberrations*, *Seidel aberrations* or (perversely) *third-order aberrations*. The latter designation relates not to the order of a term in the wavefront expansion (9.189) but to the nature of the *ray aberrations*, a topic covered briefly in Sec. 9.6.6. For clear diagrams illustrating these aberrations, see Gaskill (1978) or Hecht (1987).

Note that spherical aberration, like defocus, is independent of \mathbf{r}_0 , which is the position of the object point in the field of view; for this reason, defocus and spherical aberration are called *field-independent aberrations*. The other Seidel aberrations are field dependent, varying as some power of \mathbf{r}_0 . For source points on or near the optical axis, the field-dependent aberrations can be ignored.

9.6.5 Field curvature and distortion

If field curvature is the only aberration present, Φ_{lens} takes the form,

$$\Phi_{lens}(\mathbf{r}; \mathbf{r}_0) = -\frac{\pi r^2}{\lambda f} + kw_{220}r_0^2r^2 \equiv -\frac{\pi r^2}{\lambda f_{eff}(r_0)}, \quad (9.193)$$

where

$$\frac{1}{f_{eff}(r_0)} = \frac{1}{f} - 2w_{220}r_0^2. \quad (9.194)$$

The effective focal length $f_{eff}(r_0)$ thus varies with position of the source point. A point described by the 2D vector \mathbf{r}_0 in the plane $z = -p$ forms an image at $z = q(r_0)$, where $q(r_0)$ is given by a slightly modified (9.169):

$$\frac{1}{p} + \frac{1}{q(r_0)} = \frac{1}{f_{eff}(r_0)}. \quad (9.195)$$

Since the z coordinate of the image point depends on r_0 , the image surface is not a plane, hence the name field curvature.

To understand distortion, we make use of (9.176), replacing T_{ap} by T_{pupil} to allow for the aberration. If distortion is the only aberration present, we have

$$t_{pupil}(\mathbf{r}; \mathbf{r}_0) = t_{ap}(\mathbf{r}) \exp[ikw_{311}r_0^2(\mathbf{r} \cdot \mathbf{r}_0)]. \quad (9.196)$$

Note the second argument in $T_{pupil}(\boldsymbol{\rho}; \mathbf{r}_0)$, indicating that the Fourier transform of the pupil function depends on the spatial location of the source point in general.

We see from (9.196) that distortion is described by a linear phase factor in the pupil function (linear in \mathbf{r}), so it produces a shift in the Fourier domain. The Fourier transform of the pupil function is obtained via (3.237) as

$$T_{pupil}(\boldsymbol{\rho}; \mathbf{r}_0) = T_{ap} \left(\boldsymbol{\rho} - \frac{w_{311}r_0^2\mathbf{r}_0}{\lambda} \right), \quad (9.197)$$

and the field in the image, from (9.176), is given by

$$u_{im}(\mathbf{r}) = \text{const} \cdot T_{ap} \left(\frac{\mathbf{r}}{\lambda q} + \frac{\mathbf{r}_0}{\lambda p} - \frac{w_{311}r_0^2\mathbf{r}_0}{\lambda} \right). \quad (9.198)$$

By analogy to (9.177), we can rewrite this result as

$$u_{im}(\mathbf{r}) = const \cdot T_{ap} \left[\frac{1}{\lambda q} (\mathbf{r} - m_{eff} \mathbf{r}_0) \right], \quad (9.199)$$

where the effective lateral magnification m_{eff} is given by

$$m_{eff} = -q \left(\frac{1}{p} - w_{311} r_0^2 \right). \quad (9.200)$$

Since the lateral magnification depends on source location, the image is distorted.

9.6.6 Probing the pupil

To understand the other aberrations, it is useful to imagine placing masks over the lens so we can determine where light from different regions of the pupil is directed. The trick is to choose the size of the mask small enough so that the phase of the wave can be approximated by a linear function of position in the pupil, yet large enough that diffraction from the mask is negligible. As we shall see, the mathematics is essentially the same as that developed in Sec. 5.1 for local spectral analysis.

The starting point is (9.170), which gives the field in the image plane for an arbitrary field in the lens plane. The field $u_+(\mathbf{r}')$ in that formula, now interpreted as the field emerging from the mask, is given in the Fresnel approximation by [cf. (9.174)]

$$u_+(\mathbf{r}') = const \cdot \exp \left(i\pi \frac{|\mathbf{r}' - \mathbf{r}_0|^2}{\lambda p} \right) \exp \left(-i\pi \frac{r'^2}{\lambda f} \right) \exp[ikW(\mathbf{r}'; \mathbf{r}_0)] t_{mask}(\mathbf{r}'), \quad (9.201)$$

where t_{mask} is the transmittance of the mask. The Fourier integral in (9.170) now takes the form

$$\left[\mathcal{F}_2 \left\{ \exp \left(i\pi \frac{r'^2}{\lambda q} \right) u_+(\mathbf{r}') \right\} \right]_{\rho=\mathbf{r}/\lambda q} = \int_{mask} d^2 r' \exp[i\Phi(\mathbf{r}'; \mathbf{r}_0)] \exp \left(-2\pi \frac{i\mathbf{r} \cdot \mathbf{r}'}{\lambda q} \right), \quad (9.202)$$

where

$$\Phi(\mathbf{r}'; \mathbf{r}_0) = \frac{\pi |\mathbf{r}' - \mathbf{r}_0|^2}{\lambda p} - \frac{\pi r'^2}{\lambda f} + kW(\mathbf{r}'; \mathbf{r}_0) + \frac{\pi r'^2}{\lambda q}. \quad (9.203)$$

The four terms in (9.203) come from, respectively, the wave incident on the lens, the phase transformation of an ideal lens, the phase distortion due to aberrations and the quadratic phase factor in the Fresnel formula. To recapitulate the meaning of the various 2D position vectors, \mathbf{r}_0 is the source position in plane $z = -p$, \mathbf{r} is the observation point in the plane $z = q$, and \mathbf{r}' is a dummy variable of integration.

If we now apply the imaging condition (9.169), all of the terms quadratic in \mathbf{r}' cancel, and we find

$$\Phi(\mathbf{r}'; \mathbf{r}_0) = -2\pi \frac{\mathbf{r}' \cdot \mathbf{r}_0}{\lambda p} + kW(\mathbf{r}'; \mathbf{r}_0) + \frac{\pi r_0^2}{\lambda q}. \quad (9.204)$$

Except for the last term, which is an irrelevant constant, $\Phi(\mathbf{r}'; \mathbf{r}_0)$ now describes a tilted plane wave (with tilt dependent on the object location) plus the wavefront error.

If the mask is a small circular opening of radius b centered at \mathbf{r}_m and $\Phi(\mathbf{r}'; \mathbf{r}_0)$ varies sufficiently slowly over this opening, we can express it as a truncated Taylor series of the form

$$\Phi(\mathbf{r}'; \mathbf{r}_0) \approx \Phi(\mathbf{r}_m; \mathbf{r}_0) + (\mathbf{r}' - \mathbf{r}_m) \cdot \nabla \Phi(\mathbf{r}_m; \mathbf{r}_0), \quad (9.205)$$

where $\nabla \Phi(\mathbf{r}; \mathbf{r}_0)$ denotes the gradient of $\Phi(\mathbf{r}; \mathbf{r}_0)$ with respect to the first argument. By analogy to (5.35), we can define

$$\nabla \Phi(\mathbf{r}_m; \mathbf{r}_0) \equiv 2\pi \boldsymbol{\rho}_{loc}(\mathbf{r}_m), \quad (9.206)$$

where $\boldsymbol{\rho}_{loc}(\mathbf{r}_m)$ is a local frequency vector.

The requisite Fourier transform can now be performed by means of (3.237) and (3.259), with the result

$$u_{im}(\mathbf{r}) \propto \left[\mathcal{F}_2 \left\{ \exp \left(i\pi \frac{r'^2}{\lambda q} \right) u_+(\mathbf{r}') \right\} \right]_{\boldsymbol{\rho}=\mathbf{r}/\lambda q} = \pi b^2 \text{besinc} \left\{ 2b \left[\frac{\mathbf{r}}{\lambda q} - \frac{\nabla \Phi(\mathbf{r}_m; \mathbf{r}_0)}{2\pi} \right] \right\}. \quad (9.207)$$

In the image plane ($z = q$), the light diffracted from the mask is a besinc function centered at the point $\mathbf{r} = \mathbf{r}_c$ where the argument of the besinc vanishes. Specifically,

$$\mathbf{r}_c = \frac{\lambda q}{2\pi} \nabla \Phi(\mathbf{r}_m; \mathbf{r}_0) = \lambda q \boldsymbol{\rho}_{loc}(\mathbf{r}_m). \quad (9.208)$$

Within the small-angle approximation, this expression is consistent with (9.113). The x component of $\lambda \boldsymbol{\rho}_{loc}(\mathbf{r}_m)$ is the deviation angle with respect to the x axis, and when multiplied by q it gives the corresponding lateral deflection in the x direction (and similarly for y). This deflection arises for two reasons: the source is displaced from the axis and the lens is aberrated.

The width of the besinc function in (9.207), measured from peak to first zero, is $1.22\lambda q/2b$, which is the diffraction-limited spot size for a circular aperture of radius b . If we can choose b relatively large without invalidating (9.205), we can think of the besinc as a small spot, almost a point, and investigate how it moves around as we explore the pupil with the mask.

To see how (9.208) works, consider first an unaberrated lens, where $W(\mathbf{r}'; \mathbf{r}_0) = 0$. In that case,

$$\mathbf{r}_c = \frac{\lambda q}{2\pi} \frac{\nabla(-2\pi \mathbf{r} \cdot \mathbf{r}_0)}{\lambda p} = -\frac{q}{p} \mathbf{r}_0. \quad (9.209)$$

Thus \mathbf{r}_c is independent of the mask location \mathbf{r}_m , so all segments of the lens direct their light to the same spot. This spot is centered at $m\mathbf{r}_0$, where again the lateral magnification m is given by $-q/p$.

If aberrations are present, on the other hand, the field distribution in the plane $z = q$ is centered at

$$\mathbf{r}_c = q \nabla W(\mathbf{r}_m; \mathbf{r}_0) - \frac{q}{p} \mathbf{r}_0. \quad (9.210)$$

This equation provides another interpretation of $W(\mathbf{r}; \mathbf{r}_0)$. In the paraxial approximation, $\nabla W(\mathbf{r}_m; \mathbf{r}_0)$ is the angle by which the centroid of the light passing through the mask is deflected (see Fig. 9.11). When this angle is multiplied by the distance q , the displacement of \mathbf{r}_c specified by the first term in (9.210) is seen.

Fig. 9.11 Illustration of an aberrated lens with a mask over the pupil.

9.6.7 Interpretation of the other Seidel aberrations

If spherical aberration is the only aberration present, Φ_{lens} takes the form

$$\Phi_{lens}(\mathbf{r}; \mathbf{r}_0) = -\pi \frac{r^2}{\lambda f} + kw_{040}r^4. \quad (9.211)$$

Since Φ_{lens} is now independent of \mathbf{r}_0 , we may as well consider an on-axis point source and take $\mathbf{r}_0 = 0$.

From (9.208), light from a mask at \mathbf{r}_m produces a diffraction pattern centered at

$$\mathbf{r}_c = z \left(\frac{1}{p} - \frac{1}{f} + \frac{1}{z} + 4w_{040}r_m^2 \right) \mathbf{r}_m. \quad (9.212)$$

Since we are considering an on-axis point source, we would hope that $\mathbf{r}_c = 0$, but this does not occur in the paraxial focal plane $z = q$. Instead, $\mathbf{r}_c = 0$ when

$$\frac{1}{z} = \frac{1}{f} - \frac{1}{p} - 4w_{040}r_m^2. \quad (9.213)$$

Since this distance depends on r_m , but not on the orientation of the vector \mathbf{r}_m , light passing through different annular zones in the lens focuses at different distances from the lens, as illustrated in Fig. 9.12. If we observe the light in the plane $z = q$ without the mask, the zones near the center of the lens form a sharp focus, but the outer zones are defocused in this plane.

Fig. 9.12 Illustration of spherical aberration.

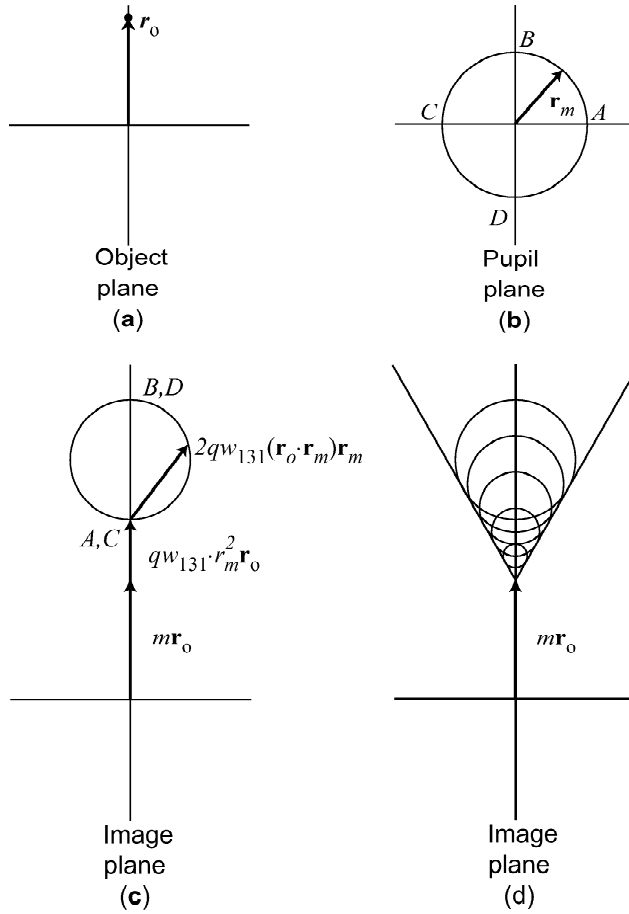

Fig. 9.13 Illustration of coma. (a) A single off-axis point in the object plane. (b) Locus of a probing mask that traverses a circle around the optical axis in the pupil plane. (c) Locus of image points as the mask traverses the pupil-plane path shown in (b). (d) Loci of points in the image plane for several circles of different diameter in the pupil plane.

Next consider coma. If coma is the only aberration present, then

$$\Phi_{lens}(\mathbf{r}; \mathbf{r}_0) = -\pi \frac{r^2}{\lambda f} + kw_{131}r^2(\mathbf{r} \cdot \mathbf{r}_0). \tag{9.214}$$

By writing the vectors out in Cartesian coordinates, we can show that

$$\nabla [r^2(\mathbf{r} \cdot \mathbf{r}_0)] = r^2\mathbf{r}_0 + 2(\mathbf{r}_0 \cdot \mathbf{r})\mathbf{r}. \tag{9.215}$$

Now the light from the mask at \mathbf{r}_m yields a diffraction pattern centered at \mathbf{r}_c in the plane $z = q$, where

$$\mathbf{r}_c = -\frac{q}{p}\mathbf{r}_0 + qw_{131} [r_m^2\mathbf{r}_0 + 2(\mathbf{r}_m \cdot \mathbf{r}_0)\mathbf{r}_m]. \tag{9.216}$$

The first term is the Gaussian image, $m\mathbf{r}_0$, while the terms proportional to w_{131} specify the lateral displacement of the spot away from the Gaussian image. There

are two components to this displacement, one in the direction of \mathbf{r}_0 and one in the direction of \mathbf{r}_m ; both of these components increase linearly with r_0 and quadratically with r_m . If we explore the pupil by rotating the mask in a circle around the optical axis (constant r_m), then the image spot also describes a circle (see Fig. 9.13). Increasing r_m increases the radius of this circle and also shifts its center. If we remove the mask, the resulting superposition of circles of various sizes and center positions resembles a comet, whence the term *coma*.

A similar analysis can be applied to astigmatism. To describe the results of this analysis, we define two orthogonal planes. The *tangential* or *meridional* plane contains the off-axis point and the optical axis (and the Gaussian image point). The *sagittal* plane is perpendicular to the tangential plane and contains the *chief ray* (defined as the ray from the object point that passes through the center of the pupil). Exploring the pupil with a mask shows that the lens has different focal lengths for the two planes. Details can be worked out by the reader as an exercise; since different focal planes are involved, it is necessary to allow both astigmatism and defocus in the pupil function.

Thick lenses and lens systems: Pupil planes and principal planes Our treatment of aberrations to this point has been confined to thin lenses with the stop at the lens. We have made no distinction between the lens plane, entrance and exit pupil planes and front and rear principal planes; all were assumed to be the single plane $z = 0$. Real optical systems, however, consist of lenses with finite thicknesses and usually multiple lens elements, and we can no longer think of the system as confined to a plane. Here we briefly consider how the thin-lens theory must be modified to accommodate more realistic optical systems.

Fig. 9.14 Illustration of the pupil planes of an optical system.

It is usually assumed that there is a single limiting aperture, called the *stop*, in an optical system. The plane where this stop is physically located is called the *stop plane* or *aperture plane*. As shown in Fig. 9.14, the image of the stop on the

object side of the system is called the *entrance pupil*, and the image of the stop on the image side is called the *exit pupil*. Thus the entrance pupil, the stop and the exit pupil lie in conjugate planes (*i.e.*, each plane is an image of the other two through the intervening optics).

To compute the field in the image plane, we can write the field in the exit pupil as a spherical wave converging on the Gaussian image point times two factors: a phase factor of the form $\exp[ikW(\mathbf{r})]$ representing the aberrations and a binary-valued factor analogous to $t_{ap}(\mathbf{r})$ representing the stop as imaged to the exit pupil. The pupil function is the product of these two factors as in (9.181), but both $W(\mathbf{r})$ and $t_{ap}(\mathbf{r})$ now refer to the exit pupil rather than the physical aperture. All of the effects of the optical elements are included in the field in the exit pupil (spherical wave times pupil function), and only free-space propagation is needed to get to the image plane. Since the spherical wave converges on the Gaussian image plane, the field in this plane is given by the Fourier transform of the pupil function, and the formalism developed above for thin lenses is still applicable.

The other significant planes in practical optical systems are the front and rear principal planes (see Fig. 9.15). In paraxial optics the principal planes are defined as conjugate planes with unit transverse magnification. Thus a ray that passes the front principal plane at height h passes the rear principal plane at height h also, by definition, so long as h is small (compared to the focal length). For first-order analysis, one can treat a complicated optical system as a thin lens if distances are measured from the principal planes. For example, the basic imaging equation, $p^{-1} + q^{-1} = f^{-1}$, still works and the magnification is still given by $m = -q/p$ so long as p and q are defined from object to front principal plane and from rear principal plane to image, respectively.

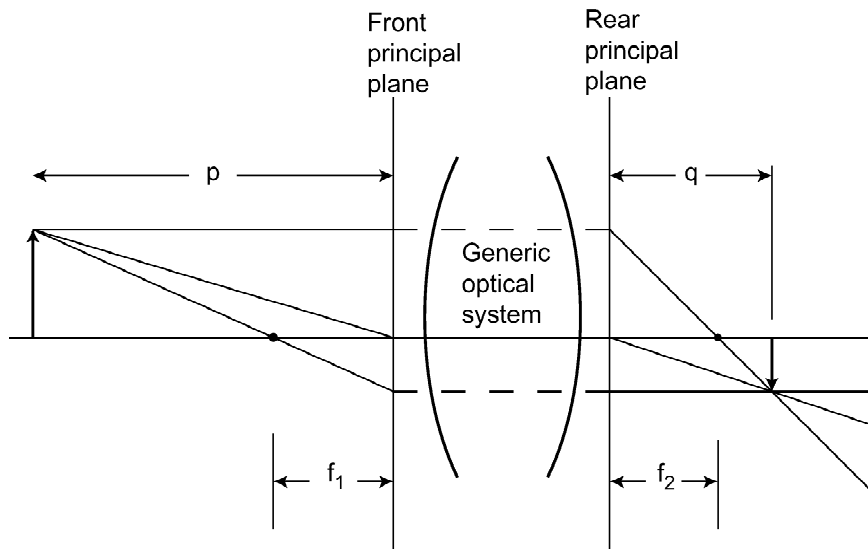

Fig. 9.15 Illustration of the principal planes of an optical system.

Abbe sine condition There is an important condition, known as the Abbe sine condition, that guarantees images free of spherical aberration and coma. In brief, this happy condition occurs when any ray leaving an axial object point at angle θ to the optical axis arrives at the image plane at an angle θ' such that $\sin \theta / \sin \theta'$ is

Fig. 9.16 Illustration of the Abbe sine condition.

constant. Remarkably, this condition has to apply only to the rays from a point on the optical axis, even though coma is an off-axis aberration.

There are several ways to understand the Abbe sine condition. A simple argument (Lipson *et al.*, 1995) regards the angles θ and θ' as specifying the directions of plane waves rather than rays. From Sec. 9.2.1 we know that $\sin \theta/\lambda$ is a spatial frequency, so the sine condition says that all spatial frequencies are scaled by the same magnification in going from object to image.

Another viewpoint, illustrated with lucid graphics, is provided by Mansuripur (2002). This treatment starts with the recognition that the front and rear principal planes are conjugate only paraxially, where $\sin \theta \approx \tan \theta \approx \theta$. When this approximation does not hold, it is useful to consider spherical surfaces rather than principal planes. Specifically, for an object point on the optical axis and a distance p from the front principal plane, Mansuripur constructs a sphere of radius p centered on the object point and hence tangent to the principal plane. In a geometrical optics view (see Fig. 9.16), he then defines the height h of a ray by the point where the ray strikes the sphere rather than by where it strikes the principal plane; thus $h(\theta) = \sin \theta/p$. If the image plane is a distance q from the rear focal plane, a similar sphere of radius q is constructed in image space, centered on the Gaussian image point and hence tangent to the rear principal plane. The sine condition is then stated as $\sin \theta/p = \sin \theta'/q$, rather than $\tan \theta/p = \tan \theta'/q$ as would apply if h were the height on the principal planes.

Mansuripur goes on to explain the sine condition in wave-optical terms. He considers an object point a small distance r_0 from the optical axis and shows that the wave emerging from the rear principal plane is a perfect spherical wave converging to the Gaussian image point if the sine condition is satisfied, but not otherwise.

Though the argument is valid only to first order in r_0 , this is sufficient to show that coma and spherical aberration vanish.

9.7 IMAGING OF EXTENDED PLANAR OBJECTS

Section 9.6 discussed the images of point objects in considerable detail. In the language of Chap. 7, these images are point response functions¹⁴ (PRFs). To complete the story, we must now show how the PRFs are superimposed to give images of extended objects. In this section we consider specifically planar or 2D object. Volume objects and 3D imaging are treated in Sec. 9.8.

The reader who has studied Chap. 7 might think that the transition from a point image to the image of an extended object is just a matter of computing an integral, and in one sense that is correct. If we know the object field and the PRF for an arbitrary point in the object, we can simply add up PRFs to get the image; details of this procedure are given in Secs. 9.7.1–9.7.3 for various imaging systems.

In many cases, however, we do not — and cannot — know the object field since it is a rapidly oscillating random process. In those cases, we must be content with computing the average irradiance in the image, which is the average of the squared modulus of the field. The averaging process requires that we make some statement about the statistical properties of the source, and coherence theory, the topic of Sec. 9.7.4 provides the language for doing so. The effects of coherence on imaging with quasimonochromatic light will be discussed in detail in Sec. 9.7.5.

Formation of the squared modulus of a complex field is a nonlinear process, but nevertheless, as we shall see in Sec. 9.7.6, there is one important limit (spatial incoherence) in which it is possible to salvage the machinery of linear superposition and define a new PRF for this situation. We shall explore this important case in detail in Secs. 9.7.6 and 9.7.7. In Sec. 9.7.8, however, we shall finally encounter a case — partial spatial coherence — where linear systems theory fails us.

9.7.1 Monochromatic objects and a simple lens

We have discussed in some detail the imaging of a single monochromatic point source with a thin lens. To apply these results to a continuous object, we decompose the object amplitude distribution into delta functions by means of the sifting relation,

$$u_{obj}(\mathbf{r}) = \int_{\infty} d^2r_0 u_{obj}(\mathbf{r}_0) \delta(\mathbf{r} - \mathbf{r}_0). \quad (9.217)$$

The field in the image plane produced by each delta function was calculated in Sec. 9.6.2, except that we have to get the amplitude A correct. We know from (9.94) that a delta function in plane $z = -p$ produces a spherical wave with amplitude $1/(i\lambda p)$ in the plane $z = 0$. Comparison with (9.173) shows that we should set $A = 1/(i\lambda)$ (though we can again delete the i since constant phase factors are irrelevant). With this substitution, the field in the image plane is given by (9.177), with T_{ap} replaced

¹⁴As discussed in Chap. 7, we use the term *point response function* or PRF to denote the general shift-variant image of a point, reserving the more common term *point spread function* or PSF specifically for the shift-invariant case.

by T_{pupil} for generality:

$$u_{im}^{(\delta)}(\mathbf{r}) = \frac{1}{\lambda^2 qp} T_{pupil} \left[\frac{1}{\lambda q} (\mathbf{r} - m\mathbf{r}_0); \mathbf{r}_0 \right], \quad (9.218)$$

where the superscript (δ) indicates that this is the field due to $\delta(\mathbf{r} - \mathbf{r}_0)$ only.

By linear superposition, the total image-plane field is

$$u_{im}(\mathbf{r}) = \frac{1}{\lambda^2 qp} \int_{\infty} d^2 r_0 u_{obj}(\mathbf{r}_0) T_{pupil} \left[\frac{1}{\lambda q} (\mathbf{r} - m\mathbf{r}_0); \mathbf{r}_0 \right]. \quad (9.219)$$

This integral describes a magnifier with possibly shift-variant blur; it is not a convolution because of the magnification factor m and also because the pupil function itself depends on \mathbf{r}_0 if the lens has off-axis aberrations. Systems of this form were discussed in general terms in Sec. 7.2.7, and the concepts introduced there will now be applied to (9.219).

Reduction to a convolution For the moment, neglect field-dependent aberrations so that $T_{pupil}(\boldsymbol{\rho}; \mathbf{r}_0)$ is independent of \mathbf{r}_0 and we can drop the second argument. In that case we can force (9.219) to look like a convolution by defining a rescaled image, the same size as the object, by

$$u_{im}^{(s)}(\mathbf{r}) = m u_{im}(m\mathbf{r}), \quad (9.220)$$

where the superscript s indicates the scaling.

From (9.219), the scaled image field is related to the object field by

$$u_{im}^{(s)}(\mathbf{r}) = \frac{m}{\lambda^2 qp} \int_{\infty} d^2 r_0 u_{obj}(\mathbf{r}_0) T_{pupil} \left[\frac{m}{\lambda q} (\mathbf{r} - \mathbf{r}_0) \right] \equiv u_{obj}(\mathbf{r}) * p_{coh}(\mathbf{r}), \quad (9.221)$$

where the PSF $p_{coh}(\mathbf{r})$ is given by

$$p_{coh}(\mathbf{r}) = \frac{m}{\lambda^2 qp} T_{pupil} \left(m \frac{\mathbf{r}}{\lambda q} \right). \quad (9.222)$$

The subscript *coh* stands for *coherent*, a designation that will become clearer in Sec. 9.7.4 when we introduce incoherent fields and objects.

The key conclusion from this discussion is that the coherent PSF is a scaled version of the Fourier transform of the pupil. Note that the scaling factors lead to dimensionally correct expressions. The space-domain pupil function $t_{pupil}(\mathbf{r})$ is dimensionless, so its Fourier transform $T_{pupil}(\boldsymbol{\rho})$ has dimensions of L^2 (from the $d^2 r$ in the Fourier integral). The substitutions in the argument do not alter the dimensions of T_{pupil} , and the factors out front have net dimensions of L^{-4} . Thus p_{coh} has dimensions of L^{-2} , as it must if (9.221) is to be dimensionally correct.

Since $m = -q/p$ we can also write (9.222) as

$$p_{coh}(\mathbf{r}) = \frac{-1}{(\lambda p)^2} T_{pupil} \left(-\frac{\mathbf{r}}{\lambda p} \right). \quad (9.223)$$

This form shows that the PSF, as we have defined it, is really independent of the magnification; we have scaled the image to match the scale of the object, so only the object-to-lens distance p affects the PSF. Recall, however, that we are considering only a simple thin lens with the aperture stop at the lens. For more complicated systems the key distance is from the object to the entrance pupil.

Effect of aberrations If field-dependent aberrations are present, the integral in (9.221) is not a convolution since T_{pupil} is a function of \mathbf{r}_0 . With field-dependent aberrations, the system is shift variant, and the point response function must depend on two arguments.

To show the field dependence explicitly, we write

$$t_{pupil}(\mathbf{r}; \mathbf{r}_0) = \exp[ikW(\mathbf{r}; \mathbf{r}_0)] t_{ap}(\mathbf{r}). \quad (9.224)$$

The Fourier transform of this function with respect to the \mathbf{r} variable is

$$T_{pupil}(\boldsymbol{\rho}; \mathbf{r}_0) = \mathcal{F}_2\{t_{pupil}(\mathbf{r}; \mathbf{r}_0)\}. \quad (9.225)$$

The counterpart of (9.221) is

$$\begin{aligned} u_{im}^{(s)}(\mathbf{r}) &= \frac{m}{\lambda^2 qp} \int_{\infty} d^2 r_0 u_{obj}(\mathbf{r}_0) T_{pupil} \left[\frac{m}{\lambda q} (\mathbf{r} - \mathbf{r}_0; \mathbf{r}_0) \right] \\ &\equiv \int_{\infty} d^2 r_0 u_{obj}(\mathbf{r}_0) p_{coh}(\mathbf{r} - \mathbf{r}_0; \mathbf{r}_0), \end{aligned} \quad (9.226).$$

where now the *shift-variant* point response function $p_{coh}(\mathbf{r}; \mathbf{r}_0)$ is given by

$$p_{coh}(\mathbf{r}; \mathbf{r}_0) = \frac{m}{\lambda^2 qp} T_{pupil} \left(\frac{m}{\lambda q} \mathbf{r}; \mathbf{r}_0 \right) = -\frac{1}{(\lambda p)^2} T_{pupil} \left(-\frac{\mathbf{r}}{\lambda p}; \mathbf{r}_0 \right). \quad (9.227)$$

A useful approximation is to consider a small region of the object plane over which $t_{pupil}(\mathbf{r}, \mathbf{r}_0)$ does not vary much with \mathbf{r}_0 . If we let \mathbf{r}_{0c} denote the center of this so-called *isoplanatic patch*, we can set

$$p_{coh}(\mathbf{r} - \mathbf{r}_0; \mathbf{r}_0) \approx p_{coh}(\mathbf{r} - \mathbf{r}_0; \mathbf{r}_{0c}). \quad (9.228)$$

If the object lies entirely within the isoplanatic patch, the image is approximately a convolution. For more discussion of approximately shift-invariant systems, see Sec. 7.2.8.

Coherent transfer function In the shift-invariant case, we can define the coherent transfer function as the Fourier transform of $p_{coh}(\mathbf{r})$:

$$P_{coh}(\boldsymbol{\rho}) = \mathcal{F}_2\{p_{coh}(\mathbf{r})\} = \frac{1}{(\lambda p)^2} \mathcal{F}_2 \left\{ T_{pupil} \left(-\frac{\mathbf{r}}{\lambda p} \right) \right\}. \quad (9.229)$$

From (3.113) and (3.239),

$$P_{coh}(\boldsymbol{\rho}) = t_{pupil}(\lambda p \boldsymbol{\rho}). \quad (9.230)$$

An extra factor of -1 occurs in (9.230) since $\mathcal{F}_2 \mathcal{F}_2\{f(-\mathbf{r})\} = f(\mathbf{r})$.

Thus *the coherent transfer function is the pupil function itself, suitably scaled*. Object Fourier components for which $\lambda p \boldsymbol{\rho}$ lies outside the lens aperture are not passed by the system.

9.7.2 $4f$ imaging system

Even in the absence of aberrations, a thin lens is not exactly shift invariant; to get convolutions in Sec. 9.7.1, we had to drop quadratic phase factors at several junctures. A somewhat more complicated imaging system that avoids the need for this approximation (but requires some others) is illustrated in Fig. 9.17. We introduce this system here both as an interesting exercise in the application of diffraction theory to imaging and also because it will provide insights into coherence and 3D imaging when we get to those topics.

Fig. 9.17 A $4f$ imaging system. The object is a photographic transparency placed in the plane $z = 0$, and the illumination is a monochromatic plane wave normally incident on the transparency.

The focal length of both lenses is f , and the object to be imaged is located a distance f from the first lens. The object plane is called the *front focal plane* of the first lens. The spacing between the lenses is $2f$, and an aperture stop or other mask is placed midway between them, in the back focal plane of the first lens and the front focal plane of the second one. The image is formed in the back focal plane of the second lens, so the total distance from object to image is $4f$, and this configuration of lenses is often referred to as a $4f$ system.

For this analysis, we shall ignore lens aberrations and treat the lenses as thin. We shall assume also that the object is a thin photographic transparency, and that it is illuminated with a monochromatic plane wave propagating along the z axis. The incident wave is thus a constant in the plane of the object, and the wave emerging from the object is this constant (call it A) times the amplitude transmittance of the object transparency. If the plane of the object is $z = 0$, we can write the field emerging from the object as

$$u_{0^+}(\mathbf{r}) = A t_{obj}(\mathbf{r}), \quad (9.231)$$

where the 0^+ subscript indicates the field just to the right of $z = 0$.

As we know from Sec. 9.5.1, this wave can be decomposed into plane-wave components, each of which propagates independently to the lens. To get a qualitative understanding of the action of this imaging system, consider one such plane wave. An ideal lens of focal length f converts an incident plane wave into a spherical wave with radius of curvature f . This wave comes to a focus in the back focal plane, producing a bright spot at a position determined by the direction cosines of the plane wave (see Fig. 9.18). Since these direction cosines correspond to spatial-frequency

components by (9.42), the field distribution in the back focal plane of the first lens is the Fourier transform of the object field. For this reason, the back focal plane in this system is often referred to as the *Fourier plane*.

Fig. 9.18 Illustration of one diffracted plane wave emerging from the object and forming a focus in the back focal plane of a lens.

The field in the Fourier plane, incident on the aperture stop, is multiplied by the transmittance of the aperture and then propagates through the second lens to the image plane. Since the second half of the system is identical to the first, it also takes a Fourier transform of the field in its front focal plane. The overall imaging system thus has the following action: it takes the Fourier transform of the input, multiplies it by an aperture stop, and then takes a second Fourier transform.

If the second transform were an inverse Fourier transform, this action would immediately constitute a linear, shift-invariant imaging system, with a transfer function given by the transmittance of the aperture stop. The distinction between forward and inverse transforms, however, is rather trivial. Since $\exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) = \exp[2\pi i \boldsymbol{\rho} \cdot (-\mathbf{r})]$, a forward transform followed by a coordinate inversion is the same as an inverse transform. In the $4f$ system, the image is inverted (magnification $= -1$), but otherwise it is the expected shift-invariant system.

Fresnel-diffraction analysis Now we look more quantitatively at the $4f$ system, using the framework of Fresnel diffraction theory. If we use the Fresnel diffraction formula (9.98) to propagate the object field to the lens (*i.e.*, to a plane just to the left of $z = f$), the result is

$$u_{f-}(\mathbf{r}) = \frac{\exp(ikf)}{i\lambda f} \exp\left(i\pi \frac{r^2}{\lambda f}\right) \mathcal{F}_2 \left\{ u_{0+}(\mathbf{r}_0) \exp\left(i\pi \frac{r_0^2}{\lambda f}\right) \right\}_{\boldsymbol{\rho}=\mathbf{r}/\lambda f}. \quad (9.232)$$

The field emerging from the lens is obtained by multiplying this expression by the lens transmittance, given in the Fresnel approximation by (9.159), so

$$\begin{aligned} u_{f+}(\mathbf{r}) &= u_{f-}(\mathbf{r}) \exp\left(-i\pi \frac{r^2}{\lambda f}\right) t_{ap}(\mathbf{r}) \\ &= \frac{\exp(ikf)}{i\lambda f} t_{ap}(\mathbf{r}) \mathcal{F}_2 \left\{ u_{0+}(\mathbf{r}_0) \exp\left(i\pi \frac{r_0^2}{\lambda f}\right) \right\}_{\boldsymbol{\rho}=\mathbf{r}/\lambda f}. \end{aligned} \quad (9.233)$$

Note that the quadratic phase factor $\exp(i\pi r^2/\lambda f)$ in (9.232) has been cancelled by the quadratic phase factor in the lens transmittance.

Next we assume that the lens diameter D_{lens} is large enough that $t_{ap}(\mathbf{r})$ does not substantially truncate the field incident on it. There are two components to this assumption. It requires that the size of the object transparency be small compared to the lens diameter, but it also requires that t_{obj} not contain fine structures that would diffract light substantially out of the geometric shadow of the object. Roughly speaking, if ρ_{max} is the highest spatial frequency in the object, it will diffract light at an angle given by $\sin \theta_{max} \approx \lambda \rho_{max}$, and the lens aperture is unimportant if $f \tan \theta_{max}$ is less than about $\frac{1}{2} D_{lens}$. This is the major assumption of this analysis: in contrast to the single lens, the lens aperture plays essentially no role in determining the characteristics of a $4f$ system. All of the light is assumed to get through the lens, and the imaging characteristics are set by the stop between the lenses, not by the lens apertures.

If we set $t_{ap}(\mathbf{r}) = 1$, then (9.233) becomes

$$u_{f+}(\mathbf{r}) = const \cdot \mathcal{F}_2 \left\{ u_{0+}(\mathbf{r}_0) \exp \left(i\pi \frac{r_0^2}{\lambda f} \right) \right\}_{\boldsymbol{\rho}=\mathbf{r}/\lambda f}. \quad (9.234)$$

A Fourier transformation yields the angular-spectrum representation:

$$\begin{aligned} & U_{f+}(\boldsymbol{\rho}) \\ &= const \cdot \int_{\infty} d^2 r \exp(-2\pi i \boldsymbol{\rho} \cdot \mathbf{r}) \int_{\infty} d^2 r_0 u_{0+}(\mathbf{r}_0) \exp \left(i\pi \frac{r_0^2}{\lambda f} \right) \exp \left(-2\pi i \frac{\mathbf{r} \cdot \mathbf{r}_0}{\lambda f} \right) \\ &= const \cdot \int_{\infty} d^2 r_0 u_{0+}(\mathbf{r}_0) \exp \left(i\pi \frac{r_0^2}{\lambda f} \right) \delta \left(\boldsymbol{\rho} + \frac{\mathbf{r}_0}{\lambda f} \right) \\ &= const \cdot u_{0+}(-\lambda f \boldsymbol{\rho}) \exp(i\pi \lambda f \rho^2). \end{aligned} \quad (9.235)$$

In the plane immediately after the lens, therefore, the Fourier transform of the field is a scaled version of the object field times a quadratic phase factor. To propagate this field to the back focal plane of the lens, we multiply (9.235) by the transfer function for free-space propagation, given in the Fresnel approximation by (9.118); the quadratic phase factors cancel, so

$$U_{2f-}(\boldsymbol{\rho}) = const \cdot u_{0+}(-\lambda f \boldsymbol{\rho}), \quad (9.236)$$

where the subscript $2f^-$ indicates a plane just to the left of $z = 2f$, or immediately before the aperture stop. An inverse Fourier transform of (9.236) yields

$$u_{2f-}(\mathbf{r}) = const \cdot U_{0+} \left(\frac{\mathbf{r}}{\lambda f} \right), \quad (9.237)$$

which confirms the conclusion that we reached qualitatively by considering Fig. 9.18: The space-domain field in the back focal plane is proportional to the Fourier transform of the object field.

Relation to Fraunhofer diffraction The relation of (9.237) to Fraunhofer diffraction theory should not be overlooked. Except for a quadratic phase factor, (9.237) is identical to the Fraunhofer formula (9.99), yet nowhere in this section have we made a Fraunhofer approximation. For (9.99) to be valid, the observation distance z has to be large, but no similar requirement applies to the focal length f .

We can understand this result by realizing that the Fraunhofer approximation becomes exact as the distance z goes to infinity. With the lens in the system, however, a plane at infinity is imaged to $z = f$. Thus (9.237) is a Fraunhofer field imaged to the back focal plane of the first lens.

Propagation to the image plane The field at $z = 2f^+$ is found by multiplying $u_{2f^-}(\mathbf{r})$ by the amplitude transmittance of the aperture stop. If we denote this transmittance by $t_{pupil}(\mathbf{r})$, then

$$u_{2f^+}(\mathbf{r}) = t_{pupil}(\mathbf{r}) u_{2f^-}(\mathbf{r}) = \text{const} \cdot t_{pupil}(\mathbf{r}) U_{0^+} \left(\frac{\mathbf{r}}{\lambda f} \right). \quad (9.238)$$

We can now use (9.236) to propagate the field from $z = 2f^+$ to the image plane, $z = 4f$; the result is

$$U_{4f}(\boldsymbol{\rho}) = \text{const} \cdot u_{2f^+}(-\lambda f \boldsymbol{\rho}) = \text{const} \cdot t_{pupil}(-\lambda f \boldsymbol{\rho}) U_{0^+}(-\boldsymbol{\rho}). \quad (9.239)$$

The constant in this equation turns out just to be the phase factor $\exp(4ikf)$. That the modulus of the constant is unity follows from conservation of energy; we have assumed that the diffracted light all goes through the aperture of the first lens, and if $t_{pupil}(\mathbf{r}) = 1$, there is no light loss at all.

The minus signs in the arguments in (9.239) imply that the image is inverted. As in Sec. 9.7.1, we can define a scaled function that removes the uninteresting magnification factors. In the present case, the scaling amounts to removing a minus sign, so that

$$U_{im}^{(s)}(\boldsymbol{\rho}) \equiv U_{4f}(-\boldsymbol{\rho}) = \exp(4ikf) t_{pupil}(\lambda f \boldsymbol{\rho}) U_{obj}(\boldsymbol{\rho}), \quad (9.240)$$

where $U_{obj}(\boldsymbol{\rho}) = U_{0^+}(-\boldsymbol{\rho})$ is the Fourier transform of the object field but plotted on inverted axes.

The form of (9.240) shows that the $4f$ system is a linear, shift-invariant mapping from the object field to the (scaled) image field. In the frequency domain, this mapping is the simple multiplication shown in (9.239), and in the space domain it is a convolution. By inspection of (9.240), the coherent transfer function for a $4f$ system is

$$P_{coh}(\boldsymbol{\rho}) = \exp(4ikf) t_{pupil}(\lambda f \boldsymbol{\rho}). \quad (9.241)$$

If we neglect the constant phase factor $\exp(4ikf)$, (9.241) is essentially the same as the transfer function (9.230) for a simple lens, only now the pupil is interpreted as the transmittance of the aperture stop, and f appears rather than p .

To appreciate the form of (9.241), suppose that the pupil is a square aperture of side L centered on the optic axis, so that $t_{pupil}(\mathbf{r}) = \text{rect}(x/L) \text{rect}(y/L)$, where x and y are the Cartesian components of \mathbf{r} . Consider an object with an amplitude transmittance of $\exp(2\pi i \xi_0 x)$. This object can be realized as a thin prism, but it can also be regarded as one Fourier component of a more general object. With either interpretation, the field emerging from the object (for a normally incident

plane-wave illumination) is a plane wave propagating in the x - z plane at an angle θ_x to the z axis, where, in the small-angle approximation, $\theta_x \approx \xi_0 \lambda$.

An elementary function of a lens is to focus a plane wave into a point in the back focal plane. For the plane wave emerging from our test object, this point is located (in the small-angle approximation) at coordinates $(f\theta_x, 0)$. Thus the focal point is at $(\lambda f \xi_0, 0)$, which is precisely the argument of t_{pupil} in (9.241) for the frequency under discussion. If this focal spot lies outside the clear aperture, *i.e.*, if $\lambda f |\xi_0| > \frac{1}{2}L$, then the spot is blocked by the aperture and makes no contribution to the image field. If $\lambda f |\xi_0| < \frac{1}{2}L$, on the other hand, the focused wave travels unimpeded past the focal spot, producing an expanding spherical wave of radius of curvature f incident on the next lens. This lens converts the spherical wave into another tilted plane wave (this time with $\theta_x = -\xi_0 \lambda$), which reproduces the object wave. Thus the aperture transmittance directly controls the transfer function of the system.

9.7.3 More complicated lens systems

In geometrical optics, the action of a lens system is described by specifying what it does to rays. Often we consider all of the rays crossing some input plane P_{in} (commonly, but not necessarily, the object plane) and trace them through to some output plane P_{out} (commonly the image plane). If we know what happens to all such rays, we have completely specified the mapping operation from P_{in} to P_{out} so far as geometric optics goes. In this section we shall see that this geometric-optics description also tells us a good deal about the physical-optics properties of the system.

Paraxial ray optics As discussed in Sec. 7.2.10, we often consider systems with a well-defined optical axis (perhaps an axis of rotational symmetry), which we can call the z -axis. For such systems it is natural to construct the planes P_{in} and P_{out} perpendicular to the z -axis. The rays are then described by their x - y coordinates on the plane and their direction cosines relative to the x and y axes. For the output plane P_{out} , we shall denote the coordinates of a particular ray as simply x and y , with the corresponding direction cosines α and β . For P_{in} we shall use x' , y' , α' and β' .

Elementary geometric optics often considers only *paraxial rays* for which α and β are small, and it restricts the input field of view sufficiently that the system is shift-invariant. It may then be a good approximation to describe the mapping from P_{in} to P_{out} as a simple matrix multiplication. If the system has rotational symmetry, the mapping is *separable*, in the sense that the mapping of x' and α' to x and α is independent of y' and β' , and we can write

$$\begin{bmatrix} x \\ \alpha \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} x' \\ \alpha' \end{bmatrix}, \quad (9.242)$$

with a similar expression for the y coordinates.¹⁵

¹⁵If the paraxial approximation does not hold, (9.242) can still be used, but the matrix elements must be functions of x' and α' .

For example, if the input and output planes are separated by a distance z in free space, then the $ABCD$ matrix is given by

$$\mathbf{M}_z = \begin{bmatrix} 1 & z \\ 0 & 1 \end{bmatrix}. \quad (9.243)$$

The transformation action of this segment of free space is thus

$$\mathbf{M}_z \begin{bmatrix} x' \\ \alpha' \end{bmatrix} = \begin{bmatrix} x' + \alpha'z \\ \alpha' \end{bmatrix}. \quad (9.244)$$

We see that the angle of the ray remains constant as z is varied but that the ray is displaced parallel to the x -axis by an amount $\alpha'z$.

To describe a thin lens in the paraxial approximation, we take the input and output planes to be immediately adjacent to the lens; thus P_{in} and P_{out} are effectively the same plane since the lens is thin. The matrix that describes a thin lens of focal length f with this choice of planes is

$$\mathbf{M}_{lens} = \begin{bmatrix} 1 & 0 \\ -\frac{1}{f} & 1 \end{bmatrix}, \quad (9.245)$$

and the transformation is

$$\mathbf{M}_{lens} \begin{bmatrix} x' \\ \alpha' \end{bmatrix} = \begin{bmatrix} x' \\ -\frac{x'}{f} + \alpha' \end{bmatrix}. \quad (9.246)$$

Thus the position of the ray is unaltered (which is the operational definition of a thin optical element), but the angle is deviated by an amount proportional to x' .

Concatenation of matrices We can construct matrix representations for more complicated systems from the building blocks \mathbf{M}_z and \mathbf{M}_{lens} . For example, if we consider free-space propagation over distance p , followed by a thin lens of focal length f and then propagation over q , where p , q and f are related by the imaging equation (9.169), then the overall matrix is

$$\mathbf{M}_q \mathbf{M}_{lens} \mathbf{M}_p = \begin{bmatrix} 1 & q \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ -\frac{1}{f} & 1 \end{bmatrix} \begin{bmatrix} 1 & p \\ 0 & 1 \end{bmatrix} = \begin{bmatrix} m & 0 \\ -\frac{1}{f} & \frac{1}{m} \end{bmatrix}, \quad (9.247)$$

where m is the magnification, $-q/p$.

The overall transformation from input to output for this example is

$$\begin{bmatrix} m & 0 \\ -\frac{1}{f} & \frac{1}{m} \end{bmatrix} \begin{bmatrix} x' \\ \alpha' \end{bmatrix} = \begin{bmatrix} mx' \\ \frac{\alpha'}{m} - \frac{x'}{f} \end{bmatrix}. \quad (9.248)$$

As expected, $x = mx'$ since m is the magnification. If we define an angular magnification as $m_{ang} = \frac{d\alpha}{d\alpha'}$, then we see that $m_{ang} = m^{-1}$, so systems that magnify the image demagnify the angles. The angular offset $-x'/f$ can be understood by considering the ray with $\alpha' = 0$; this ray must pass through the focal point in image space and hence makes an angle $-x'/f$ with the axis.

As an exercise, the reader may show that the $ABCD$ matrix for the $4f$ system of Fig. 9.17 is just $-\mathbf{I}$, where \mathbf{I} is the 2×2 unit matrix. Thus the lateral and angular magnifications are both -1 .

Lens group All matrices considered so far in this section have determinant = 1, that is, $AD - BC = 1$. In fact, this is a general rule: whenever an optical system can be described geometrically by a 2×2 $ABCD$ matrix, that matrix must have unit determinant (Stavroudis, 1972). We know from Sec. 6.5.2 that the group of all such matrices is the special linear group $\mathbf{SL}(2)$, which we can now regard as the group of all realizable optical systems that can be described by 2×2 $ABCD$ matrices. (Recall that this description requires the paraxial and shift-invariant approximations and that it applies only to rotationally symmetric or other separable systems where the x and y variables transform independently.)

We know also from Chap. 6 that a set of operators constitutes a group only if the inverse of every operator is in the group. That condition is satisfied for this lens group. For example, the inverse of propagation over distance z is propagation over $-z$, and the inverse of a positive lens of focal length f is a negative lens of focal length $-f$.

Generalized diffraction integral The Fresnel diffraction integral for a rotationally symmetric optical system was first written in terms of matrix optics by Collins (1970) and further explored by Nazarathy and colleagues (Nazarathy and Shamir, 1982a, 1982b) For textbook treatments see Saleh and Teich (1981) and Siegman (1986).

The main result of these discussions is that, when the mapping from P_{in} to P_{out} is described geometrically by a 2×2 $ABCD$ matrix, the field is mapped in the Fresnel approximation according to

$$u_{out}(x, y) = -\frac{i}{B\lambda} \int_{-\infty}^{\infty} dx_0 \int_{-\infty}^{\infty} dy_0 u_{in}(x_0, y_0) \times \exp \left\{ \frac{i\pi}{\lambda B} [A(x_0^2 + y_0^2) + D(x^2 + y^2) - 2(xx_0 + yy_0)] \right\}, \quad (9.249)$$

or, in our usual vector notation,

$$u_{out}(\mathbf{r}) = -\frac{i}{B\lambda} \int_{\infty} d^2r_0 u_{in}(\mathbf{r}_0) \exp \left[\frac{i\pi}{\lambda B} (Ar_0^2 + Dr^2 - 2\mathbf{r} \cdot \mathbf{r}_0) \right]. \quad (9.250)$$

One special case of this result is already known from earlier in this chapter. For free-space propagation over distance z , $A = 1$, $B = z$, $C = 0$ and $D = 1$, so (9.250) reproduces (9.97) except for the irrelevant constant $\exp(ikz)$.

$ABCD$ matrices for systems without rotational symmetry The use of a 2×2 $ABCD$ matrix presumes that the x and y variables can be transformed independently, as they can for systems with rotational symmetry. More generally, however, we can use a 4×4 matrix and write the transformation as

$$\begin{bmatrix} M_{11} & M_{12} & M_{13} & M_{14} \\ M_{21} & M_{22} & M_{23} & M_{24} \\ M_{31} & M_{32} & M_{33} & M_{34} \\ M_{41} & M_{42} & M_{43} & M_{44} \end{bmatrix} \begin{bmatrix} x' \\ y' \\ \alpha' \\ \beta' \end{bmatrix} = \begin{bmatrix} x \\ y \\ \alpha \\ \beta \end{bmatrix}. \quad (9.251)$$

This expression still assumes shift-invariance, and it applies only to paraxial rays, but it does not require separability in x and y .

It is convenient to define a 2×1 vector $\mathbf{r} = (x, y)^t$ (which is just our usual 2D position vector written in column-vector form) and similarly to define a 2×1 vector of direction cosines by $\boldsymbol{\theta} = (\alpha, \beta)^t$. With this notation, (9.251) can be written in the form

$$\begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix} \begin{bmatrix} \mathbf{r}' \\ \boldsymbol{\theta}' \end{bmatrix} = \begin{bmatrix} \mathbf{r} \\ \boldsymbol{\theta} \end{bmatrix}, \quad (9.252)$$

where \mathbf{A} , \mathbf{B} , \mathbf{C} and \mathbf{D} are all 2×2 matrices. We shall refer to matrices in this form as **ABCD** matrices rather than *ABCD* matrices.

Note that (9.252) is equivalent to (9.242) (plus the similar equation for the y direction) if $\mathbf{A} = A\mathbf{I}$, and similarly for \mathbf{B} , \mathbf{C} and \mathbf{D} .

Symplectic group Stavroudis (1972) shows that the **ABCD** matrix for all realizable optical systems must satisfy the *symplectic condition*,

$$\mathbf{M}^t \mathbf{J} \mathbf{M} = \mathbf{J}, \quad (9.253)$$

where

$$\mathbf{J} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{bmatrix} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{I} & \mathbf{0} \end{bmatrix}, \quad (9.254)$$

with \mathbf{I} being the 2×2 identity matrix and $\mathbf{0}$ being the 2×2 matrix of all zeros. The importance of the symplectic condition is indicated by the fact that Stavroudis calls it the *lens equation*.

The group of all matrices that satisfy the symplectic condition is called the *symplectic group* and denoted \mathbf{Sp}_2 . All **ABCD** matrices for realizable optical systems are in this group, but the converse does not hold. Since the determinant of a product is the product of the determinants, and since the determinant of \mathbf{J} is 1, it follows from (9.253) that all matrices in the symplectic group have determinant ± 1 , and in fact the plus sign is required for optical systems. Moreover, more than one optical system may have the same symplectic matrix.

Diffraction integral further generalized When the full 4×4 **ABCD** matrix is required rather than two 2×2 *ABCD* matrices, the field propagation from input to output plane is described in the Fresnel approximation by (Siegman, 1986)

$$u_{out}(\mathbf{r}) = -\frac{i}{\lambda \sqrt{\det \mathbf{B}}} \int_{\infty} d^2 r_0 u_{in}(\mathbf{r}_0) \exp \left[\frac{i\pi}{\lambda} (\mathbf{r}_0^t \mathbf{B}^{-1} \mathbf{A} \mathbf{r}_0 + \mathbf{r}^t \mathbf{D} \mathbf{B}^{-1} \mathbf{r} - 2\mathbf{r}_0^t \mathbf{B}^{-1} \mathbf{r}) \right]. \quad (9.255)$$

Note that (9.255) reduces to (9.250) if $\mathbf{A} = A\mathbf{I}$, and similarly for \mathbf{B} , \mathbf{C} and \mathbf{D} .

9.7.4 Random fields and coherence

So far in this chapter we have concentrated on perfectly monochromatic radiation, and we have expressed the scalar optical field at a point specified by the 3D vector \mathbf{r} as $\text{Re}\{u(\mathbf{r}) \exp(-2\pi i \nu_0 t)\}$. For random but narrowband fields, it is natural to write the field as $\text{Re}\{\tilde{u}(\mathbf{r}, t) \exp(-2\pi i \bar{\nu} t)\}$, where $\bar{\nu}$ is the center frequency of the spectral band and $\tilde{u}(\mathbf{r}, t)$ is a random complex amplitude that varies with spatial position and time. If the field is random but not narrowband, it can be written as

the real part of the analytic signal (see Sec. 4.2.4), but there is no loss of generality in writing this signal as $\tilde{u}(\mathbf{r}, t) \exp(2\pi i\bar{\nu}t)$ for some convenient frequency $\bar{\nu}$. In either case, $\tilde{u}(\mathbf{r}, t)$ is a spatio-temporal random process, and we must specify its statistical properties before we can understand how the randomness affects imaging properties. The basics of random processes were presented in Sec. 8.2.

Statistical description of natural light sources For chaotic light sources, such as incandescent bulbs and fluorescent lights, the complex field is a phasor that is randomly oriented in the complex plane. Since all angles in this plane are equally probable,

$$\langle \tilde{u}(\mathbf{r}, t) \rangle = 0. \quad (9.256)$$

The angular brackets here denote an ensemble average, but the assumption of ergodicity (see Sec. 8.2.5) allows us to interpret them as time averages as well. If the light were perfectly monochromatic, $\tilde{u}(\mathbf{r}, t)$ would be independent of t and the time average would not be zero, but for chaotic light with a finite spectral bandwidth, the random time-varying phase of $\tilde{u}(\mathbf{r}, t)$ makes the complex field average to zero.

The complex spatio-temporal autocorrelation function of this random process is defined by

$$R_{\tilde{u}}(\mathbf{r}, t; \mathbf{r}', t') \equiv \langle \tilde{u}(\mathbf{r}, t) \tilde{u}^*(\mathbf{r}', t') \rangle. \quad (9.257)$$

It is often useful to assume that the process is temporally stationary (though not necessarily spatially stationary), so that $R_{\tilde{u}}(\mathbf{r}, t; \mathbf{r}', t')$ is a function of $t - t'$ and not t and t' individually. This assumption will be valid if parameters of the light source, such as the temperature of a blackbody radiator, are not themselves functions of time. Under this assumption, we define the *mutual coherence function* $\Gamma(\mathbf{r}, \mathbf{r}', \tau)$ as

$$\Gamma(\mathbf{r}, \mathbf{r}', \tau) \equiv R_{\tilde{u}}(\mathbf{r}, t + \tau; \mathbf{r}', t) = \langle \tilde{u}(\mathbf{r}, t + \tau) \tilde{u}^*(\mathbf{r}', t) \rangle. \quad (9.258)$$

A common alternative notation is $\Gamma_{12}(\tau) \equiv \Gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)$, but in imaging applications it is convenient to show the spatial variables explicitly. Note that we define $\Gamma(\mathbf{r}, \mathbf{r}', \tau)$ as the autocorrelation of the envelope $\tilde{u}(\mathbf{r}, t)$ rather than the total complex field $u(\mathbf{r}, t)$; the latter definition is more common in the literature but ours avoids uninteresting factors of $\exp(-2\pi i\bar{\nu}t)$ when we consider narrowband light, and it entails no loss of generality in the broadband case.

Coherence as interferability A normalized version of $\Gamma(\mathbf{r}, \mathbf{r}', \tau)$, called the *complex degree of coherence*, is defined by

$$\gamma(\mathbf{r}, \mathbf{r}', \tau) \equiv \frac{\Gamma(\mathbf{r}, \mathbf{r}', \tau)}{\sqrt{\langle |\tilde{u}(\mathbf{r}, t)|^2 \rangle \langle |\tilde{u}(\mathbf{r}', t)|^2 \rangle}}. \quad (9.259)$$

The complex degree of coherence tells us the degree to which light from the space-time point (\mathbf{r}, t) is capable of interfering with light from point (\mathbf{r}', t') . An interferometer is basically a device for bringing together light from these two points and superimposing them at a third space-time point (\mathbf{r}'', t'') . When we do so, $|\gamma(\mathbf{r}, \mathbf{r}', t - t')|$ gives the relative strength of the interference term, and the phase tells us about the position of the fringes.

As a simple example, consider the double-pinhole experiment shown in Fig. 9.19. Two identical small pinholes at points \mathbf{r} and \mathbf{r}' are illuminated by a field of arbitrary coherence. The irradiance distribution on an observation screen will show

interference fringes if the light arriving there from the two pinholes is capable of interfering.

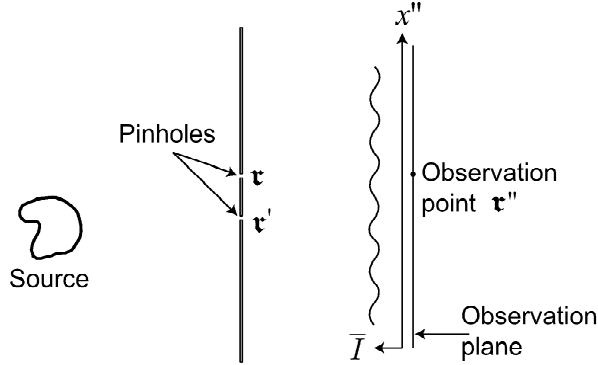

Fig. 9.19 Double-pinhole experiment for measuring the complex degree of coherence.

If we denote the complex field on the screen at (\mathbf{r}'', t'') resulting from light coming through pinhole 1 as $u_1(\mathbf{r}'', t'')$, and similarly for light from pinhole 2, then the time-averaged mean irradiance at \mathbf{r}'' is given by

$$\begin{aligned} \bar{I}(\mathbf{r}'') &= \langle |u_1(\mathbf{r}'', t'') + u_2(\mathbf{r}'', t'')|^2 \rangle \\ &= \langle |u_1(\mathbf{r}'', t'')|^2 \rangle + \langle |u_2(\mathbf{r}'', t'')|^2 \rangle + 2 \operatorname{Re} \langle u_1(\mathbf{r}'', t'') u_2^*(\mathbf{r}'', t'') \rangle. \end{aligned} \quad (9.260)$$

If we think of the pinholes as effective sources, we know from (9.66) that the field at the observation point is determined by the field at the pinhole at a retarded time, so $u_1(\mathbf{r}'', t'') \propto u\left(\mathbf{r}, t'' - \frac{|\mathbf{r}'' - \mathbf{r}|}{c}\right)$. A similar expression holds for $u_2(\mathbf{r}'', t'')$, and we can write

$$\frac{\langle u_1(\mathbf{r}'', t'') u_2^*(\mathbf{r}'', t'') \rangle}{\sqrt{\bar{I}_1(\mathbf{r}'') \bar{I}_2(\mathbf{r}'')}} = \frac{\langle u\left(\mathbf{r}, t'' - \frac{|\mathbf{r}'' - \mathbf{r}|}{c}\right) u^*\left(\mathbf{r}', t'' - \frac{|\mathbf{r}'' - \mathbf{r}'|}{c}\right) \rangle}{\sqrt{\bar{I}(\mathbf{r}) \bar{I}(\mathbf{r}')}}, \quad (9.261)$$

where all factors of proportionality have been normalized away. (Note carefully that $\bar{I}(\mathbf{r})$ is the mean irradiance emerging from the pinhole at \mathbf{r} , while $\bar{I}_1(\mathbf{r}'') \equiv \langle |u_1(\mathbf{r}'', t'')|^2 \rangle$ is the mean irradiance that would appear at the observation point if that pinhole alone were open.)

Since $u(\mathbf{r}, t) = \tilde{u}(\mathbf{r}, t) \exp(-2\pi i \bar{\nu} t)$, the right-hand side of (9.261) simplifies to

$$\frac{\langle u\left(\mathbf{r}, t'' - \frac{|\mathbf{r}'' - \mathbf{r}|}{c}\right) u^*\left(\mathbf{r}', t'' - \frac{|\mathbf{r}'' - \mathbf{r}'|}{c}\right) \rangle}{\sqrt{\bar{I}(\mathbf{r}) \bar{I}(\mathbf{r}')}} = \gamma(\mathbf{r}, \mathbf{r}', \tau) \exp(-2\pi i \bar{\nu} \tau), \quad (9.262)$$

where we have invoked temporal stationarity and defined

$$\tau = \frac{1}{c} |\mathbf{r}'' - \mathbf{r}'| - \frac{1}{c} |\mathbf{r}'' - \mathbf{r}|. \quad (9.263)$$

Thus τ is the difference in propagation times from the two pinholes to the observation point.

If we write $\gamma(\mathbf{r}, \mathbf{r}', \tau)$ as $|\gamma(\mathbf{r}, \mathbf{r}', \tau)| \exp[i\Phi_\gamma(\mathbf{r}, \mathbf{r}', \tau)]$, we obtain

$$\bar{I}(\mathbf{r}'') = \bar{I}_1(\mathbf{r}'') + \bar{I}_2(\mathbf{r}'') + 2|\gamma(\mathbf{r}, \mathbf{r}', \tau)| \sqrt{\bar{I}_1(\mathbf{r}'') \bar{I}_2(\mathbf{r}'')} \cos[2\pi\bar{\nu}\tau - \Phi_\gamma(\mathbf{r}, \mathbf{r}', \tau)]. \quad (9.264)$$

Though it is hidden somewhat by our notation, τ is a function of the observation point \mathbf{r}'' as well as the pinhole locations \mathbf{r} and \mathbf{r}' . For fixed pinholes, the dependence of τ on \mathbf{r}'' makes the cosine a spatially oscillating function on the observation plane, *i.e.*, a fringe pattern. The modulation of these fringes is reduced by the factor $|\gamma(\mathbf{r}, \mathbf{r}', \tau)|$, and the fringes are shifted by $\Phi_\gamma(\mathbf{r}, \mathbf{r}', \tau)$ from what we would observe in the fully coherent case of $\gamma(\mathbf{r}, \mathbf{r}', \tau) = 1$. Thus the modulus of the complex degree of coherence tells us the fringe visibility, and the phase gives us fringe position.

We have carried along the arguments in $\gamma(\mathbf{r}, \mathbf{r}', \tau)$ to emphasize that it refers to the coherence between the fields at the two pinhole locations. The observation point appears only in that it determines the time delay τ . To probe the dependence of $\gamma(\mathbf{r}, \mathbf{r}', \tau)$ on τ , we could move the point \mathbf{r} laterally as shown in Fig. 9.19 or otherwise introduce a time delay between the two paths, but to probe the dependence on the spatial arguments, we have to move the pinholes.

Summary measures of temporal and spatial coherence The state of coherence of a radiation field is fully specified by the complex degree of coherence $\gamma(\mathbf{r}, \mathbf{r}', \tau)$, a function of seven variables in all. It is often useful to summarize this complicated function by one or two scalar measures, much as we summarize a point response function by some measure of its width (see Sec. 7.2.1).

If we adopt a measure of width, such as full width at half maximum, then the width of a plot of $\gamma(\mathbf{r}, \mathbf{r}', \tau)$ vs. τ will be called the *coherence time* and denoted τ_c . The distance $c\tau_c$, where c is the speed of light, is the *coherence length*. For natural light sources τ_c is approximately the reciprocal of the spectral bandwidth $\Delta\nu$ of the light, so we can control τ_c simply by using narrowband spectral filters to control the bandwidth of the light.

If τ_c is long compared to any relevant time *differences* in a problem, the light is said to be *quasimonochromatic*. In an interferometer, for example, two beams may travel along different paths, requiring different propagation times. If the difference in path lengths is small compared to the coherence length (or, equivalently, the difference in propagation times is small compared to the coherence time), the light can be treated as if it were monochromatic. The implications of this condition for imaging will be taken up in Sec. 9.7.5.

For temporally stationary light, the mutual coherence function at equal time ($\tau = 0$) will be denoted

$$\Gamma(\mathbf{r}, \mathbf{r}') \equiv \Gamma(\mathbf{r}, \mathbf{r}', 0). \quad (9.265)$$

This quantity is referred to variously as the *spatial coherence function*, the *mutual intensity* or the *mutual optical intensity*. Since the word *intensity* has a different meaning in radiometry (see Sec. 10.2), we shall adopt the first of these designations.

The mean irradiance of the field at point \mathbf{r} , denoted $\bar{I}(\mathbf{r})$, is related to the spatial coherence function by

$$\bar{I}(\mathbf{r}) = \langle |\tilde{u}(\mathbf{r}, t)|^2 \rangle = \Gamma(\mathbf{r}, \mathbf{r}). \quad (9.266)$$

The complex degree of coherence at $\tau = 0$ is given by

$$\gamma(\mathbf{r}, \mathbf{r}') \equiv \frac{\Gamma(\mathbf{r}, \mathbf{r}')}{\sqrt{\Gamma(\mathbf{r}, \mathbf{r})\Gamma(\mathbf{r}', \mathbf{r}')}} = \frac{\Gamma(\mathbf{r}, \mathbf{r}')}{\sqrt{I(\mathbf{r})I(\mathbf{r}')}}. \quad (9.267)$$

From (9.258) and (9.259), we see that

$$\gamma(\mathbf{r}, \mathbf{r}) = 1. \quad (9.268)$$

Any of the resolution measures discussed in Sec. 7.2.1 can be used to specify the width of $\gamma(\mathbf{r}, \mathbf{r}')$ or $\Gamma(\mathbf{r}, \mathbf{r}')$. Without attempting to be very precise at this stage, we shall denote this width as L_c and refer to it as the *correlation length* (not to be confused with the coherence length defined above).

An incoherent assumption For many natural light sources, $\gamma(\mathbf{r}, \mathbf{r}')$ is a sharply peaked function of $\mathbf{r} - \mathbf{r}'$, and it is convenient mathematically to approximate it with a delta function. When this approximation is valid, we refer to the field as *spatially incoherent*, or *incoherent* for short. Conversely, if $\gamma(\mathbf{r}, \mathbf{r}') \approx 1$ for two points of interest, then the field is said to be spatially coherent between these points.

In many imaging applications, we are interested in the case where \mathbf{r} and \mathbf{r}' lie on a specified plane. If, as usual, we call that plane $z = 0$, then we can characterize the field by the function $\gamma(\mathbf{r}, \mathbf{r}')$, where \mathbf{r} and \mathbf{r}' are 2D vectors. Then the incoherent-field approximation is

$$\gamma(\mathbf{r}, \mathbf{r}') \approx A_c \delta(\mathbf{r} - \mathbf{r}'), \quad (9.269)$$

where A_c is a constant with units of area needed for dimensional consistency and proper normalization. We shall refer to A_c as the *coherence area*. Roughly speaking, $A_c \approx L_c^2$, but the exact relation depends on the particular definition of L_c and the functional form of $\gamma(\mathbf{r}, \mathbf{r}')$.

Note that (9.269) does not satisfy (9.268), so it cannot be interpreted pointwise; instead, (9.269) makes sense only when it is used in an integral where the other factors in the integrand are slowly varying in comparison to $\gamma(\mathbf{r}, \mathbf{r}')$.

The closest we can come to justifying (9.269) is with *Lambertian sources* (see Sec. 10.2.1), of which blackbodies are an important example. As we shall see in Sec. 10.2.7, $\gamma(\mathbf{r}, \mathbf{r}') = \sin(k|\mathbf{r} - \mathbf{r}'|)/(k|\mathbf{r} - \mathbf{r}'|)$ for a quasimonochromatic Lambertian. In this expression, $k = 2\pi/\lambda$, so $\gamma(\mathbf{r}, \mathbf{r}')$ has a width (peak to first zero) of $\lambda/2$. If $\lambda/2$ is small compared to the width of the system PSF, then it may be valid to approximate the sinc function with a delta function, but the approximation is not entirely justified with high-resolution imaging systems that can resolve details on the order of a wavelength. For further discussion, see Sec. 9.7.7.

9.7.5 Quasimonochromatic imaging

In Sec. 9.7.4, we presented the vocabulary needed for discussing spatial and temporal coherence, and we introduced two useful single-parameter descriptions needed to speak in qualitative terms about degree of coherence. For spatial coherence, the relevant parameter is the correlation length L_c , and for temporal coherence the parameter is the coherence time τ_c or the coherence length $c\tau_c$. We noted that τ_c is approximately the reciprocal of the spectral bandwidth $\Delta\nu$.

A common situation in imaging is when τ_c is relatively long, in a sense to be defined below, but L_c is very short. When both of these conditions are satisfied for the field emerging from the source, it is common in the literature to speak of *quasimonochromatic, incoherent imaging*, but this terminology is potentially confusing. When the word *incoherent* is used without a clarifying modifier, it usually refers to spatial coherence, and that is the only possible interpretation if the modifier *quasimonochromatic* is included; a nearly monochromatic source has a small spectral bandwidth, hence a large coherence time, and is essentially coherent in a temporal sense whatever its spatial properties.

In this section we shall discuss the effects on imaging systems of using light with a small but finite spectral bandwidth without making any assumptions about spatial coherence. In Sec. 9.7.5, we shall add the assumption that the source is spatially incoherent as well as quasimonochromatic. Later, in Secs. 9.7.6 and 9.7.7, we shall return to polychromatic imaging and partial spatial coherence.

Temporal Fourier analysis In Sec. 9.7.1 we discussed coherent, monochromatic imaging by a simple lens, and in Sec. 9.7.2 we extended the discussion to a $4f$ system. For a nonmonochromatic light source we can perform a temporal Fourier analysis to resolve the object field into monochromatic components, and each component can be analyzed by the formalism we have developed. Linear superposition then yields the total image field.

Recalling from Sec. 9.1.2 that the usual Fourier sign convention is reversed for temporal transforms, we represent a general object field $u_{obj}(\mathbf{r}, t)$ as¹⁶

$$u_{obj}(\mathbf{r}, t) = \int_{-\infty}^{\infty} d\nu U_{obj}(\mathbf{r}, \nu) \exp(-2\pi i\nu t). \quad (9.270)$$

For narrowband light, $U_{obj}(\mathbf{r}, \nu)$ will be appreciable only for ν in the vicinity of some center frequency $\bar{\nu}$.

After rescaling to account for magnification, we can write the image field as

$$u_{im}^{(s)}(\mathbf{r}, t) = \int_{-\infty}^{\infty} d\nu \exp(-2\pi i\nu t) \int_{\infty} d^2r_0 U_{obj}(\mathbf{r}_0, \nu) p_{coh}(\mathbf{r} - \mathbf{r}_0; \mathbf{r}_0; \nu), \quad (9.271)$$

where we have added an argument ν to the coherent point response function since it can depend on frequency. For all systems we have studied thus far, this PRF has the form [cf. (9.227)]

$$p_{coh}(\mathbf{r} - \mathbf{r}_0; \mathbf{r}_0; \nu) = \frac{1}{\lambda^2 q p} \exp[ikw(\mathbf{r}, \mathbf{r}_0)] \left| T_{pupil} \left(\frac{m}{\lambda q} (\mathbf{r} - \mathbf{r}_0); \mathbf{r}_0 \right) \right|, \quad (9.272)$$

where $\exp[ikw(\mathbf{r}, \mathbf{r}_0)]$ accounts for the phase of T_{pupil} as well as various phase factors that we somewhat cavalierly dropped in the monochromatic case. For the ideal $4f$ system, for example, $w(\mathbf{r}, \mathbf{r}_0) = 4f$, but for a simple lens $w(\mathbf{r}, \mathbf{r}_0)$ also includes terms quadratic in r and r_0 , even if there are no aberrations.

The frequency dependence is hidden in several places in (9.272); the wave-number k is given by $2\pi\nu/c$ and the wavelength λ is c/ν . (Note that c rather than

¹⁶Do not confuse $U_{obj}(\mathbf{r}, \nu)$ with $U_{obj}(\boldsymbol{\rho})$ used earlier; the former is a temporal Fourier transform of the object field, the latter a spatial transform.

c_m appears here since we assume that the object and image planes are in air, where c_m is the same as c to an excellent approximation.) In the quasimonochromatic approximation, we replace ν with $\bar{\nu}$ (or equivalently, λ with $\bar{\lambda}$) in the constant in front of the integral and in the scale factor in the argument of $|T_{pupil}|$. In the factor $\exp[i\bar{k}w(\mathbf{r}, \mathbf{r}_0)]$, however, we must retain the original form since $w(\mathbf{r}, \mathbf{r}_0)$ may vary by several wavelengths as \mathbf{r} and \mathbf{r}_0 vary. With (9.271) and (9.272), we then obtain

$$u_{im}^{(s)}(\mathbf{r}, t) = \frac{m}{\bar{\lambda}^2 qp} \int_{-\infty}^{\infty} d\nu \exp(-2\pi i\nu t) \int_{\infty}^{\infty} d^2r_0 U_{obj}(\mathbf{r}_0, \nu) \times \exp\left(2\pi i\nu \frac{w(\mathbf{r}, \mathbf{r}_0)}{c}\right) \left| T_{pupil}\left(\frac{m}{\bar{\lambda}q}(\mathbf{r} - \mathbf{r}_0); \mathbf{r}_0\right) \right|. \quad (9.273)$$

The integral over ν is an inverse Fourier transform of $U_{obj}(\mathbf{r}_0, \nu)$ with a shift:

$$\int_{-\infty}^{\infty} d\nu \exp(-2\pi i\nu t) U_{obj}(\mathbf{r}_0, \nu) \exp\left(2\pi i\nu \frac{w(\mathbf{r}, \mathbf{r}_0)}{c}\right) = u_{obj}\left(\mathbf{r}_0, t - \frac{w(\mathbf{r}, \mathbf{r}_0)}{c}\right), \quad (9.274)$$

so

$$u_{im}^{(s)}(\mathbf{r}, t) = \frac{m}{\bar{\lambda}^2 qp} \int_{\infty}^{\infty} d^2r_0 u_{obj}\left(\mathbf{r}_0, t - \frac{w(\mathbf{r}, \mathbf{r}_0)}{c}\right) \left| T_{pupil}\left(\frac{m}{\bar{\lambda}q}(\mathbf{r} - \mathbf{r}_0); \mathbf{r}_0\right) \right|. \quad (9.275)$$

As in Sec. 9.7.4, we can write the general object field $u_{obj}(\mathbf{r}_0, t)$ as the product $\tilde{u}_{obj}(\mathbf{r}, t) \exp(2\pi i\bar{\nu}t)$, where the envelope $\tilde{u}(\mathbf{r}, t)$ is slowly varying for narrowband light. With a similar representation for the scaled image field, (9.275) becomes

$$\tilde{u}_{im}^{(s)}(\mathbf{r}, t) = \frac{m}{\bar{\lambda}^2 qp} \int_{\infty}^{\infty} d^2r_0 \tilde{u}_{obj}\left(\mathbf{r}_0, t - \frac{w(\mathbf{r}, \mathbf{r}_0)}{c}\right) \times \exp[i\bar{k}w(\mathbf{r}, \mathbf{r}_0)] \left| T_{pupil}\left(\frac{m}{\bar{\lambda}q}(\mathbf{r} - \mathbf{r}_0); \mathbf{r}_0\right) \right|, \quad (9.276)$$

where $\bar{k} = 2\pi\bar{\nu}/c$, and a common factor of $\exp(2\pi i\bar{\nu}t)$ on both sides has been cancelled. From (9.272), we recognize the product of the last two factors in the integrand as the coherent PRF at the mean frequency, yielding finally,

$$\tilde{u}_{im}^{(s)}(\mathbf{r}, t) = \int_{\infty}^{\infty} d^2r_0 \tilde{u}_{obj}\left(\mathbf{r}_0, t - \frac{w(\mathbf{r}, \mathbf{r}_0)}{c}\right) p_{coh}(\mathbf{r} - \mathbf{r}_0; \mathbf{r}_0; \bar{\nu}). \quad (9.277)$$

Optical path retard Equations (9.276) and (9.277) are reminiscent of (9.66), where the field at an observation point at time t is related to the source at other points at the retarded time $t - \tau_p$, where τ_p is a propagation time. In (9.66), however, τ_p is the straight-line distance R from source point to observation point divided by the speed of light in the medium, c_m . Since $c_m = c/n$, where n is the refractive index, τ_p is also the optical path nR divided by c .

The simple identification of an optical path in (9.66) came about because the system to which that equation applies was just a homogeneous medium. The discussion leading up to (9.276) and (9.277), however, allowed a rather complicated optical system, with inhomogeneous index distributions (*i.e.*, lenses) interposed between regions of free-space propagation. Nevertheless, we are able to identify an

optical path from \mathbf{r}_0 to \mathbf{r} without appealing to Fermat's principle or any other construct from geometrical optics. Any time we can write the monochromatic coherent PRF in the form $\exp[2\pi i\nu w(\mathbf{r}, \mathbf{r}_0)/c]$ times a slowly varying function of ν , we obtain a retarded-time expression with the phase delay τ_p given by the coefficient of $2\pi i\nu$ in the phase, and we can define $c\tau_p$ as the optical path. In this way we can define optical path in a physical-optics framework without having to say that the light *follows* that path (which, of course, waves are reluctant to do).

How nearly monochromatic is quasi? From (9.277), we see that light emitted from a particular source point \mathbf{r}_0 arrives at the image point \mathbf{r} after a time delay $\tau_p(\mathbf{r}, \mathbf{r}_0) = w(\mathbf{r}, \mathbf{r}_0)/c$. In the fully monochromatic case, this delay did not appear (mainly because we consistently dropped phase factors). The remaining question is: When are we justified in ignoring this delay, or equivalently, when can we drop the phase factors that give rise to the delay?

To answer this question, recall that we always observe the mean image irradiance, given by

$$\bar{I}_{im}^{(s)}(\mathbf{r}) = \left\langle \left[\tilde{u}_{im}^{(s)}(\mathbf{r}) \right] \left[\tilde{u}_{im}^{(s)}(\mathbf{r}) \right]^* \right\rangle. \quad (9.278)$$

Inserting (9.277) for each appearance of $\tilde{u}_{im}^{(s)}$ (with a different dummy variable for each integral), we obtain

$$\begin{aligned} \bar{I}_{im}^{(s)}(\mathbf{r}) = & \left\langle \int_{\infty} d^2 r' \tilde{u}_{obj}[\mathbf{r}', t - \tau_p(\mathbf{r}, \mathbf{r}')] p_{coh}(\mathbf{r} - \mathbf{r}'; \mathbf{r}'; \bar{\nu}) \right. \\ & \left. \cdot \int_{\infty} d^2 r'' \tilde{u}_{obj}^*[\mathbf{r}'', t - \tau_p(\mathbf{r}, \mathbf{r}'')] p_{coh}^*(\mathbf{r} - \mathbf{r}''; \mathbf{r}''; \bar{\nu}) \right\rangle. \end{aligned} \quad (9.279)$$

Under broad conditions discussed in Sec. 8.2.2, it is valid to interchange the order of integration and statistical averaging, which yields

$$\begin{aligned} \bar{I}_{im}^{(s)}(\mathbf{r}) = & \int_{\infty} d^2 r' \int_{\infty} d^2 r'' \langle \tilde{u}_{obj}[\mathbf{r}', t - \tau_p(\mathbf{r}, \mathbf{r}')] \tilde{u}_{obj}^*[\mathbf{r}'', t - \tau_p(\mathbf{r}, \mathbf{r}'')] \rangle \\ & \times p_{coh}(\mathbf{r} - \mathbf{r}'; \mathbf{r}'; \bar{\nu}) p_{coh}^*(\mathbf{r} - \mathbf{r}''; \mathbf{r}''; \bar{\nu}). \end{aligned} \quad (9.280)$$

The average is now recognized as the spatio-temporal autocorrelation function of the object field as defined in (9.257). Under the assumption of temporal stationarity, this autocorrelation function reduces to the mutual coherence function defined in (9.258), and we have

$$\langle \tilde{u}_{obj}[\mathbf{r}', t - \tau_p(\mathbf{r}, \mathbf{r}')] \tilde{u}_{obj}^*[\mathbf{r}'', t - \tau_p(\mathbf{r}, \mathbf{r}'')] \rangle = \Gamma_{obj}[\mathbf{r}', \mathbf{r}'', \Delta\tau(\mathbf{r}, \mathbf{r}', \mathbf{r}'')], \quad (9.281)$$

where $\Delta\tau(\mathbf{r}, \mathbf{r}', \mathbf{r}'')$ is the difference in propagation delays to point \mathbf{r} from points \mathbf{r}' and \mathbf{r}'' , that is,

$$\Delta\tau(\mathbf{r}, \mathbf{r}', \mathbf{r}'') = \tau_p(\mathbf{r}, \mathbf{r}') - \tau_p(\mathbf{r}, \mathbf{r}''). \quad (9.282)$$

In principle, this difference in delays could be arbitrarily large since \mathbf{r} and \mathbf{r}' range independently over the infinite plane. Remember, however, that we are considering an imaging system, where a design goal is to make the PRF spatially compact. If we achieve this goal to any reasonable degree, then $p_{coh}(\mathbf{r} - \mathbf{r}'; \mathbf{r}'; \bar{\nu})$ is zero if \mathbf{r} is more than a resolution length from \mathbf{r}' , and similarly $p_{coh}(\mathbf{r} - \mathbf{r}''; \mathbf{r}''; \bar{\nu})$ is zero unless \mathbf{r} is near \mathbf{r}'' in this sense. One should not jump to the conclusion that the

propagation delays themselves are small, since the point referred to as \mathbf{r} is actually quite far from the one referred to as \mathbf{r}' , even if the 2D vectors \mathbf{r} and \mathbf{r}' are exactly equal; these vectors refer to physical points in different planes. Nevertheless, the condition that \mathbf{r}' and \mathbf{r}'' are both close to \mathbf{r} (in a 2D sense) *does* mean that the two physical points are close together three-dimensionally since \mathbf{r}' and \mathbf{r}'' are in the *same* plane, namely, the object plane.

Thus the very fact that we are dealing with an imaging system will tend to make $\Delta\tau(\mathbf{r}, \mathbf{r}', \mathbf{r}'')$ small. The essence of the quasimonochromatic approximation is that this difference in delays is so small that we can replace $\Gamma_{obj}[\mathbf{r}', \mathbf{r}'', \Delta\tau(\mathbf{r}, \mathbf{r}', \mathbf{r}'')]$ with $\Gamma_{obj}(\mathbf{r}', \mathbf{r}'', 0)$, which is the spatial coherence function $\Gamma_{obj}(\mathbf{r}', \mathbf{r}'')$. We can do this with negligible error if $\Delta\tau(\mathbf{r}, \mathbf{r}', \mathbf{r}'') \ll \tau_c$, where τ_c is the coherence time, for all points \mathbf{r}' and \mathbf{r}'' that contribute to the image at point \mathbf{r} . We know from Sec. 9.7.4 that τ_c is approximately $1/\Delta\nu$, where $\Delta\nu$ is the spectral bandwidth of the light, so a sufficiently narrowband source will always allow us to make this approximation.

When the spectral bandwidth is small enough, we can write the image irradiance as

$$\begin{aligned} \bar{I}_{im}^{(s)}(\mathbf{r}) &= \int_{\infty} d^2r' \int_{\infty} d^2r'' \Gamma_{obj}(\mathbf{r}'; \mathbf{r}'') p_{coh}^*(\mathbf{r} - \mathbf{r}'; \mathbf{r}'; \bar{\nu}) p_{coh}(\mathbf{r} - \mathbf{r}''; \mathbf{r}''; \bar{\nu}) \\ &= \int_{\infty} d^2r' \int_{\infty} d^2r'' \gamma_{obj}(\mathbf{r}'; \mathbf{r}'') \sqrt{\bar{I}_{obj}(\mathbf{r}') \bar{I}_{obj}(\mathbf{r}'')} p_{coh}^*(\mathbf{r} - \mathbf{r}'; \mathbf{r}'; \bar{\nu}) p_{coh}(\mathbf{r} - \mathbf{r}''; \mathbf{r}''; \bar{\nu}), \end{aligned} \quad (9.283)$$

where $\bar{I}_{obj}(\mathbf{r}') \equiv \langle |\tilde{u}_{obj}(\mathbf{r}')|^2 \rangle$.

It would be tempting to refer to $\bar{I}_{obj}(\mathbf{r}')$ as a mean irradiance, since it is defined analogously to $\bar{I}_{im}(\mathbf{r}')$. Both quantities are proportional to an optical power per unit area, but $\bar{I}_{obj}(\mathbf{r}')$ represents power *leaving* the object surface while $\bar{I}_{im}(\mathbf{r}')$ represents power *arriving* at the detector; for this reason $\bar{I}_{obj}(\mathbf{r}')$ is called the mean *radiant exitance*. For more discussion of these quantities, see Chap. 10.

Implications of the general expression (9.283) will be explored further in Sec. 9.7.7, but now we turn to the special case of spatial incoherence.

9.7.6 Spatially incoherent, quasimonochromatic imaging

In Sec. 9.7.4 we defined the complex degree of coherence $\gamma(\mathbf{r}', \mathbf{r}'')$ as a normalized measure of spatial coherence for quasimonochromatic light. In this section we assume that $\gamma(\mathbf{r}', \mathbf{r}'')$ is sharply peaked compared to the width of the coherent PRF, so that we can use the incoherent-object approximation of (9.269), whereby $\gamma(\mathbf{r}', \mathbf{r}'') = A_c \delta(\mathbf{r}' - \mathbf{r}'')$. Inserting this delta function into (9.283) and performing an elementary integral yields

$$\bar{I}_{im}^{(s)}(\mathbf{r}) = A_c \int_{\infty} d^2r' \bar{I}_{obj}(\mathbf{r}') |p_{coh}(\mathbf{r} - \mathbf{r}'; \mathbf{r}'; \bar{\nu})|^2. \quad (9.284)$$

If the system is shift-invariant, $p_{coh}(\mathbf{r} - \mathbf{r}'; \mathbf{r}'; \bar{\nu})$ is a function of $\mathbf{r} - \mathbf{r}'$ only, and we can drop the second spatial argument. Also dropping the frequency argument for simplicity, we write the coherent PSF as just $p_{coh}(\mathbf{r} - \mathbf{r}')$, as we did in the fully monochromatic, shift-invariant case. With this notation, (9.284) reduces to

$$\bar{I}_{im}^{(s)}(\mathbf{r}) = A_c \int_{\infty} d^2r' \bar{I}_{obj}(\mathbf{r}') |p_{coh}(\mathbf{r} - \mathbf{r}')|^2. \quad (9.285)$$

This is a key result; the mean irradiance in the image is proportional to the mean exitance of the incoherent object convolved with the squared modulus of the coherent PSF. We can thus define an incoherent PSF by

$$p_{incoh}(\mathbf{r}) = A_c |p_{coh}(\mathbf{r})|^2 = \frac{A_c}{(\lambda p)^4} \left| T_{pupil} \left(-\frac{\mathbf{r}}{\lambda p} \right) \right|^2, \quad (9.286)$$

where we have used (9.223). With this PSF, we can rewrite (9.285) as

$$\bar{I}_{im}^{(s)}(\mathbf{r}) = \bar{I}_{obj}(\mathbf{r}) * p_{incoh}(\mathbf{r}). \quad (9.287)$$

If aberrations are present, this result, like its coherent counterpart, is valid only if the object is confined to an isoplanatic patch, but (9.284) provides the analogous expression for general shift-variant incoherent imaging. In every case, the incoherent PRF is proportional to the squared modulus of the coherent one if the object is completely spatially incoherent in the sense defined by (9.269).

The important conclusion from this discussion is that linear superposition is still valid in incoherent imaging if we take the input as the radiant exitance of the object and the output as the image-plane irradiance.

Optical transfer function A linear, shift-invariant system can be specified by its transfer function as well as by its PSF. In the case of shift-invariant incoherent imaging, the transfer function is the Fourier transform of the incoherent PSF, given by

$$P_{incoh}(\boldsymbol{\rho}) = \mathcal{F}_2\{p_{incoh}(\mathbf{r})\} = A_c \mathcal{F}_2\{|p_{coh}(\mathbf{r})|^2\}. \quad (9.288)$$

From (9.288), (9.222) and (3.245), we have

$$P_{incoh}(\boldsymbol{\rho}) = \frac{A_c}{(\lambda p)^2} [t_{pupil} \star t_{pupil}^*](\lambda p \boldsymbol{\rho}), \quad (9.289)$$

where \star denotes correlation. Thus *the incoherent transfer function is a scaled version of the complex autocorrelation of the pupil function.*

Since the support of the autocorrelation of a function is twice as large (in linear dimension) as the support of the function itself, the spatial-frequency cutoff of the incoherent transfer function is twice that of the coherent transfer function.

It is often convenient to normalize the transfer function $P_{incoh}(\boldsymbol{\rho})$ to its value at $\boldsymbol{\rho} = 0$. We define the *optical transfer function* or *OTF* by

$$\text{OTF}(\boldsymbol{\rho}) = \frac{P_{incoh}(\boldsymbol{\rho})}{P_{incoh}(0)} = \frac{[t_{pupil} \star t_{pupil}^*](\lambda p \boldsymbol{\rho})}{[t_{pupil} \star t_{pupil}^*](0)}. \quad (9.290)$$

The modulation transfer function or MTF is the modulus of the OTF. (See Sec. 7.2.6 for a discussion of the significance of the MTF.) For incoherent imaging systems, the MTF is related to the pupil function by

$$\text{MTF}(\boldsymbol{\rho}) = |\text{OTF}(\boldsymbol{\rho})| = \frac{|P_{incoh}(\boldsymbol{\rho})|}{P_{incoh}(0)}. \quad (9.291)$$

Note that it is not necessary to write $|P_{incoh}(0)|$ in the denominator since $P_{incoh}(0)$ is necessarily real. Fig. 9.20 illustrates the PSF and OTF for square and circular apertures.

Fig. 9.20 PSF and OTF for incoherent imaging with square and circular pupils.

Incoherent illumination in a $4f$ system To gain more insight into the statement that the incoherent transfer function is the autocorrelation of the pupil function, we shall revisit the $4f$ system introduced in Sec. 9.7.2. In that section, we assumed that the object transparency was illuminated by a monochromatic plane wave, but we did not say where the plane wave came from. We can create a good approximation to a plane wave by placing a point source in the back focal plane of a condenser lens, as shown in Fig. 9.21a. This setup fits the analysis of Sec. 9.7.2. In the language of coherence theory, the mutual coherence function of the field incident on the object transparency is, to a good approximation, a constant. The system then performs a linear mapping from the object field to the image field, which is what we mean by coherent imaging.

To convert the system into an incoherent one, we can replace the point source by an extended incoherent source as shown in Fig. 9.21b. As seen from Fig. 9.21c, each point on the source produces a plane wave, so the illumination incident on the object transparency consists of many plane waves with random phases. Because different source points radiate independently, the mean irradiance in the image arising from many source points is the sum of the irradiances from the points individually; interference terms average to zero. To compute the total image irradiance, we simply compute it for a single source point and then integrate over the source.

The Fresnel-diffraction analysis presented in Sec. 9.7.2 shows that the field incident on the object is the Fourier transform of the instantaneous field in the object plane, at least to the extent that diffraction from the lens aperture can be neglected. It follows from (9.237) that a point source at \mathbf{r}_s produces a plane wave with amplitude proportional to $\exp(-2\pi i \mathbf{r} \cdot \mathbf{r}_s / \lambda f)$ at point \mathbf{r} in the object plane. This plane wave is multiplied by the object transmittance $t_{obj}(\mathbf{r})$ to produce the field $u_{0+}(\mathbf{r})$ presented to the $4f$ system. The field in the Fourier plane ($z = 2f$) is then proportional to

$$\mathcal{F}_2 \left\{ \exp \left(-2\pi i \frac{\mathbf{r} \cdot \mathbf{r}_s}{\lambda f} \right) t_{obj}(\mathbf{r}) \right\} = T_{obj} \left(\boldsymbol{\rho} + \frac{\mathbf{r}_s}{\lambda f} \right). \quad (9.292)$$

Fig. 9.21 Extension of the diagram of Fig. 9.17, showing the light source explicitly. (a) Illumination with a plane wave created by an on-axis point source and a condenser lens. (b) Illumination with an extended incoherent source. (c) Illumination with a tilted plane wave created by an off-axis point source, which might be one point on the extended source.

Thus the field in the Fourier plane is the Fourier transform of the object shifted laterally by an amount determined by the location of the source point. Mathematically, this result comes from the shift theorem of Fourier analysis, (3.237). Physically, it means that the object Fourier transform is centered on the image of the source point.

Another way to state this conclusion is that the coherent transfer function for a single source point at \mathbf{r}_s is given by

$$P_{coh}(\boldsymbol{\rho}; \mathbf{r}_s) = t_{pupil}(\lambda f \boldsymbol{\rho} + \mathbf{r}_s). \quad (9.293)$$

A formal way of proceeding from here would be to use this transfer function to filter the object field distribution, take the squared modulus to get the contribution from source point \mathbf{r}_s to the image irradiance and then integrate this result over \mathbf{r}_s . As the reader may demonstrate, this procedure would reproduce our previous analysis of incoherent imaging. Perhaps more insight will be obtained, however, if we consider the effect of this procedure on a particular object.

In Sec. 9.7.2 the test object was one with an amplitude transmittance given by $\exp(2\pi i\xi_0 x)$, but this choice will not work in a discussion of incoherent imaging since $|\exp(2\pi i\xi_0 x)|^2 = 1$, hence no spatial modulation can be seen with incoherent illumination. Instead we choose

$$t_{obj}(\mathbf{r}) = 1 + \exp(2\pi i\xi_0 x) = 1 + \exp(2\pi i\boldsymbol{\rho}_0 \cdot \mathbf{r}), \quad (9.294)$$

where $\boldsymbol{\rho}_0 = (\xi_0, 0)$ for purposes of illustration. An ideal incoherent image of this object would have an image-plane irradiance proportional to

$$|t_{obj}(\mathbf{r})| = 2 + \exp(4\pi i\xi_0 x) + \exp(-4\pi i\xi_0 x) = 2 + 2 \cos(2\boldsymbol{\rho}_0 \cdot \mathbf{r}), \quad (9.295)$$

which is a fringe pattern with 100% modulation and a spatial frequency vector twice that of the amplitude pattern.

The shifted transform in (9.292) is given by

$$T_{obj}\left(\boldsymbol{\rho} + \frac{\mathbf{r}_s}{\lambda f}\right) = \delta\left(\boldsymbol{\rho} + \frac{\mathbf{r}_s}{\lambda f}\right) + \delta\left(\boldsymbol{\rho} - \boldsymbol{\rho}_0 + \frac{\mathbf{r}_s}{\lambda f}\right). \quad (9.296)$$

Hence, for a point source at \mathbf{r}_s , the field distribution in the Fourier plane (immediately before the aperture stop) consists of two spots, one at $\mathbf{r} = -\mathbf{r}_s$ and one at $\mathbf{r} = \boldsymbol{\rho}_0 \lambda f - \mathbf{r}_s$. If only one of these spots passes the stop, it produces an expanding spherical wave which is converted to a plane wave by the final lens. This wave produces a uniform irradiance in the image plane, with no modulation and hence no information about the object.

If both of the spots pass unimpeded through the aperture, however, two plane waves are produced, and the resulting interference pattern has an image irradiance in the ideal form (9.295). Note that this pattern is independent of the source location, so long as both spots get through. The shift $\mathbf{r}_s/\lambda f$ in (9.296) produces a rigid lateral translation of the field pattern in the stop, hence a linear phase factor in its Fourier transform (the image field). This phase factor does not affect the image-plane irradiance.

Now consider an extended incoherent source that is larger than the aperture stop. Each source point produces two spots, and if both get through the aperture they still interfere and produce a fringe pattern; these spots are coherent with each other since they derive from the same source point, even though spots associated with two different source points do not interfere. The overall image irradiance thus contains two contributions, one from source points where both spots get through and one from source points where just one of them does. If we assume that the radiant exitance of the source is spatially uniform, the mean image irradiance has the form

$$\bar{I}_{im}(\mathbf{r}) \propto A_1(\boldsymbol{\rho}_0) + A_2(\boldsymbol{\rho}_0) [2 + 2 \cos(4\pi\boldsymbol{\rho}_0 \cdot \mathbf{r})], \quad (9.297)$$

where $A_1(\boldsymbol{\rho}_0)$ is the source area such that one spot gets through and $A_2(\boldsymbol{\rho}_0)$ is the source area where both do.

Fig. 9.22 Diagrams for the computation of relevant areas of the source. (a) Image of a test object consisting of zero spatial frequency plus a single complex exponential of frequency ξ_0 as in (9.294). The rays are drawn from a single point on the source in such a way that both plane-wave components pass through the pupil. (b) The pupil function as it is imaged in the source plane, plus a replica of the pupil shifted by $\xi_0\lambda f$. For a point on the source in the area marked A_2 , both plane waves pass through the pupil; for points in A_1 only a single wave passes the pupil, and for other source points no light at all passes.

If we consider a square aperture of side L , these areas are easy to compute, especially for our example where $\boldsymbol{\rho}_0$ is directed along the x axis (parallel to a side of the aperture). From Fig. 9.22, we see that

$$A_1(\boldsymbol{\rho}_0) = 2L|\xi_0|\lambda f, \quad A_2(\boldsymbol{\rho}_0) = L(L - |\xi_0|\lambda f), \quad (|\xi_0|\lambda f < L). \quad (9.298)$$

The image irradiance now has the form

$$\bar{I}_{im}(\mathbf{r}) \propto 2L^2 + 2L(L - |\xi_0|\lambda f) \cos(4\pi\xi_0 x). \quad (9.299)$$

From (7.157) we see that this pattern has a modulation given by

$$M_{im} = \frac{L - |\xi_0|\lambda f}{L}, \quad (|\xi_0|\lambda f < L). \quad (9.300)$$

Since the object has 100% modulation, M_{im} is also the system MTF (see Sec. 7.2.6). The MTF thus decreases linearly from unity at $\xi_0 = 0$ to zero at $\xi_0 = \pm L/\lambda f$. Precisely this form will be found by autocorrelating the pupil.

As an exercise, the reader may want to repeat this analysis for $t_{obj}(\mathbf{r}) = \cos(2\pi\xi_0 x)$.

9.7.7 Polychromatic, incoherent imaging

So far we have discussed only monochromatic or quasimonochromatic sources, but the results can be extended to broadband (polychromatic) sources. The key physical intuition is that a wave of temporal frequency ν does not interfere with one of frequency ν' if $\nu \neq \nu'$. There are several ways to justify this point. One way is to consider two plane waves of different frequency superimposed on the surface of some optical detector. The total irradiance is then the sum of the individual irradiances of the plane waves plus an interference term that oscillates at frequency $\nu - \nu'$; if this difference frequency is large compared to the reciprocal of the response time of the detector, its time average is zero and the detector output can be computed without consideration of the interference. This viewpoint is developed more fully in Sec. 10.1.5, where we address the question: What do real detectors detect?

A more formal statistical approach is based on properties of stationary random processes. We showed in Sec. 8.2.5 that the Fourier transform of a stationary random process is a delta-correlated process. That is, if $u(t)$ is a sample function of a temporally stationary random process, and we define its Fourier transform (a generalized function) as

$$U(\nu) = \int_{-\infty}^{\infty} dt u(t) \exp(-2\pi i\nu t), \quad (9.301)$$

then, by the temporal counterpart of (8.181),

$$\langle U(\nu) U^*(\nu') \rangle = S_u(\nu) \delta(\nu - \nu'). \quad (9.302)$$

In this expression, $S_u(\nu)$ is the *power spectral density*, given by the Wiener-Khinchin theorem (8.133) as

$$S_u(\nu) = \int_{-\infty}^{\infty} d\tau \langle u(t + \tau) u^*(t) \rangle \exp(-2\pi i\nu\tau). \quad (9.303)$$

To apply (9.302) to imaging, we must include the spatial variables, replacing the temporal random process $u(t)$ by the spatio-temporal one, $\tilde{u}(\mathbf{r}, t)$. The temporal stationarity leads to an expression analogous to (9.302):

$$\langle \tilde{U}(\mathbf{r}, \nu) \tilde{U}^*(\mathbf{r}', \nu') \rangle = W(\mathbf{r}, \mathbf{r}', \nu) \delta(\nu - \nu'). \quad (9.304)$$

Here, $\tilde{U}(\mathbf{r}, \nu)$ is the temporal Fourier transform of $\tilde{u}(\mathbf{r}, t)$, and $W(\mathbf{r}, \mathbf{r}', \nu)$ is called the *cross-spectral density*; by a generalization of the Wiener-Khinchin theorem, it is given by

$$\begin{aligned} W(\mathbf{r}, \mathbf{r}', \nu) &= \int_{-\infty}^{\infty} d\tau \langle \tilde{u}(\mathbf{r}, t + \tau) \tilde{u}^*(\mathbf{r}', t) \rangle \exp(-2\pi i\nu\tau) \\ &= \int_{-\infty}^{\infty} d\tau \Gamma(\mathbf{r}, \mathbf{r}', \tau) \exp(-2\pi i\nu\tau). \end{aligned} \quad (9.305)$$

We can incorporate the cross-spectral density into our imaging theory by rewriting (9.280) as

$$\begin{aligned} \bar{I}_{im}^{(s)}(\mathbf{r}) = & \int_{-\infty}^{\infty} d^2r' \int_{-\infty}^{\infty} d^2r'' \int_{-\infty}^{\infty} d\nu \int_{-\infty}^{\infty} d\nu' \langle \tilde{U}(\mathbf{r}', \nu) \tilde{U}^*(\mathbf{r}'', \nu') \rangle \exp[2\pi i(\nu - \nu')(t - \tau_p)] \\ & \times p_{coh}^*(\mathbf{r} - \mathbf{r}'; \nu) p_{coh}(\mathbf{r} - \mathbf{r}''; \nu'). \end{aligned} \quad (9.306)$$

As in Sec. 9.7.4, we have added an argument ν to $p_{coh}(\mathbf{r}, \nu)$ since the coherent PSF depends on the wavelength. We have also specialized (9.280) to the spatially stationary case for simplicity.

If we now insert (9.304) (adding a subscript *obj* to denote the object plane) and use the delta function to perform the ν' integral, we obtain

$$\bar{I}_{im}^{(s)}(\mathbf{r}) = \int_{-\infty}^{\infty} d^2r' \int_{-\infty}^{\infty} d^2r'' \int_{-\infty}^{\infty} d\nu W_{obj}(\mathbf{r}', \mathbf{r}'', \nu) [p_{coh}(\mathbf{r} - \mathbf{r}'; \nu)]^* p_{coh}(\mathbf{r} - \mathbf{r}''; \nu). \quad (9.307)$$

This expression is identical to (9.283) except that the cross-spectral density takes the place of the spatial coherence function, and the result is integrated over frequency.

The spatially incoherent limit is obtained by assuming that

$$W_{obj}(\mathbf{r}', \mathbf{r}'', \nu) = A_c \bar{I}_{obj}(\mathbf{r}', \nu) \delta(\mathbf{r}' - \mathbf{r}''), \quad (9.308)$$

where $\bar{I}_{obj}(\mathbf{r}', \nu)$ is called the *spectral radiant exitance* (see Chap. 10). We then have

$$\bar{I}_{im}^{(s)}(\mathbf{r}) = A_c \int_{-\infty}^{\infty} d\nu \int_{-\infty}^{\infty} d^2r' \bar{I}_{obj}(\mathbf{r}', \nu) |p_{coh}(\mathbf{r} - \mathbf{r}'; \nu)|^2. \quad (9.309)$$

Comparison with (9.285) shows that the polychromatic image is obtained merely by integrating the quasimonochromatic one over frequency. This mathematical result codifies the statement made at the beginning of this section that waves of different frequency do not interfere.

9.7.8 Partially coherent imaging

We have studied 2D imaging in the coherent and incoherent limits. In the completely coherent case, the field emerging from the object is essentially nonrandom, so we just calculated the field in the image plane and showed (basically from the linearity of Maxwell's equations) that the system is a linear mapping from the complex object field to the complex image field. As we have noted (and shall show in more detail in Chap. 10), an image detector responds to the time-averaged squared modulus of the complex field, so the overall imaging system, from object field to detector output, is a nonlinear mapping, but linear systems theory is still sufficient for analyzing a coherent imaging system. The detector is a simple point nonlinearity (see Sec. 7.5.1) applied to the output of a linear system.

With real radiation sources, we argued that the object field is a spatio-temporal random process, and some assumptions were needed to make progress on the analysis. In Sec. 9.7.4 we assumed that the field was a stationary random process temporally and that it was quasimonochromatic. With these assumptions, we argued that it was sufficient to consider the equal-time correlation function $\langle \tilde{u}(\mathbf{r}, t) \tilde{u}^*(\mathbf{r}', t) \rangle$,

which is the spatial coherence function $\Gamma(\mathbf{r}, \mathbf{r}')$. The fully incoherent limit corresponds to assuming further that $\Gamma(\mathbf{r}, \mathbf{r}') \propto \delta(\mathbf{r} - \mathbf{r}')$. With that assumption we were able to show that the system is a linear mapping from the object radiant exitance to the image irradiance. Since detectors often respond linearly to irradiance, we then have a linear description of the overall system, now including the detector.

In this section we look briefly at what happens when we consider a temporally stationary, quasimonochromatic source but do not assume that the correlation function is a spatial delta function. There are two main motivations for studying this case. The first is that actual radiation sources are never delta-correlated. As noted in Sec. 9.7.4, Lambertian sources are correlated over about a wavelength, and many high-resolution imaging systems are sensitive to details on this scale.

The second motivation for avoiding the delta-correlated model is that we often want to cascade linear systems. In imaging, the output of one imaging stage is often the input to a second one. Even if we can regard the input to the first stage as delta-correlated, the output of that stage is correlated over a distance comparable to the width of its PSF, so the assumption fails for analyzing the second stage unless it blurs the image much more than the first one does.

Propagation of spatial coherence Consider a quasimonochromatic but not necessarily spatially incoherent source imaged by an arbitrary system with coherent PRF $p_{coh}(\mathbf{r}, \mathbf{r}_0)$. By a straightforward generalization of the algebra that led to (9.283), we find that the spatial coherence function of the field in the image plane is

$$\Gamma_{im}(\mathbf{r}, \mathbf{r}') = \int_{\infty} d^2 r'' \int_{\infty} d^2 r''' \Gamma_{obj}(\mathbf{r}'', \mathbf{r}''') p_{coh}(\mathbf{r}, \mathbf{r}'') p_{coh}^*(\mathbf{r}', \mathbf{r}'''). \quad (9.310)$$

Note that we are not assuming here that the system is shift-invariant, and we are not using scaled variables.

We see from (9.310) that the spatial coherence function is transferred linearly through the system, no matter the functional form of the input. The linear mapping takes place in a 4D space, where one function of two 2D vectors is mapped into another such function. We can then use the output of this mapping, $\Gamma_{im}(\mathbf{r}, \mathbf{r}')$, as the input to a second stage described similarly. If $p_{coh}(\mathbf{r}, \mathbf{r}'')$ is shift invariant in a 2D sense, *i.e.*, $p_{coh}(\mathbf{r}, \mathbf{r}'') = p_{coh}(\mathbf{r} - \mathbf{r}'')$, then the mapping (9.310) is shift invariant in a 4D sense, and cascading of shift-invariant systems involves successive 4D convolutions.

At the end of this process, however, we do not observe $\Gamma_{im}(\mathbf{r}, \mathbf{r}')$; instead, the final detector responds to $\bar{I}_{im}(\mathbf{r})$, which by (9.266) is $\Gamma_{im}(\mathbf{r}, \mathbf{r})$. Moreover, we are rarely interested in the mapping of the spatial coherence function. It is more natural to specify the object in terms of its radiant exitance and the image in terms of irradiance, and this mapping is not linear except in the incoherent limit.

If we know *a priori* the complex degree of coherence in the object, we can cast the mapping from radiant exitance to irradiance into the form of a bilinear transform, as discussed in Sec. 7.5.2. For example, suppose we know that the object is Lambertian so that $\gamma(\mathbf{r}, \mathbf{r}') = \sin(k|\mathbf{r} - \mathbf{r}'|)/(k|\mathbf{r} - \mathbf{r}'|)$ (see Sec. 10.2.7). Then we can write

$$\bar{I}_{im}(\mathbf{r}) = \int_{\infty} d^2 r' \int_{\infty} d^2 r'' \sqrt{\bar{I}_{obj}(\mathbf{r}')} \sqrt{\bar{I}_{obj}(\mathbf{r}'')} \gamma_{obj}(\mathbf{r}', \mathbf{r}'') [p_{coh}(\mathbf{r}, \mathbf{r}')]^* p_{coh}(\mathbf{r}', \mathbf{r}''). \quad (9.311)$$

If we denote $\sqrt{\bar{I}_{obj}(\mathbf{r}')}$ as $f(\mathbf{r}')$ and $\bar{I}_{im}(\mathbf{r})$ as $g(\mathbf{r})$, we see that the form of (9.311) agrees with the general bilinear transform (7.366):

$$g(\mathbf{r}) = \int_{\infty} d^2r' \int_{\infty} d^2r'' f(\mathbf{r}') f(\mathbf{r}'') h(\mathbf{r}; \mathbf{r}', \mathbf{r}''). \quad (9.312)$$

Note that $\gamma_{obj}(\mathbf{r}', \mathbf{r}'')$ is now lumped into the description of the system rather than the object. As with the examples discussed in Sec. 7.5.3, it is not altogether obvious what properties of the thing being imaged should be considered object and what properties are part of the system. The key determinant is what we want to map to the output. In the present discussion, we are not interested in mapping $\gamma_{obj}(\mathbf{r}', \mathbf{r}'')$ since we assume it is known *a priori*.

van Cittert-Zernike theorem An important application of (9.310) is when the system described by $p_{coh}(\mathbf{r}, \mathbf{r}')$ isn't really imaging but rather free-space propagation over a distance z . From the discussion of Fresnel diffraction in Sec. 9.4.6, we know that the PSF for this system is the quadratic phase factor given in (9.95). The product of PSFs that appears in (9.310) is then

$$p_{coh}^*(\mathbf{r}, \mathbf{r}'') p_{coh}(\mathbf{r}', \mathbf{r}''') = \frac{1}{\lambda^2 z^2} \exp\left(-i\pi \frac{|\mathbf{r} - \mathbf{r}''|^2}{\lambda z}\right) \exp\left(i\pi \frac{|\mathbf{r}' - \mathbf{r}'''|^2}{\lambda z}\right). \quad (9.313)$$

Now let us assume that the source is incoherent, in the sense discussed in Sec. 9.7.4, so that the source is described by [cf. (9.267) and (9.269)]

$$\Gamma(\mathbf{r}'', \mathbf{r}''') \approx A_c \delta(\mathbf{r}'' - \mathbf{r}''') \sqrt{\bar{I}_s(\mathbf{r}'') \bar{I}_s(\mathbf{r}''')} = A_c \delta(\mathbf{r}'' - \mathbf{r}''') \bar{I}_s(\mathbf{r}''), \quad (9.314)$$

where the last step follows from (2.120).

We can now insert (9.313) and (9.314) into (9.310) and use the delta function to perform one integral. The result is the spatial coherence function in a plane at distance z from the source, given by

$$\Gamma_z(\mathbf{r}, \mathbf{r}') = \frac{A_c}{\lambda^2 z^2} \int_{\infty} d^2r'' \bar{I}_s(\mathbf{r}'') \exp\left(-i\pi \frac{|\mathbf{r} - \mathbf{r}''|^2}{\lambda z}\right) \exp\left(i\pi \frac{|\mathbf{r}' - \mathbf{r}''|^2}{\lambda z}\right). \quad (9.315)$$

In the first exponential, $|\mathbf{r} - \mathbf{r}''|^2 = r^2 + r''^2 - 2\mathbf{r} \cdot \mathbf{r}''$ and in the second one, $|\mathbf{r}' - \mathbf{r}''|^2 = r'^2 + r''^2 - 2\mathbf{r}' \cdot \mathbf{r}''$, so

$$\Gamma_z(\mathbf{r}, \mathbf{r}') = \frac{A_c}{\lambda^2 z^2} \exp\left(i\pi \frac{r'^2 - r^2}{\lambda z}\right) \int_{\infty} d^2r'' \bar{I}_s(\mathbf{r}'') \exp\left[-2\pi i \frac{(\mathbf{r} - \mathbf{r}') \cdot \mathbf{r}''}{\lambda z}\right]. \quad (9.316)$$

The integral is recognized as the Fourier transform of the radiant exitance of the source, with the spatial frequency given by the vector distance $\mathbf{r} - \mathbf{r}'$ normalized by λz . If \bar{I}_s is broad and structureless, this transform is peaked near zero frequency, which means that the distance between the points \mathbf{r} and \mathbf{r}' in the image plane must be small for $\Gamma_z(\mathbf{r}, \mathbf{r}')$ to be appreciable. It is then usually a good approximation to replace the remaining quadratic phase factor by unity (though this assumption must be checked in specific cases), yielding, finally,

$$\Gamma_z(\mathbf{r}, \mathbf{r}') = \frac{A_c}{\lambda^2 z^2} \mathcal{F}_2\{\bar{I}_s(\mathbf{r}'')\}|_{\boldsymbol{\rho}=(\mathbf{r}-\mathbf{r}')/\lambda z}. \quad (9.317)$$

In short, the spatial coherence function is the Fourier transform of the source distribution. This result, known as the *van Cittert-Zernike theorem*, depends critically on the assumption that the source is fully incoherent (delta-correlated). It also requires the Fresnel approximation but, in spite of the appearance of a Fourier transform, it does not require the Fraunhofer approximation.

Note that (9.317) shows that the image field is a stationary random process since $\Gamma_z(\mathbf{r}, \mathbf{r}')$ is a function of $\mathbf{r} - \mathbf{r}'$ only, but this condition would break down without the paraxial assumptions.

A rule of thumb Consider a uniform, circular, incoherent source of diameter D . The Fourier transform of $\bar{I}(\mathbf{r}'')$ is a besinc function with full width at half maximum approximately $1/D$. That means that $\Gamma_z(\mathbf{r}, \mathbf{r}')$ is near unity if $|\mathbf{r} - \mathbf{r}'|$ is less than about $\lambda z/D$, so the correlation length L_c in plane z is about $\lambda z/D$. Another way to state this conclusion is to note that D/z is the angular width $\Delta\theta$ of the source as seen from the observation plane, so $L_c \approx \lambda/\Delta\theta$. We can square both sides and identify L_c^2 with the coherence area $A_c^{(obs)}$ in the observation plane. A rule of thumb worth remembering is then

$$A_c^{(obs)} \approx \frac{\lambda^2}{\Delta\Omega}, \quad (9.318)$$

where, if we neglect factors of order unity, $\Delta\Omega \approx (\Delta\theta)^2$ is the solid angle subtended by the source at the observation plane. The source must be fully incoherent and have a uniform exitance for this rule to hold.

Partial coherence in a 4f system A simple way of generating a partially coherent field is to place a spatially incoherent, quasimonochromatic source with radiant exitance $\bar{I}_s(\mathbf{r}_s)$ in the source plane of a 4f system (see Fig. 9.21b). The derivation above of the van Cittert-Zernike theorem is easily modified to permit the propagation of the spatial coherence function through the condenser lens to the object plane; all that is required is to replace z with f and to quit fretting about dropping quadratic phase factors. The field in the object plane is multiplied pointwise by the transmittance $t_{obj}(\mathbf{r})$, and the spatial coherence function of the emerging field is

$$\Gamma_{obj}(\mathbf{r}, \mathbf{r}') = \frac{A_c}{\lambda^2 f^2} t_{obj}(\mathbf{r}) t_{obj}^*(\mathbf{r}') \mathcal{F}_2 \{ \bar{I}_s(\mathbf{r}_s) \} |_{\rho=(\mathbf{r}-\mathbf{r}')/\lambda f}. \quad (9.319)$$

We can use (9.310) to propagate to the image plane (primes proliferating in the process), with the result

$$\begin{aligned} \Gamma_{im}(\mathbf{r}, \mathbf{r}') &= \frac{A_c}{\lambda^2 f^2} \int_{\infty} d^2 r'' \int_{\infty} d^2 r''' t_{obj}(\mathbf{r}'') t_{obj}^*(\mathbf{r}''') p_{coh}(\mathbf{r}, \mathbf{r}'') p_{coh}^*(\mathbf{r}', \mathbf{r}''') \\ &\quad \times \int_{\infty} d^2 r_s \bar{I}_s(\mathbf{r}_s) \exp \left[\frac{2\pi i}{\lambda f} (\mathbf{r}'' - \mathbf{r}''') \cdot \mathbf{r}_s \right]. \end{aligned} \quad (9.320)$$

Since the 4f system is shift-invariant to a good approximation, we can replace $p_{coh}(\mathbf{r}, \mathbf{r}'')$ by $p_{coh}(\mathbf{r} - \mathbf{r}'')$. Then we recognize the integral over \mathbf{r}'' as a windowed Fourier transform [cf. (5.1)], where the coherent PSF serves as the window function and $-\mathbf{r}_s/\lambda f$ is the frequency variable. If we denote this transform as

$$g(\mathbf{r}_s; \mathbf{r}) \equiv \int_{\infty} d^2 r'' t_{obj}(\mathbf{r}'') \exp \left[\frac{2\pi i}{\lambda f} \mathbf{r}'' \cdot \mathbf{r}_s \right] p_{coh}(\mathbf{r} - \mathbf{r}''), \quad (9.321)$$

then the image irradiance is given by

$$\bar{I}_{im}(\mathbf{r}) = \Gamma_{im}(\mathbf{r}, \mathbf{r}) = \frac{A_c}{\lambda^2 f^2} \int_{\infty} d^2 r_s \bar{I}_s(\mathbf{r}_s) |g(\mathbf{r}_s; \mathbf{r})|^2. \quad (9.322)$$

In Sec. 5.1.3 we referred to the squared modulus of a local Fourier transform as a *local spectrogram*; here we see that the image-plane irradiance for an arbitrary source (hence arbitrary illumination coherence) is a weighted sum of local spectrograms.

The coherent and incoherent limits of (9.322) are instructive. The coherent case corresponds to a point source, so that $\bar{I}_s(\mathbf{r}_s) \propto \delta(\mathbf{r}_s)$. Then the integral over \mathbf{r}_s can be performed, and we find

$$\bar{I}_{im}(\mathbf{r}) \propto |g(0; \mathbf{r})|^2 = |t_{obj} * p_{coh}(\mathbf{r})|^2. \quad (9.323)$$

As expected, in the coherent limit we simply convolve the object function with the coherent PSF and take the squared modulus of the result to get the image-plane irradiance.

Complete incoherence, for this system, corresponds to constant $\bar{I}_s(\mathbf{r}_s)$, so

$$\begin{aligned} \bar{I}_{im}(\mathbf{r}) &\propto \int_{\infty} d^2 r_s |g(\mathbf{r}_s; \mathbf{r})|^2 \\ &= \int_{\infty} d^2 r'' \int_{\infty} d^2 r''' t_{obj}(\mathbf{r}'') t_{obj}^*(\mathbf{r}''') p_{coh}(\mathbf{r} - \mathbf{r}'') p_{coh}^*(\mathbf{r} - \mathbf{r}''') \\ &\quad \times \int_{\infty} d^2 r_s \exp \left[\frac{2\pi i}{\lambda f} (\mathbf{r}'' - \mathbf{r}''') \cdot \mathbf{r}_s \right]. \end{aligned} \quad (9.324)$$

The integral over \mathbf{r}_s yields a delta function, with which we can perform the integral on \mathbf{r}''' . The result is

$$\bar{I}_{im}(\mathbf{r}) \propto \int_{\infty} d^2 r'' |t_{obj}(\mathbf{r}'')|^2 |p_{coh}(\mathbf{r} - \mathbf{r}'')|^2, \quad (9.325)$$

which is just what we expect; the system now responds linearly to the object radiant exitance (proportional to $|t_{obj}(\mathbf{r})|^2$), and the incoherent PSF is the squared modulus of the incoherent one.

As an exercise, the reader may show that the result in (9.325) can be obtained even without assuming that $\bar{I}_s(\mathbf{r}_s)$ is constant over all space. It suffices if the source is uniform over the area of the pupil (into which it is imaged). Colloquially, the system is incoherent if the source fills the pupil.

9.8 VOLUME DIFFRACTION AND 3D IMAGING

So far in this chapter we have considered diffraction from planar apertures or imaging systems that map one plane to another. Now we examine scattering from a volume and imaging systems that map one volume to another. Scattering and 3D imaging are closely related, since both boil down to volume diffraction. The difference between scattering and diffraction is merely semantics (see Sec. 10.2.3), and we have seen in this chapter how diffraction theory is the foundation of imaging with waves.

In many scattering problems a spatially compact object is illuminated by some external beam such as a plane wave. The object scatters (diffracts) the incident beam, and one goal is to compute the resulting field at a large distance from the object. Ultimately, we may want to deduce some properties of the object from the scattered field or irradiance, but that is an inverse problem to be solved by methods discussed in Chap. 15; here we concentrate on the forward problem.

Three-dimensional imaging may involve a similar setup, where a volumetric object is illuminated with some known field and the objective is to compute the field at distant points. In this view, the only essential difference between scattering experiments and imaging systems is that lenses or other image-forming elements are interposed in the latter case.

Often, however, we shall be interested in self-luminous volume objects that serve simultaneously as radiation source and object to be imaged. It will simplify the treatment considerably if we can assume that the object does not absorb the radiation. In this case the object is described by a real index of refraction $n(\mathbf{r})$ that depends on position. Some approaches to analyzing imaging systems with absorbing objects will be discussed in Chap. 10, but we ignore absorption here.

As a first step in developing a theory of volume diffraction and imaging, we must find a counterpart to the Kirchhoff boundary condition. There are two common ways to do this — the Born approximation discussed in Sec. 9.8.1 and the Rytov approximation discussed in Sec. 9.8.2. It will turn out that these two approximations lead to basically the same equation, with a slight difference in interpretation. This equation will be applied to scattering in Sec. 9.8.3 and imaging in Sec. 9.8.4.

9.8.1 Born approximation

In a source-free region of a non-absorbing medium, the Helmholtz equation (9.31) can be written as

$$(\nabla^2 + n^2 k_0^2) u(\mathbf{r}) = 0, \quad (9.326)$$

where the wavenumber k , defined in Sec. 9.2.1 by $2\pi\nu_0/c_m$, has been rewritten as $k = nk_0$, where $k_0 \equiv 2\pi\nu_0/c$, and $n = c/c_m$ is the refractive index. This form of the Helmholtz equation is valid even if the index is a function of position, $n = n(\mathbf{r})$.

A simple algebraic manipulation on (9.326) yields

$$(\nabla^2 + k_0^2) u(\mathbf{r}) = V(\mathbf{r}) u(\mathbf{r}), \quad (9.327)$$

where $V(\mathbf{r})$, which can be called the *scattering potential*, is defined by

$$V(\mathbf{r}) \equiv k_0^2 [1 - n^2(\mathbf{r})]. \quad (9.328)$$

We define $u_{inc}(\mathbf{r})$ as the field that would exist at point \mathbf{r} in the absence of the inhomogeneous index distribution. Specifically, $u_{inc}(\mathbf{r})$ is the solution to

$$(\nabla^2 + k_0^2) u_{inc}(\mathbf{r}) = 0. \quad (9.329)$$

The total field can then be written as

$$u(\mathbf{r}) = u_{inc}(\mathbf{r}) + u_{sc}(\mathbf{r}), \quad (9.330)$$

where $u_{sc}(\mathbf{r}) \equiv u(\mathbf{r}) - u_{inc}(\mathbf{r})$ can be interpreted as the field scattered by the index inhomogeneities. With these definitions, (9.327) becomes

$$(\nabla^2 + k_0^2) u_{sc}(\mathbf{r}) = V(\mathbf{r}) u(\mathbf{r}). \quad (9.331)$$

The right-hand side of this equation is an effective source, though an unknown one since it depends on the total field $u(\mathbf{r})$. Nevertheless, we can use (9.67) to write

$$u_{sc}(\mathbf{r}) = -\frac{1}{4\pi} \int_{\infty} d^3\mathbf{r}_0 \frac{\exp(ik_0|\mathbf{r} - \mathbf{r}_0|)}{|\mathbf{r} - \mathbf{r}_0|} V(\mathbf{r}_0)[u_{inc}(\mathbf{r}_0) + u_{sc}(\mathbf{r}_0)]. \quad (9.332)$$

This integral equation for $u_{sc}(\mathbf{r})$ is completely equivalent to the Helmholtz equation.

If $n(\mathbf{r})$ is close to one everywhere, then the scattering is weak, and we expect to have $|u_{sc}(\mathbf{r}_0)| \ll |u_{inc}(\mathbf{r}_0)|$ in the region where $V(\mathbf{r}_0)$ is nonzero. Thus it may be a good approximation to neglect $u_{sc}(\mathbf{r})$ inside the integral of (9.332) and write

$$u_{sc}(\mathbf{r}) \approx -\frac{1}{4\pi} \int_{\infty} d^3\mathbf{r}_0 \frac{\exp(ik_0|\mathbf{r} - \mathbf{r}_0|)}{|\mathbf{r} - \mathbf{r}_0|} V(\mathbf{r}_0) u_{inc}(\mathbf{r}_0). \quad (9.333)$$

This step, known as the *first Born approximation*, is the 3D counterpart of the Kirchhoff approximation introduced in Sec. 9.4.2. If this approximation is valid and the index distribution and the incident field are specified, the scattered field can be found by performing the integral (numerically if necessary).

Born series If the first Born approximation is inadequate, an improved result can be obtained by iteration. If we denote the integral operator defined in (9.332) by \mathcal{L} , we can rewrite that equation abstractly as

$$\mathbf{u}_{sc} = \mathcal{L}\mathbf{u} = \mathcal{L}(\mathbf{u}_{inc} + \mathbf{u}_{sc}), \quad (9.334)$$

or

$$(\mathbf{I} - \mathcal{L})\mathbf{u}_{sc} = \mathcal{L}\mathbf{u}_{inc}. \quad (9.335)$$

We can obtain a formal solution of this equation by use of the Neumann series introduced in Sec. A.3.4. From (A.59),

$$\mathbf{u}_{sc} = (\mathbf{I} - \mathcal{L})^{-1}\mathcal{L}\mathbf{u}_{inc} = \sum_{j=0}^{\infty} \mathcal{L}^{j+1}\mathbf{u}_{inc}. \quad (9.336)$$

The first Born approximation corresponds to retaining only the $j = 0$ term in this expansion. This approximation is equivalent to assuming that the radiation field interacts with the medium just once, producing a scattered field that then propagates as if in free space. The second Born approximation allows the scattered field to be scattered again, and so forth.

9.8.2 Rytov approximation

The first Born approximation is valid when $n(\mathbf{r})$ is close to unity everywhere, so it would hold for a tenuous medium such as fog. A slight reformulation of the theory in Sec. 9.8.1 would allow $n(\mathbf{r})$ to be close to some mean value \bar{n} so long as the variations $n(\mathbf{r}) - \bar{n}$ were small, and in that case it could apply to weak volume phase gratings such as acousto-optic devices where small variations in refractive index are produced by acoustic waves. The Rytov approximation is fundamentally different; it places restrictions on the gradient of the refractive index instead of its value. Large variations are allowed so long as they occur slowly on the scale of the wavelength.

Reformulation of the wave equation To set the stage for the Rytov approximation, we first represent the total field as

$$u(\mathbf{r}) = u_{inc}(\mathbf{r}) \exp[i\Psi(\mathbf{r})]. \quad (9.337)$$

If we allow $\Psi(\mathbf{r})$ to be complex, this representation can be used without approximation in any region where $u_{inc}(\mathbf{r})$ is nonzero. For example, if we take $u_{inc}(\mathbf{r})$ to be a plane wave, the representation will apply in all space. If, however, we illuminate a scattering object with a beam of finite cross-section, then (9.337) applies only in the region that would be covered by the beam in the absence of the scatterer.

Next we substitute (9.337) into the wave equation (9.327). With the identity $\nabla^2 fg = f\nabla^2 g + g\nabla^2 f + 2\nabla f \cdot \nabla g$, we can write

$$\begin{aligned} & [\nabla^2 + k_0^2] u(\mathbf{r}) \\ &= [-|\nabla\Psi(\mathbf{r})|^2 + i\nabla^2\Psi(\mathbf{r})] u_{inc}(\mathbf{r}) \exp[i\Psi(\mathbf{r})] + 2i \exp[i\Psi(\mathbf{r})] \nabla u_{inc}(\mathbf{r}) \cdot \nabla\Psi(\mathbf{r}) \\ &= V(\mathbf{r}) u_{inc}(\mathbf{r}) \exp[i\Psi(\mathbf{r})], \end{aligned} \quad (9.338)$$

where we have made use of (9.329) to cancel two terms. Using the above identity again, we see that

$$\begin{aligned} \nabla^2[\Psi(\mathbf{r}) u_{inc}(\mathbf{r})] &= \Psi(\mathbf{r}) \nabla^2 u_{inc}(\mathbf{r}) + u_{inc}(\mathbf{r}) \nabla^2\Psi(\mathbf{r}) + 2\nabla\Psi(\mathbf{r}) \cdot \nabla u_{inc}(\mathbf{r}) \\ &= -k_0^2\Psi(\mathbf{r}) u_{inc}(\mathbf{r}) + u_{inc}(\mathbf{r}) \nabla^2\Psi(\mathbf{r}) + 2\nabla\Psi(\mathbf{r}) \cdot \nabla u_{inc}(\mathbf{r}), \end{aligned} \quad (9.339)$$

where the second line has used (9.329). Thus (9.338) becomes

$$(\nabla^2 + k_0^2) [\Psi(\mathbf{r}) u_{inc}(\mathbf{r})] = -iV(\mathbf{r}) u_{inc}(\mathbf{r}) - i|\nabla\Psi(\mathbf{r})|^2 u_{inc}(\mathbf{r}). \quad (9.340)$$

Now we have an inhomogeneous Helmholtz equation with the unknown $\Psi(\mathbf{r})$ appearing in the source term on the right. As in Sec. 9.8.1, we can use the Green's function to convert the differential equation to an integral equation [*cf.* (9.332)]:

$$\Psi(\mathbf{r}) u_{inc}(\mathbf{r}) = \frac{i}{4\pi} \int_{\infty} d^3\mathbf{r}_0 \frac{\exp(ik_0|\mathbf{r} - \mathbf{r}_0|)}{|\mathbf{r} - \mathbf{r}_0|} [V(\mathbf{r}_0) + |\nabla\Psi(\mathbf{r}_0)|^2] u_{inc}(\mathbf{r}_0). \quad (9.341)$$

To this point we have made no approximations, and (9.341) is equivalent to the original wave equation (9.326).

Rytov approximation The Rytov approximation consists of neglecting $|\nabla\Psi(\mathbf{r}_0)|^2$ compared to $V(\mathbf{r}_0)$ in the integrand of (9.341). Recall that the scattering potential $V(\mathbf{r}_0)$ is defined in (9.328) with a factor of k_0^2 , so it gets larger as the wavelength gets shorter. Thus the Rytov approximation is valid in the geometrical-optics or short-wavelength limit. It does not apply when abrupt changes in index such as air-glass interfaces are present or for scatterers that are small compared to the wavelength. For more discussion of the validity of the Rytov approximation, see Fiddy (1992).

Within the Rytov approximation, the complex phase $\Psi(\mathbf{r})$ is given by

$$\Psi(\mathbf{r}) = \frac{i}{4\pi u_{inc}(\mathbf{r})} \int_{\infty} d^3\mathbf{r}_0 \frac{\exp(ik_0|\mathbf{r} - \mathbf{r}_0|)}{|\mathbf{r} - \mathbf{r}_0|} V(\mathbf{r}_0) u_{inc}(\mathbf{r}_0). \quad (9.342)$$

Since $u_{inc}(\mathbf{r})$ is known and presumed nonzero, there is no difficulty in dividing through by it. Except for this factor, then, the integral in the Rytov approximation

has exactly the same form as in the first Born approximation. The only difference is the interpretation; in the Born approximation, the integral gives the scattered wave directly, while in the Rytov approximation it gives $\Psi(\mathbf{r})u_{inc}(\mathbf{r})$, and the scattered field must be constructed from

$$u_{sc}(\mathbf{r}) = u(\mathbf{r}) - u_{inc}(\mathbf{r}) = u_{inc}(\mathbf{r}) \{ \exp[i\Psi(\mathbf{r})] - 1 \}. \quad (9.343)$$

The basic problem in scattering or 3D imaging is thus the same within either approximation: evaluate the diffraction integral.

Eikonal equation Closely related to the Rytov approximation is an important relation known as the *eikonal equation*. The eikonal (Greek *eikon*, likeness, image) is a function known also as the *characteristic function* or *point characteristic*. Many theoretical developments of geometrical optics are built on this function.

The starting point for deriving the eikonal equation is a representation of the total field in the form

$$u(\mathbf{r}) = A(\mathbf{r}) \exp[ik_0 W(\mathbf{r})], \quad (9.344)$$

where $W(\mathbf{r})$ is the eikonal. The key difference between this form and the Rytov form (9.337) is that $A(\mathbf{r})$ is not the incident field and might be slowly varying.

The Laplacian of (9.344) is

$$\begin{aligned} \nabla^2 u(\mathbf{r}) &= [\nabla^2 A(\mathbf{r}) + 2ik_0 \nabla W(\mathbf{r}) \cdot \nabla A(\mathbf{r}) - k_0^2 A(\mathbf{r}) |\nabla W(\mathbf{r})|^2 \\ &\quad + ik_0 A(\mathbf{r}) \nabla^2 W(\mathbf{r}) \exp[ik_0 W(\mathbf{r})]. \end{aligned} \quad (9.345)$$

In the short-wavelength limit, $k_0 \rightarrow \infty$, and we can neglect the term linear in k_0 compared to the quadratic one, so that

$$\nabla^2 u(\mathbf{r}) \rightarrow -k_0^2 |\nabla W(\mathbf{r})|^2 A(\mathbf{r}) \exp[ik_0 W(\mathbf{r})] = -k_0^2 |\nabla W(\mathbf{r})|^2 u(\mathbf{r}). \quad (9.346)$$

In this same limit, the Helmholtz equation (9.326) becomes

$$[-k_0^2 |\nabla W(\mathbf{r})|^2 + n^2 k_0^2] u(\mathbf{r}) = 0, \quad (9.347)$$

from which we immediately obtain the eikonal equation,

$$|\nabla W(\mathbf{r})|^2 = [n(\mathbf{r})]^2. \quad (9.348)$$

This equation is a nonlinear partial differential equation for $W(\mathbf{r})$. Solution is often difficult except for a few textbook problems, but in principle it contains all of geometrical optics. The familiar ray direction in geometric optics is interpreted as $\nabla W(\mathbf{r})$ in this approach; we shall see why in Sec. 10.2.7.

9.8.3 Fraunhofer diffraction from volume objects

In the Fraunhofer approximation, we expand $|\mathbf{r} - \mathbf{r}_0|$ as in (9.101), retaining only the leading term in the denominator of the Green's function but also the term $\mathbf{r}_0 \cdot \mathbf{r}/|\mathbf{r}|$ in the exponent. With this approximation, the scattered field in the first Born approximation, (9.333), can be written as

$$u_{sc}(\mathbf{r}) \approx -\frac{\exp(ik_0 |\mathbf{r}|)}{4\pi |\mathbf{r}|} \int_{\infty} d^3 \mathbf{r}_0 V(\mathbf{r}_0) u_{inc}(\mathbf{r}_0) \exp\left(-2\pi i \frac{\mathbf{r}_0 \cdot \mathbf{r}}{\lambda_0 |\mathbf{r}|}\right). \quad (9.349)$$

This result should be compared to its 2D counterpart, (9.103). In both cases, the integral is a Fourier transform, but here it is the 3D transform of the effective field $V(\mathbf{r}_0) u_{inc}(\mathbf{r}_0)$, and the 3D spatial frequency that contributes to the scattered field is given by [cf. (9.104)]

$$\boldsymbol{\sigma}_{sc} = \frac{\mathbf{r}}{\lambda_0 |\mathbf{r}|}. \tag{9.350}$$

Since $\mathbf{r}/|\mathbf{r}|$ is the unit vector $\hat{\mathbf{n}}$ from the origin of coordinates to the observation point, radiation scattered in direction $\hat{\mathbf{n}}$ results from the spatial frequency $\boldsymbol{\sigma}_{sc} = \hat{\mathbf{n}}/\lambda_0$ in the Fourier transform of the effective field.

Ewald sphere An important special case of (9.349) is when the illumination is a plane wave, so that

$$u_{inc}(\mathbf{r}_0) = A \exp(i\mathbf{k}_{inc} \cdot \mathbf{r}_0). \tag{9.351}$$

In order to satisfy the wave equation, the magnitude of \mathbf{k}_{inc} must be $2\pi/\lambda_0$. If we define $\boldsymbol{\sigma}_{inc} = \mathbf{k}_{inc}/2\pi$, then (9.349) becomes

$$u_{sc}(\mathbf{r}) \approx -A \frac{\exp(ik_0|\mathbf{r}|)}{4\pi|\mathbf{r}|} \int_{\infty} d^3\mathbf{r}_0 V(\mathbf{r}_0) \exp[-2\pi i(\boldsymbol{\sigma}_{sc} - \boldsymbol{\sigma}_{inc}) \cdot \mathbf{r}_0]. \tag{9.352}$$

Now we see explicitly that the scattered field is proportional to the 3D Fourier transform of the scattering potential evaluated at the spatial frequency $\boldsymbol{\sigma}_{sc} - \boldsymbol{\sigma}_{inc}$.

In many scattering experiments, we fix the illumination direction and observe the scattered radiation over a range of points in the far field simultaneously, for example with a viewing screen or a detector array. Since $\boldsymbol{\sigma}_{sc}$ is related to the observation point by (9.350), that means we should consider $\boldsymbol{\sigma}_{sc}$ as a variable but $\boldsymbol{\sigma}_{inc}$ as a constant in (9.352). As shown in Fig. 9.23, $\boldsymbol{\sigma}_{sc} - \boldsymbol{\sigma}_{inc}$ traces out a spherical cap in the 3D Fourier space as the viewing direction $\hat{\mathbf{n}}$ is varied. This sphere, called the *Ewald sphere* in x-ray crystallography, defines the region of the object Fourier transform that contributes to the scattered radiation in this geometry.

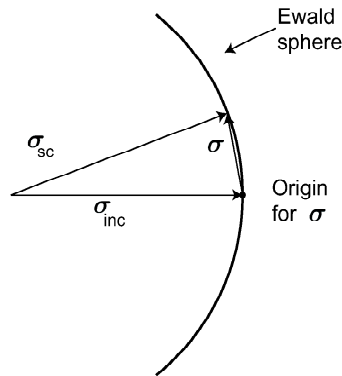

Fig. 9.23 The Ewald sphere.

Crystals are periodic structures, and we know from (3.275) that such structures contain only spatial frequencies that lie on the reciprocal lattice in Fourier space. Thus diffraction occurs in x-ray crystallography only when the Ewald sphere intersects a reciprocal lattice point. This requirement is called the *Bragg condition* or *Bragg matching*.

The Ewald sphere is also an important concept when we are concerned with the inverse problem of reconstructing a scattering potential from measurements in the far field. Since the Ewald sphere is a 2D manifold in a 3D space, we cannot expect to be able to learn very much about the potential with a fixed illumination direction. Some variation of the direction and/or magnitude of \mathbf{k}_{inc} is required.

9.8.4 Coherent 3D imaging

A coherent 3D imaging system is one in which a 3D scattering or reflecting object is illuminated by a coherent monochromatic wave. If the object is transparent and the first Born approximation is applicable, then each point in the object produces a scattered wave proportional to the scattering potential defined in (9.328), and that potential can be regarded as the input to the imaging system. In the Rytov approximation the input can still be regarded as the scattering potential, but there is a more complicated nonlinear relation between this potential and the diffracted field. For a reflecting object, we can consider the system input to be the complex amplitude reflectance defined at every point on the object surface.

In each of these cases, the wave emerging from the object is determined by both the object characteristics and the illumination. This wave is passed through some assembly of lenses, mirrors or other focusing elements to an image space. Though we may eventually observe the wave on a planar image detector in image space, the interest in this section will be on computation of the wave at all points within some volume in this image space. Our goal is thus to analyze the mapping from the object scattering potential or reflectance to the wave in a 3D image space. Since the scattered or reflected field at each object point is a simple product of the illuminating field and an object property, all we really have to do is study the mapping from one 3D field to another.

Coherent imaging with an ideal thin lens Consider a transparent object defined by the scattering potential $V(\mathbf{r})$ lying entirely in the space $z < 0$. An ideal thin lens is placed in the plane $z = 0$, and we want to find an expression for the resulting field in the space $z > 0$. Methods developed in Sec. 9.6 can be adapted for this purpose.

In the first Born approximation, the field at a point just to the left of the lens can be obtained from (9.333) by setting $\mathbf{r} = (\mathbf{r}, 0^-)$, where $\mathbf{r} = (x, y, z)$ and $\mathbf{r} = (x, y)$. If the object is spatially compact and far enough from the lens, we can also make a Fresnel approximation; noting that z_0 is a negative number, we can then write [cf. (9.94)]

$$u_-(\mathbf{r}) \approx -\frac{1}{4\pi} \int_{\infty} d^3\mathbf{r}_0 \frac{\exp(-ik_0z_0)}{z_0} \exp\left(-i\pi \frac{|\mathbf{r} - \mathbf{r}_0|^2}{\lambda_0 z_0}\right) V(\mathbf{r}_0) u_{inc}(\mathbf{r}_0), \quad (9.353)$$

where we have used $k_0 = 2\pi/\lambda_0$.

The field emerging from the lens (*i.e.*, in the plane $z = 0^+$) is given by (9.153) and (9.159) as

$$\begin{aligned} u_+(\mathbf{r}) &= u_-(\mathbf{r}) t_{lens}(\mathbf{r}) \\ &= -\frac{1}{4\pi} \exp\left(-i\pi \frac{r^2}{\lambda_0 f}\right) t_{ap}(\mathbf{r}) \int_{\infty} d^3\mathbf{r}_0 \frac{\exp(-ik_0z_0)}{z_0} \exp\left(-i\pi \frac{|\mathbf{r} - \mathbf{r}_0|^2}{\lambda_0 z_0}\right) V(\mathbf{r}_0) u_{inc}(\mathbf{r}_0). \end{aligned} \quad (9.354)$$

Since we have now specified the field on a plane, we can use ordinary Fresnel diffraction theory to propagate it to an arbitrary point in the space $z > 0$. From (9.97),

$$\begin{aligned} u(\mathbf{r}) &= -\frac{\exp(ik_0z)}{4\pi i\lambda_0z} \exp\left(i\pi\frac{r^2}{\lambda_0z}\right) \\ &\times \int_{\infty} d^2r' \exp\left(-i\pi\frac{r'^2}{\lambda_0f}\right) t_{ap}(\mathbf{r}') \exp\left(i\pi\frac{r'^2}{\lambda_0z}\right) \exp\left(-2\pi i\frac{\mathbf{r}\cdot\mathbf{r}'}{\lambda_0z}\right) \\ &\times \int_{\infty} d^3\mathbf{r}_0 \frac{\exp(-ik_0z_0)}{z_0} \exp\left(-i\pi\frac{|\mathbf{r}'-\mathbf{r}_0|^2}{\lambda_0z_0}\right) V(\mathbf{r}_0) u_{inc}(\mathbf{r}_0), \end{aligned} \quad (9.355)$$

where $u(\mathbf{r})$ means the same thing as $u_z(\mathbf{r})$.

Point response function To understand the meaning of the complicated expression (9.355), we write

$$u(\mathbf{r}) = \int_{\infty} d^3\mathbf{r}_0 h_{coh}(\mathbf{r}, \mathbf{r}_0) V(\mathbf{r}_0), \quad (9.356)$$

where the PRF is given by

$$\begin{aligned} h_{coh}(\mathbf{r}, \mathbf{r}_0) &= -u_{inc}(\mathbf{r}_0) \frac{\exp[ik_0(z-z_0)]}{4\pi i\lambda_0zz_0} \exp\left[\frac{i\pi}{\lambda_0}\left(\frac{r^2}{z} - \frac{r_0^2}{z_0}\right)\right] \\ &\times \int_{\infty} d^2r' t_{ap}(\mathbf{r}') \exp(i\pi\beta r'^2) \exp(-2\pi i\boldsymbol{\rho}\cdot\mathbf{r}'), \end{aligned} \quad (9.357)$$

with

$$\beta = \frac{1}{\lambda_0} \left(\frac{1}{z} - \frac{1}{z_0} - \frac{1}{f} \right); \quad (9.358)$$

$$\boldsymbol{\rho} = \frac{1}{\lambda_0} \left(\frac{\mathbf{r}}{z} - \frac{\mathbf{r}_0}{z_0} \right). \quad (9.359)$$

Note that β vanishes if plane z_0 is imaged onto plane z since $p = -z_0$ and $q = z$ in that case, and p , q and f are then related by the imaging condition (9.169). The two planes are said to be *conjugate* (one is imaged onto the other) if $\beta = 0$.

When $\beta = 0$, the integral in (9.357) is just the Fourier transform of the aperture transmittance evaluated at the spatial frequency given in (9.359). Since the Fourier transform of a clear aperture is maximum at zero frequency, the maximum value of $h_{coh}(\mathbf{r}, \mathbf{r}_0)$ when \mathbf{r} and \mathbf{r}_0 define conjugate planes is determined by setting $\boldsymbol{\rho}$ to zero. This procedure shows that $\mathbf{r} = m_t\mathbf{r}_0$, where the transverse magnification m_t is z/z_0 . (Recall that z_0 is negative, so the image is inverted.)

For nonzero β , comparison with (9.97) shows that the integral in (9.357) has the same structure as the Fresnel diffraction pattern of the aperture, but with different constants. In (9.97) β is just $1/\lambda_0z$, so large values of β correspond to small distances from the aperture, and the Fresnel diffraction pattern is approximately a geometrical shadow of the aperture in this case. Note that β is also proportional to $1/\lambda_0$, so for fixed z (not in a conjugate plane), β increases as the wavelength gets shorter. In the geometric-optics limit ($\lambda_0 \rightarrow 0$), the diffraction pattern is exactly the geometric shadow of the aperture except at the focus.

To see where this shadow is located and how big it is, we can use the principle of stationary phase. If we define

$$\Phi(\mathbf{r}') = \pi\beta r'^2 - 2\pi\boldsymbol{\rho}\cdot\mathbf{r}', \quad (9.360)$$

then the exponential factor in the integrand in (9.357) is rapidly oscillating except in the vicinity of the point where $\nabla\Phi(\mathbf{r}') = 0$, or where $\boldsymbol{\rho} \approx \beta\mathbf{r}'$. For large β , only a small region in the vicinity of $\mathbf{r} = \boldsymbol{\rho}/\beta$ will contribute to the integral. If this point lies in the domain of integration as set by $t_{ap}(\mathbf{r}')$, we can write

$$\begin{aligned} & \int_{\infty} d^2r' t_{ap}(\mathbf{r}') \exp(i\pi\beta r'^2) \exp(-2\pi i\boldsymbol{\rho} \cdot \mathbf{r}') \\ & \approx t_{ap}(\boldsymbol{\rho}/\beta) \int_{\infty} d^2r' \exp(i\pi\beta r'^2) \exp(-2\pi i\boldsymbol{\rho} \cdot \mathbf{r}') = \beta^{-1} t_{ap}(\boldsymbol{\rho}/\beta) \exp(-i\pi\rho^2/\beta), \end{aligned} \quad (9.361)$$

where the last step follows from (3.263).

The factor $t_{ap}(\boldsymbol{\rho}/\beta)$ in (9.361) is the geometric shadow of the aperture. It is centered at the point where $\boldsymbol{\rho}/\beta = 0$, or $\mathbf{r} = (z/z_0)\mathbf{r}_0$. The size of the shadow is determined by β as well as $\boldsymbol{\rho}$. If we consider a circular lens aperture of radius R_{ap} , then the radius of the shadow R_{shad} is obtained by setting the magnitude of the vector $\boldsymbol{\rho}/\beta$ to R_{ap} ; the result is

$$R_{shad} = R_{ap} \left(1 - \frac{z}{z_0} - \frac{z}{f} \right). \quad (9.362)$$

When $z = 0$, $R_{shad} = R_{ap}$ as expected, and R_{shad} decreases linearly with z as we move toward the plane conjugate to z_0 . In geometrical-optics terms, the shadow is centered on the chief ray, which in this problem is a line drawn from the point \mathbf{r}_0 through the center of the lens and extended into the image space. The 3D PRF is a cone of light centered on the chief ray and converging to the geometrical focus (see Fig. 9.24).

Fig. 9.24 Illustration of the 3D PRF of an ideal lens. The geometric-optics approximation corresponds to the cone shown.

In this large- β or geometric-optics approximation, the full coherent PRF (9.357) becomes (after some messy algebra)

$$h_{coh}(\mathbf{r}, \mathbf{r}_0) \approx -u_{inc}(\mathbf{r}_0) \frac{\exp[ik_0(z - z_0)]}{4\pi i \lambda_0 \beta z z_0} t_{ap}(\boldsymbol{\rho}/\beta) \exp \left[-\frac{i\pi}{\lambda_0} \frac{|\mathbf{r} - (q_0/z_0)\mathbf{r}_0|^2}{q_0 - z} \right], \quad (9.363)$$

where q_0 is the distance from the lens plane to the plane where the source point is in focus:

$$\frac{1}{q_0} = \frac{1}{f} + \frac{1}{z_0}. \quad (9.364)$$

The phase factor in (9.363) represents (in the Fresnel approximation) a spherical wave converging toward the geometric focal point. The factor $t_{ap}(\boldsymbol{\rho}/\beta)$ indicates

(unphysically) that the spherical wave is truncated abruptly at the edge of the cone shown in Fig. 9.24. The approximate expression (9.363) must break down near the focus since it requires large β . The inset in the figure was computed numerically from (9.357).

10

Energy Transport and Photons

Imaging requires some form of radiation. Objects can emit their own radiation, or they can transmit, reflect or scatter radiation from an external source. The goal of the imaging system is to probe these emission, transmission, reflection or scattering characteristics of the object. The detector in an imaging system responds to the energy in the radiation, so imaging is ultimately about how energy is transported from the object to the detector.

This chapter is about the transport and measurement of radiant energy. In Sec. 10.1 we survey some basic concepts of energy flow specifically for electromagnetic radiation; both classical and quantum-mechanical viewpoints are presented. The concept of irradiance, already alluded to in previous chapters, is elucidated in more detail here and related to detector response, and the concept of a photon is discussed. The reader who is well versed in the basic physics of electromagnetic fields, or one who simply wants to move directly to a more phenomenological description, can skip to Sec. 10.2 without loss of continuity.

In Sec. 10.2 we introduce a variety of quantities that have been used to describe energy flow. Included are the constructs of classical radiometry, as well as a phase-space distribution function more familiar from statistical mechanics.

Section 10.3 deals with the Boltzmann equation, an integro-differential equation that describes radiative energy transport, and in Sec. 10.4 we relate the Boltzmann equation to imaging.

10.1 ELECTROMAGNETIC ENERGY FLOW AND DETECTION

Our main goal in this section is to introduce the word *photon* and show why it is a useful way of thinking about energy transport in imaging systems. We start, however, with a short survey of energy concepts in classical electromagnetic theory.

10.1.1 Energy flow in classical electrodynamics

An important result in electromagnetic theory is *Poynting's theorem*. This theorem, derived by consideration of the work done on a system of charges by an electromagnetic field (see, *e.g.*, Jackson, 1998), states that

$$\nabla \cdot \mathbf{\Pi}(\mathbf{r}, t) + \frac{\partial}{\partial t} U(\mathbf{r}, t) = -\mathbf{j}(\mathbf{r}, t) \cdot \mathbf{e}(\mathbf{r}, t), \quad (10.1)$$

where $\mathbf{\Pi}(\mathbf{r}, t)$ is the *Poynting vector*, defined by

$$\mathbf{\Pi}(\mathbf{r}, t) \equiv \mathbf{e}(\mathbf{r}, t) \times \mathbf{h}(\mathbf{r}, t), \quad (10.2)$$

and $U(\mathbf{r}, t)$ is the *energy density*, defined as

$$U(\mathbf{r}, t) \equiv \frac{1}{2} \mathbf{e}(\mathbf{r}, t) \cdot \mathbf{d}(\mathbf{r}, t) + \frac{1}{2} \mathbf{b}(\mathbf{r}, t) \cdot \mathbf{h}(\mathbf{r}, t). \quad (10.3)$$

In these equations, \mathbf{r} is a 3D position vector, and the field quantities are defined in Sec. 9.1.1. (The notation is more or less standard, the main exception being that lower-case letters replace the usual capitals for fields.)

The Poynting vector has dimensions of power per unit area (watts/m² in SI units), and it provides a measure of energy flow. As the name implies, the energy density has dimensions of energy per unit volume (Joules/m³); it describes the energy stored in the electric and magnetic fields.

These interpretations are reinforced by considering a region of space where there are no charges, so that the current density $\mathbf{j}(\mathbf{r}, t) = 0$. We denote this region by V and its boundary surface by S . If we integrate both sides of (10.1) over V and use the divergence theorem, we obtain

$$\int_S da \hat{\mathbf{n}} \cdot \mathbf{\Pi}(\mathbf{r}, t) = -\frac{\partial}{\partial t} \int_V d^3\mathbf{r} U(\mathbf{r}, t), \quad (10.4)$$

where $\hat{\mathbf{n}}$ is an outwardly directed unit vector normal to S . If $U(\mathbf{r}, t)$ is the energy per unit volume, then the volume integral on the right represents the total energy stored in V . Since no work is done in V if there are no charges there, the surface integral on the left must represent the energy per unit time transported across S . Energy per unit time is power, but in radiometry it is called *energy flux* or *radiant flux*; thus we can interpret $\hat{\mathbf{n}} \cdot \mathbf{\Pi}(\mathbf{r}, t) da$ as the energy flux through the differential area da .

10.1.2 Plane waves

As discussed in Sec. 9.2.1, monochromatic plane waves have the structure $\text{Re}\{A \exp[i(\mathbf{k} \cdot \mathbf{r} - 2\pi\nu_0 t)]\}$, where A is a (possibly complex) amplitude and $\text{Re}\{\cdot\}$ denotes the real part. For plane electromagnetic waves, this structure applies (with different amplitudes) to each Cartesian component of each vector field. For example, we can represent the electric field in a plane wave by

$$\mathbf{e}(\mathbf{r}, t) = \text{Re}\{\mathbf{E} \exp[i(\mathbf{k} \cdot \mathbf{r} - 2\pi\nu_0 t)]\}, \quad (10.5)$$

where Cartesian component E_n (where $n = x, y, z$) of the vector \mathbf{E} is the amplitude associated with the field component $e_n(\mathbf{r}, t)$; similar representations apply to $\mathbf{h}(\mathbf{r}, t)$

and the other fields. We use capital letters for the amplitudes since they are, in effect, in the Fourier domain. Specifically, the 4D Fourier transform of $e_j(\mathbf{r}, t)$ is E_j times a 4D delta function. We shall customarily delete the designator Re with the convention that the real part of all complex quantities is understood.

By Maxwell's equations, the fields in a source-free region must satisfy $\nabla \cdot \mathbf{d} = 0$ and $\nabla \cdot \mathbf{b} = 0$. In terms of the amplitudes, these equations imply that $\mathbf{k} \cdot \mathbf{D} = 0$ and $\mathbf{k} \cdot \mathbf{B} = 0$, so \mathbf{D} and \mathbf{B} are both perpendicular to the wavevector \mathbf{k} .

If we assume an isotropic, homogeneous medium, as discussed in Sec. 9.1.3, then the constitutive relations are $\mathbf{b}(\mathbf{r}, t) = \mu_0 \mathbf{h}(\mathbf{r}, t)$ and $\mathbf{d}(\mathbf{r}, t) = \epsilon \mathbf{e}(\mathbf{r}, t)$. These relations imply that \mathbf{H} is parallel to \mathbf{B} and \mathbf{E} is parallel to \mathbf{D} , so \mathbf{E} and \mathbf{H} are also perpendicular to \mathbf{k} . Since $\nabla \times \mathbf{e} = -\partial \mathbf{b} / \partial t$, we also require

$$i\mathbf{k} \times \mathbf{E} = -2\pi i \nu_0 \mathbf{B}. \quad (10.6)$$

Hence \mathbf{E} and \mathbf{B} are perpendicular to each other as well as to \mathbf{k} . It follows, then, that the Poynting vector $\mathbf{\Pi}$ is parallel to \mathbf{k} . The energy flow for a plane wave in an isotropic, homogeneous medium is in the direction of the wavevector.

Another consequence of (10.6) is that the amplitudes are related by

$$\frac{|\mathbf{E}|}{|\mathbf{B}|} = \frac{E}{B} = \frac{2\pi\nu_0}{k} = c_m, \quad (10.7)$$

where c_m is the speed of light in the medium, given in Sec. 9.1.4 as $c_m = 1/\sqrt{\mu_0\epsilon}$, and we have used (9.38). The notation $|\mathbf{E}|$ in (10.7) implies both the norm of the vector and the modulus of the complex quantity:

$$|\mathbf{E}| = \sqrt{\mathbf{E} \cdot \mathbf{E}^*} = \sqrt{\sum_{j=1}^3 |E_j|^2}. \quad (10.8)$$

Time averages The Poynting vector is a product of factors that oscillate at frequency ν_0 , so it consists of a static term and a term that oscillates at $2\nu_0$. As we shall discuss in more detail in Sec. 10.1.5, optical detectors are time-averaging devices, so we are not interested in the rapidly oscillating part, and we must therefore compute the time-averaged Poynting vector. If we choose to average over one cycle of the oscillation, we can employ the *cycle-average theorem*: If $a(t)$ and $b(t)$ are two complex quantities that both vary as $\exp(-2\pi i \nu_0 t)$, then

$$\langle \text{Re}(a) \text{Re}(b) \rangle_T = \frac{1}{2} \text{Re}(ab^*), \quad (10.9)$$

where $\langle \rangle_T$ denotes a time average over one cycle of period $T = 1/\nu_0$. To prove this theorem, one writes $\text{Re}(a) = \frac{1}{2}(a + a^*)$, and similarly for b , and recognizes that $\langle a^2 \rangle_T = \langle b^2 \rangle_T = 0$ and that ab^* and a^*b are independent of time.

Applying (10.9) to the energy density for a plane wave in a homogeneous medium, we find

$$\langle U \rangle_T = \frac{1}{4}\epsilon |\mathbf{E}|^2 + \frac{1}{4}\mu_0 |\mathbf{H}|^2 = \frac{1}{2}\epsilon |\mathbf{E}|^2, \quad (10.10)$$

where the last form follows from (10.7) and the constitutive relation $\mathbf{B} = \mu_0 \mathbf{H}$.

Similarly, the average Poynting vector for a plane wave is given by

$$\langle \mathbf{\Pi} \rangle_T = \frac{1}{2} \text{Re}(\mathbf{E} \times \mathbf{H}^*) = \frac{1}{2} \epsilon c_m |\mathbf{E}|^2 \hat{\mathbf{k}}, \quad (10.11)$$

where $\hat{\mathbf{k}}$ is a unit vector in the direction of \mathbf{k} , and we have used (10.6) and the constitutive relations.

Since $\frac{1}{2}\epsilon|\mathbf{E}|^2$ is the time-averaged energy density, (10.11) has a simple geometric interpretation: If we consider a rectangular volume of dimensions $L_x \times L_y \times L_z$ and take the z axis to be parallel to \mathbf{k} , then $\frac{1}{2}\epsilon|\mathbf{E}|^2 L_x L_y L_z$ is the average stored energy. This energy flows through the face of the volume perpendicular to the z axis in a time $\tau = L_z/c_m$, so the average power per unit area through this face is $\frac{1}{2}\epsilon|\mathbf{E}|^2 L_x L_y L_z / L_x L_y \tau$, or simply $\langle \Pi \rangle_T$, the magnitude of the time-averaged Poynting vector.

Terminology and notation The magnitude of the time-averaged Poynting vector is frequently called the *intensity* of the wave, but this term is at variance with the strict radiometric definitions given in Sec. 10.2. In the radiometry community, the term *intensity* (or *radiant intensity*) means power per unit solid angle, while the power per unit area incident on some surface is called *irradiance*.

On the other hand, the magnitude of the time-averaged Poynting vector, though it has units of power per unit area, is not necessarily irradiance; irradiance is a property of the surface as well as the wave. Consider a collimated Gaussian beam propagating along the z axis (see Sec. 9.5.3). The irradiance on a surface normal to the z axis is $\langle |\mathbf{\Pi}| \rangle$, but if we tip the surface so that its normal $\hat{\mathbf{n}}$ makes an angle θ with the axis, then the irradiance is reduced by a factor of $\cos \theta$ since the same amount of power is spread over a larger area, but $\langle |\mathbf{\Pi}| \rangle$ is unchanged. Since $\langle |\mathbf{\Pi}| \rangle$ is the irradiance on a surface normal to the Poynting vector, we shall refer to it as the *normal irradiance* and denote it as I_0 .

We caution the reader that our notation for irradiance is not standard in the radiometry literature, where irradiance is denoted by E , from the French *éclairagement*. The letter E gets used for many other purposes (Big Bird, 1969). We use E (in script form) for the photon energy and for the Fourier transform of the electric field, and the photography community uses it for exposure, which is irradiance times exposure time. To avoid wasting E on an application where it has no mnemonic value (except to Francophones), we denote the irradiance by I .

10.1.3 Photons

So far our discussion of energy transport in an electromagnetic field has been cast in terms of classical fields and energies, but it is very useful to picture energy transport in terms of radiation quanta called *photons*. A complete understanding of photons, and more generally quantum states of the radiation field, requires the use of quantum electrodynamics (QED). We present here a brief introduction to QED, including a simplified treatment of field quantization, photon-number states and photodetection.

For this section, the reader is presumed to be familiar with the basic principles of quantum mechanics, including the concept of a state vector. Dirac notation is used freely.

Modes A useful starting point for QED is the classical Fourier series. If we consider a cube of side L in free space (where L can eventually be allowed to approach

infinity), the real electric field in this region can be expressed as [cf. (10.5)]

$$\mathbf{e}(\mathbf{r}, t) = \frac{1}{2} \sum_j \boldsymbol{\gamma}_j [E_j \exp(i\mathbf{k}_j \cdot \mathbf{r} - i\omega_j t) + E_j^* \exp(-i\mathbf{k}_j \cdot \mathbf{r} + i\omega_j t)]. \quad (10.12)$$

Each term in (10.12), called a *mode*, is characterized by its wavevector \mathbf{k}_j , polarization direction¹ $\boldsymbol{\gamma}_j$ and radian frequency $\omega_j = 2\pi\nu_j$. The vectors \mathbf{k}_j fall on the *reciprocal lattice* (see Sec. 3.4.6), which in this problem is a cubic lattice of spacing $2\pi/L$. For each \mathbf{k}_j there are two orthogonal directions for the electric field, hence two unit vectors $\boldsymbol{\gamma}_j$. The radian frequency associated with mode j is $\omega_j = ck_j$, where c is the speed of light and $k_j = |\mathbf{k}_j|$.

It will prove convenient to define time-dependent amplitudes $a_j(t)$ by

$$E_j \exp(-i\omega_j t) = 2iN_j a_j(t), \quad N_j = \sqrt{\frac{\hbar\omega_j}{\epsilon_0 L^3}}, \quad (10.13)$$

where \hbar is Planck's constant divided by 2π and N_j is a constant with dimensions of electric field. With these definitions,

$$\mathbf{e}(\mathbf{r}, t) = i \sum_j \boldsymbol{\gamma}_j N_j [\exp(i\mathbf{k}_j \cdot \mathbf{r}) a_j(t) - \exp(-i\mathbf{k}_j \cdot \mathbf{r}) a_j^*(t)]. \quad (10.14)$$

A similar expansion can be used for the magnetic field, and the coefficients in the two expansions can be related to each other by (10.6). When the resulting expansions are plugged into (10.3), the energy density in the field is found to be

$$U = \frac{1}{L^3} \sum_j \frac{1}{2} \hbar\omega_j [a_j^* a_j + a_j a_j^*]. \quad (10.15)$$

Details of this calculation can be found in Cohen-Tannoudji *et al.* (1989).

The expression in (10.15) can be cast into a more familiar form by defining two other amplitudes:

$$q_j = \sqrt{\frac{\hbar}{2\omega_j}} (a_j^* + a_j), \quad p_j = i\sqrt{\frac{\hbar\omega_j}{2}} (a_j^* - a_j). \quad (10.16)$$

We can also define a total energy or *Hamiltonian* $H = L^3 U$; in terms of the new variables q_j and p_j , the Hamiltonian is given by

$$H = \frac{1}{2} \sum_j [p_j^2 + \omega_j^2 q_j^2]. \quad (10.17)$$

Both p_j and q_j are functions of time. Specifically, if E_j is a complex constant $|E_j| \exp(i\phi_j)$, then

$$\omega_j q_j = \sqrt{\frac{\hbar\omega_j}{2}} \frac{|E_j|}{N_j} \cos(\omega_j t - \phi_j), \quad (10.18a)$$

¹The vector $\boldsymbol{\gamma}_j$ is a unit vector but we leave off the usual caret since we shall shortly need that ornament for another purpose. Also, the word *polarization* is ambiguous; here it refers to the direction of the electric field, not to dipole moment per unit volume.

$$p_j = \sqrt{\frac{\hbar\omega_j}{2}} \frac{|E_j|}{N_j} \sin(\omega_j t - \phi_j). \quad (10.18b)$$

Since the amplitudes of these two oscillations are the same, a plot of p_j vs. $\omega_j q_j$ traces out a circle during one period of the oscillation. The energy, on the other hand, remains constant.

Each term in the sum in (10.17) has the same form as for a classical particle of unit mass executing simple harmonic motion in a quadratic potential. If we think of p_j as the momentum of the oscillating particle and q_j as its displacement, the kinetic energy is given by $\frac{1}{2}p_j^2$ and the potential energy is given by $\frac{1}{2}\omega_j^2 q_j^2$.

The formal analogy to a mechanical harmonic oscillator is useful, but we should not lose sight of the fact that we are merely choosing different representations for the amplitude of the electric field in each mode. Choice of p_j and q_j leads to a real representation, while choice of a_j and a_j^* leads to a complex representation. In all cases, the final expression for the field $\mathbf{e}(\mathbf{r}, t)$ is real.

Field quantization A simple heuristic way to get a quantized field theory is just to replace the field amplitudes by quantum-mechanical operators. More sophisticated approaches based on the Hamiltonian or Lagrangian formulation of continuum mechanics can also be invoked (Cohen-Tannoudji *et al.*, 1989), but in the end they lead to the same results, so we shall jump immediately to the heuristic method.²

We shall denote quantum-mechanical operators with a caret. Thus \hat{H} is the total Hamiltonian operator, \hat{P}_j is the momentum operator associated with mode j , and \hat{Q}_j is the corresponding position operator. For a single mode, these operators act in the Hilbert space $\mathbb{L}_2(\mathbb{R})$. In Dirac notation, a general vector in this space will be denoted $|\psi\rangle$, analogous to the abstract vector \mathbf{f} we have used in previous chapters to represent a square-integrable function $f(x)$. Since \hat{H} , \hat{P}_j and \hat{Q}_j all represent physical observables, we know from the basic axioms of quantum mechanics that they are Hermitian operators. See Sec. 1.4.4 for important background information on Hermitian operators.

In spite of the mechanical terminology, \hat{Q}_j and \hat{P}_j represent field amplitudes, but we shall assume (heuristically) that they obey the same rules as for mechanical position and momentum operators. Specifically, \hat{Q}_j and \hat{P}_j do not commute; instead they satisfy

$$[\hat{Q}_j, \hat{P}_j] \equiv \hat{Q}_j \hat{P}_j - \hat{P}_j \hat{Q}_j = i\hbar, \quad (10.19)$$

where the square brackets denote a *commutator*. Any operator commutes with itself, so $[\hat{Q}_j, \hat{Q}_j] = [\hat{P}_j, \hat{P}_j] = 0$. Moreover, operators associated with different field modes commute, so $[\hat{Q}_j, \hat{P}_{j'}] = 0$ if $j \neq j'$.

Two useful non-Hermitian operators are the operator equivalents of a_j and a_j^* , which we shall call \hat{a}_j and \hat{a}_j^\dagger , respectively. The dagger (\dagger) denotes an adjoint, and quantum-mechanical adjoints are defined just as in classical linear algebra (see Sec. 1.3.5). For reasons that will emerge below, \hat{a}_j is called an *annihilation operator* and \hat{a}_j^\dagger is called a *creation operator*. From (10.19) and the operator counterparts

²One meaning of *heuristic* is that it refers to a method of teaching or discovery based on experimentation or trial and error. That meaning applies here since we cannot know if the procedure of replacing amplitudes by operators will have any physical meaning until we perform many experiments. To date, all such experiments have been spectacularly successful.

of (10.16), we can show that

$$[\hat{a}_j, \hat{a}_{j'}^\dagger] = \delta_{jj'}. \quad (10.20)$$

In terms of the creation and annihilation operators, the Hamiltonian can be written as

$$\hat{H} = \sum_j \frac{1}{2} \hbar \omega_j (\hat{a}_j^\dagger \hat{a}_j + \hat{a}_j \hat{a}_j^\dagger) = \sum_j \hbar \omega_j (\hat{a}_j^\dagger \hat{a}_j + \frac{1}{2}), \quad (10.21)$$

where the equivalence of the two forms follows from (10.20). In either form, we can identify a single term as the partial Hamiltonian for the j^{th} mode and denote it as \hat{H}_j .

The operator for the total electric field is given by [cf. (10.14)]

$$\hat{\mathbf{e}}(\mathbf{r}, t) = i \sum_j \gamma_j N_j \left[\exp(i\mathbf{k}_j \cdot \mathbf{r}) \hat{a}_j - \exp(-i\mathbf{k}_j \cdot \mathbf{r}) \hat{a}_j^\dagger \right]. \quad (10.22)$$

In quantum optics it is often useful to label the individual terms in the sum (10.22) according to whether they involve positive or negative frequencies. We know from (10.13) that the classical amplitude $a_j(t)$ varies as $\exp(-i\omega_j t)$ for positive ω_j , and in fact the same is true for the operator \hat{a}_j . We can therefore refer to $i\gamma_j N_j \exp(i\mathbf{k}_j \cdot \mathbf{r}) \hat{a}_j$ as the *positive-frequency part* of the field in mode j and denote it as $\hat{\mathbf{e}}_j^+(\mathbf{r}, t)$, and similarly for the negative-frequency part.³ Thus we write

$$\hat{\mathbf{e}}(\mathbf{r}, t) = \hat{\mathbf{e}}^+(\mathbf{r}, t) + \hat{\mathbf{e}}^-(\mathbf{r}, t) = \sum_j [\hat{\mathbf{e}}_j^+(\mathbf{r}, t) + \hat{\mathbf{e}}_j^-(\mathbf{r}, t)]. \quad (10.23)$$

Note that $\hat{\mathbf{e}}^+$ contains all the annihilation operators and $\hat{\mathbf{e}}^-$ contains all the creation operators. The usefulness of this decomposition in the analysis of optical detectors will be seen in Sec. 10.1.4.

Quantum harmonic oscillator The properties of quantum-mechanical harmonic oscillators are discussed in detail in virtually every book on quantum mechanics; some key points are listed here for reference.

An important difference between classical and quantum-mechanical harmonic oscillators is in the allowed energies. The total energy of a classical oscillator of resonant frequency ν_j can be any positive number since the amplitude can have any value. A quantum oscillator with the same resonant frequency, however, can take on only the energies \mathcal{E}_{jn_j} which are eigenvalues of the Hamiltonian. An eigenvector of \hat{H}_j will be denoted $|n_j\rangle$, and the eigenvalue equation is

$$\hat{H}_j |n_j\rangle = \mathcal{E}_{jn_j} |n_j\rangle. \quad (10.24)$$

For the harmonic oscillator, this equation will have a solution if and only if

$$\mathcal{E}_{jn_j} = (n_j + \frac{1}{2}) \hbar \omega_j, \quad n_j = 0, 1, \dots. \quad (10.25)$$

Thus the nonnegative integer n_j specifies the number of quanta of excitation of the oscillator, and each quantum has energy ω_j . If the oscillator describes the j^{th} mode

³The reader should not confuse the plus superscript with a pseudoinverse.

of the radiation field, we say that the mode contains n_j photons. The minimum energy $\frac{1}{2}\omega_j$ is called the *zero-point energy*; in quantum mechanics each mode of the radiation field contains some energy even if no photons are present.

Since $\hat{H}_j = \hbar\omega_j(\hat{a}_j^\dagger\hat{a}_j + \frac{1}{2})$ by (10.21), and since any vector is an eigenvector of an operator that simply multiplies the vector by a constant, we can see that $|n_j\rangle$ is also an eigenvector of $\hat{a}_j^\dagger\hat{a}_j$:

$$\hat{a}_j^\dagger\hat{a}_j|n_j\rangle = n_j|n_j\rangle. \quad (10.26)$$

As a result of this equation, $\hat{a}_j^\dagger\hat{a}_j$ is called the *number operator*; its eigenvalue is the number of photons in the state described by vector $|n_j\rangle$. This state is known variously as a *number state*, *Fock state*, *energy eigenstate* or *stationary state*.

Though $|n_j\rangle$ is an eigenstate of $\hat{a}_j^\dagger\hat{a}_j$, it is not an eigenstate of \hat{a}_j^\dagger or \hat{a}_j separately. Instead, these operators have the following effect on number states:

$$\hat{a}_j^\dagger|n_j\rangle = \sqrt{n_j+1}|n_j+1\rangle, \quad (10.27a)$$

$$\hat{a}_j|n_j\rangle = \sqrt{n_j}|n_j-1\rangle. \quad (10.27b)$$

Thus the creation operator acting on a number state increases the number of photons by one and the annihilation operator decreases the number by one—whence the names.

Other quantum states So far we have discussed only number states. A more general state of the j^{th} mode is a linear superposition of number states, expressed by

$$|\psi_j\rangle = \sum_{n_j=0}^{\infty} c_{jn_j}|n_j\rangle. \quad (10.28)$$

The coefficients in this expansion are the *probability amplitudes* for the individual states. In terms of these (generally complex) amplitudes, the actual probability of observing an eigenenergy \mathcal{E}_{jn_j} is $|c_{jn_j}|^2$. According to the basic tenets of quantum mechanics, only an eigenenergy can ever be observed, even in this superposition state.

As an example, the so-called *coherent states* (Glauber, 1963) are the best quantum approximation to a classical nonrandom wave. They have probabilities given by the Poisson distribution,

$$|c_{jn_j}|^2 = \exp(-|\alpha_j|^2) \frac{|\alpha_j|^{2n}}{n!}, \quad (10.29)$$

where α_j is a complex number designating a particular coherent state for mode j . Thus the probability of observing n photons in mode j obeys a Poisson law with mean $|\alpha_j|^2$ if the mode is excited to a coherent state. We shall discuss coherent states in more detail in Chap. 11 when we analyze photon-counting experiments.

Many other quantum states of the field are possible, some with no classical analog (see Sec. 11.5), but all can be expressed as linear superpositions of states with definite numbers of photons. Regardless of the amplitudes c_{jn_j} , however, the spatio-temporal character of the radiation in a single mode is that of a monochromatic plane wave.

Multimode states and localized photons Strictly speaking, photons are defined as quanta of excitation of a single mode of the radiation field, but colloquially we often speak as though photons were localized bundles of energy. Since all excitations of a single mode are monochromatic plane waves, a photon must strictly be uniformly distributed over the cavity, and the only way we can construct localized excitations is by considering multiple modes.

A multimode number state can be denoted $|\{n_j\}\rangle$; it is simultaneously an eigenstate of all of the single-mode number operators, *i.e.*,

$$\hat{a}_i^\dagger \hat{a}_i |\{n_j\}\rangle = n_i |\{n_j\}\rangle, \quad (10.30)$$

where $\{n_j\}$ denotes an infinite set of nonnegative integers. The state $|\{n_j\}\rangle$ is also an eigenstate of the total number operator $\sum_i \hat{a}_i^\dagger \hat{a}_i$, so the total number of photons in all modes is precisely $\sum_j n_j$. A special case of $|\{n_j\}\rangle$ is the state with one photon in mode i and zero in all other modes; we shall denote this state as $|1_i, \{0\}_{j \neq i}\rangle$.

A straightforward approach to constructing a localized one-photon state uses an analogy to classical wave packets (Mandel and Wolf, 1995). Suppose we define a multimode state $|\psi\rangle$ by

$$|\psi\rangle = \sum_i c_i |1_i, \{0\}_{j \neq i}\rangle. \quad (10.31)$$

No matter what we choose for the coefficients c_i , this state is an eigenstate of the total number operator with eigenvalue 1:

$$\left[\sum_m \hat{a}_m^\dagger \hat{a}_m \right] |\psi\rangle = \sum_i c_i \sum_m \hat{a}_m^\dagger \hat{a}_m |1_i, \{0\}_{j \neq i}\rangle = \sum_i c_i |1_i, \{0\}_{j \neq i}\rangle = 1 \cdot |\psi\rangle. \quad (10.32)$$

As an example, we can choose c_i such that the only wavevectors included in the sum are those with $|\mathbf{k}_i| \simeq \omega_0/c$, thus creating a quasimonochromatic state, and we can further apply a Gaussian weighting on directions around some chosen vector \mathbf{k}_0 . More precisely, we can set $c_i = 0$ if $|k_i - \omega_0/c| > \delta$ and, within this range,

$$c_i = C \exp \left[-\frac{|\mathbf{k}_i - \mathbf{k}_0|^2}{2\sigma^2} \right], \quad (10.33)$$

where C is a suitable normalizing constant. With these conditions, $|\psi\rangle$ represents a Gaussian beam (see Sec. 9.5.3) with mean wavevector \mathbf{k}_0 and some spread around this direction, but all spatially dependent operators such as $\hat{\mathbf{e}}(\mathbf{r}, t)$ are confined laterally (in a sense that will be clarified in Sec. 10.1.4) in the plane perpendicular to \mathbf{k}_0 , just as a classical Gaussian beam would be. We can say that the state is localized to this beam, yet it contains precisely one photon.

Another way to associate photons with particular positions is through an operator corresponding to the energy density:

$$\hat{U}(\mathbf{r}, t) \equiv \epsilon_0 \hat{\mathbf{e}}^-(\mathbf{r}, t) \cdot \hat{\mathbf{e}}^+(\mathbf{r}, t). \quad (10.34)$$

Like the classical energy density, this operator has dimensions of energy per unit volume. To get the total energy, we can integrate $\hat{U}(\mathbf{r}, t)$ over the cavity volume and make use of the orthogonality of the cavity modes along with (10.22) and (10.23); the result is

$$\int_{cav} d^3\mathbf{r} \hat{U}(\mathbf{r}, t) = \sum_j \hbar \omega_j \hat{a}_j^\dagger \hat{a}_j, \quad (10.35)$$

which is the same as the Hamiltonian operator except that there are no zero-point terms.

Integration of $\hat{U}(\mathbf{r}, t)$ over a smaller volume yields an operator related to the energy in that volume. For quasimonochromatic radiation of frequency ω_0 , the operator

$$\frac{1}{\hbar\omega_0} \int_V d^3\mathbf{r} \hat{U}(\mathbf{r}, t) \quad (10.36)$$

corresponds to a local photon number, and its expectation in any quantum state can be interpreted as the average number of photons in the volume V for that state.

Similarly, for quasimonochromatic radiation with all wavevectors nearly parallel, we can define an operator $\hat{I}_p(\mathbf{r}, t)$ by

$$\hat{I}_p(\mathbf{r}, t) = \frac{c}{\omega_0} \hat{U}(\mathbf{r}, t) = \frac{c\epsilon_0}{\omega_0} \hat{\mathbf{e}}^-(\mathbf{r}, t) \cdot \hat{\mathbf{e}}^+(\mathbf{r}, t). \quad (10.37)$$

In the quantum-optics literature, $\hat{I}_p(\mathbf{r}, t)$ is called the *photon intensity operator*, but in our terminology $\omega_0 \hat{I}_p(\mathbf{r}, t)$ corresponds to the classical normal irradiance I_0 , or magnitude of the Poynting vector.

Though the operators $\hat{I}_p(\mathbf{r}, t)$ and $\hat{U}(\mathbf{r}, t)$ have an appealing analogy to the corresponding classical quantities, they must be used with caution. For example, $\hat{I}_p(\mathbf{r}, t)$ and $\hat{I}_p(\mathbf{r}', t')$ do not commute in general, and theories making use of $\hat{I}_p(\mathbf{r}, t)$ are often restricted in the kinds of fields for which they apply. Many books simply dismiss the issue by saying that it is impossible to define a strict photon-position operator. Nevertheless, as we shall see in Sec. 10.1.4, the basic operator $\hat{\mathbf{e}}^-(\mathbf{r}, t) \cdot \hat{\mathbf{e}}^+(\mathbf{r}, t)$ used in the definition of $\hat{I}_p(\mathbf{r}, t)$ and $\hat{U}(\mathbf{r}, t)$ is of fundamental importance in describing photon absorption by a small detector located at point \mathbf{r} , and in this sense at least we can speak of localized photons.

Mandel and Wolf (1995) give a detailed discussion of issues associated with photon localization. They conclude that localized photons can be defined, at least approximately, provided we do not try to localize them to a scale comparable to or smaller than a wavelength. The problem was also analyzed in detail by Bialynicki-Birula (1998) who concluded that localization with exponential falloff in energy density and photodetection rates was possible.

These results provide some impetus for the intuitive notion of a photon as a fuzzy blob, but there are some well-known situations where this intuition can fail us. In an interferometer, for example, any attempt to localize the photon to one arm will necessarily destroy the fringes. We shall revisit the issue of photon localization in Sec. 10.1.4 after developing some background on photodetection.

10.1.4 Physics of photodetection

There are many kinds of detectors of electromagnetic radiation (Dereniak and Crowe, 1984; Kingston, 1995). They are often classified as either thermal or photoelectric, but in fact even thermal detectors start by absorbing the radiation through a photoelectric interaction. The distinction is whether the photoelectron is observed directly as a current or it produces heat, which in turn alters some other property of the material such as its conductivity. Basically, all detectors of electromagnetic radiation are photoelectric.

In this section we briefly discuss the photoelectric interaction process, first by use of QED and then from a semiclassical perspective in which the atom is treated quantum mechanically but the field is assumed to be classical. Excellent references for both approaches include Loudon (1973), Sargent *et al.* (1974), Meystre and Sargent (1990), Cohen-Tannoudji *et al.* (1989) and Mandel and Wolf (1995).

Quantum-mechanical perspective Electromagnetic fields interact with matter predominantly through electric-dipole interactions. Considered as a point charge $-e$, an electron bound to an atom has a classical electrical dipole moment given by $-e\mathbf{r}$, where \mathbf{r} is the position of the electron. The energy of the electron in an external electric field $\mathbf{e}(\mathbf{r}, t)$ is $e\mathbf{r} \cdot \mathbf{e}(\mathbf{r}, t)$. To get the corresponding quantum-mechanical interaction Hamiltonian, we replace the classical field by the operator defined in (10.23) and the classical electron position by the operator $\hat{\mathbf{r}}$. The \mathbf{r} in the argument of $\mathbf{e}(\mathbf{r}, t)$, on the other hand, specifies the center-of-mass position of the atom, which we do not usually quantize. To distinguish these two positions, we simply omit the caret on the atom's center-of-mass position and denote it as \mathbf{r} , which we regard as a classical parameter. Then the interaction Hamiltonian has the form

$$\hat{H}_{int} = e\hat{\mathbf{r}} \cdot \hat{\mathbf{e}}(\mathbf{r}, t) = e\hat{\mathbf{r}} \cdot [\hat{\mathbf{e}}^+(\mathbf{r}, t) + \hat{\mathbf{e}}^-(\mathbf{r}, t)]. \quad (10.38)$$

We now want to use this Hamiltonian to compute the transition rate $R_{i \rightarrow f}$ for transitions from some specified initial state $|i\rangle$ to any final state $|f\rangle$. A well-known result, called *Fermi's Golden Rule*, states that this rate is given by

$$R_{i \rightarrow f} = \frac{2\pi}{\hbar} \sum_f |\langle f | \hat{H}_{int} | i \rangle|^2 \delta(\mathcal{E}_f - \mathcal{E}_i), \quad (10.39)$$

where in principle the sum is over all possible final states, but the delta function picks out only transitions for which the total energy (atom plus field) in the initial state, denoted \mathcal{E}_i , is the same as in the final state, \mathcal{E}_f . For photodetection problems we are interested only in final states where the electron is free and can be detected somehow, so the sum is over free-electron states. Moreover, if we assume that the transition is from the ground state of the atom to some excited state, it must involve absorption of energy from the field, so only photon annihilation operators contribute. These operators are contained in the term $e\hat{\mathbf{r}} \cdot \hat{\mathbf{e}}^+$ in the interaction Hamiltonian, and matrix elements of $e\hat{\mathbf{r}} \cdot \hat{\mathbf{e}}^-$ can be dropped.

For simplicity, we now assume that the light is linearly polarized, which means that all modes present have the same polarization unit vector $\boldsymbol{\gamma}_j$ and the index j is superfluous. Then the important term in \hat{H}_{int} is the product of two scalar operators, $e\boldsymbol{\gamma} \cdot \hat{\mathbf{r}}$ and a scalar operator \hat{e}^+ . The first of these factors involves only the atomic operators and the second involves only the field operators; therefore the interaction matrix element factors as

$$\langle f | \hat{H}_{int} | i \rangle = \langle f_{at} | e\boldsymbol{\gamma} \cdot \hat{\mathbf{r}} | i_{at} \rangle \langle f_{rad} | \hat{e}^+ | i_{rad} \rangle, \quad (10.40)$$

where $|i_{rad}\rangle$ and $|f_{rad}\rangle$ are the initial and final states of the radiation field and $|i_{at}\rangle$ and $|f_{at}\rangle$ are those of the atom. The summation over final states factors similarly, and we can write

$$R_{i \rightarrow f} = \frac{2\pi}{\hbar} \sum_{f_{rad}} |\langle f_{rad} | \hat{e}^+ | i_{rad} \rangle|^2 \sum_{f_{at}} |\langle f_{at} | e\boldsymbol{\gamma} \cdot \hat{\mathbf{r}} | i_{at} \rangle|^2 \delta(\mathcal{E}_f - \mathcal{E}_i). \quad (10.41)$$

For quasimonochromatic radiation of radian frequency ω_0 , the initial and final energies of the field will differ by $\hbar\omega_0$ since $e\boldsymbol{\gamma} \cdot \hat{\mathbf{t}}$ involves only annihilation operators. Then the delta function in (10.41) can be written as $\delta(\mathcal{E}_{f,at} - \mathcal{E}_{i,at} - \hbar\omega_0)$, which does not depend explicitly on the states of the field. Thus the sum over final atomic states can be performed independently of the one over final field states.

To proceed in detail, we would convert the sum over atomic states in (10.41) into an integral over $\mathcal{E}_{f,at}$ with an appropriate density of states. The essential points can be seen, however, simply by defining an atomic property $C(\omega_0)$ by

$$C(\omega_0) \equiv \frac{2\pi}{\hbar} \sum_{f_{at}} |\langle f_{at} | e\boldsymbol{\gamma} \cdot \hat{\mathbf{t}} | i_{at} \rangle|^2 \delta(\mathcal{E}_{f,at} - \mathcal{E}_{i,at} - \hbar\omega_0). \quad (10.42)$$

With this definition, we have

$$R_{i \rightarrow f} = C(\omega_0) \sum_{f_{rad}} |\langle f_{rad} | \hat{e}^+ | i_{rad} \rangle|^2. \quad (10.43)$$

A further simplification follows by realizing that \hat{e}^- is the adjoint of \hat{e}^+ , so

$$R_{i \rightarrow f} = C(\omega_0) \sum_{f_{rad}} \langle i_{rad} | \hat{e}^- | f_{rad} \rangle \langle f_{rad} | \hat{e}^+ | i_{rad} \rangle = C(\omega_0) \langle i_{rad} | \hat{e}^- \hat{e}^+ | i_{rad} \rangle, \quad (10.44)$$

where we have used the closure relation (see Sec. 1.3.7),

$$\sum_{f_{rad}} |f_{rad}\rangle \langle f_{rad}| = \hat{I}_{rad}, \quad (10.45)$$

with \hat{I}_{rad} being the unit operator in the state space of the field (not to be confused with the photon intensity operator). The final form for the transition rate can be written most simply as

$$R_{i \rightarrow f} = C(\omega_0) \langle \hat{e}^- \hat{e}^+ \rangle, \quad (10.46)$$

where $\langle \rangle$ denotes a quantum-mechanical expectation value, in this case an expectation of the field operator $\hat{e}^- \hat{e}^+$ in the initial state of the field. We encountered this same operator in Sec. 10.1.3 and saw that it could be identified with the square of the classical field. Moreover, within a constant, $\hat{e}^- \hat{e}^+$ is the same as the photon intensity operator or normal irradiance [see (10.37)]. Thus (10.46) shows that the photoelectric detection rate is proportional to the expectation of the square of the field or to the expectation of the normal irradiance.

Semiclassical perspective Perhaps surprisingly, photodetection can also be analyzed successfully (in most cases) with a semiclassical model in which the atom is treated quantum mechanically but the field is assumed to be classical, obeying Maxwell's equations. For a nonrandom, quasimonochromatic classical field $\mathbf{e}(\mathbf{r}, t)$, the interaction Hamiltonian has the same form as in (10.38) but with no caret on \mathbf{e} . The sum over final states now includes only the atomic states (since the field is not quantized), and (10.46) becomes

$$R_{i \rightarrow f} = C(\omega_0) \langle [e(\mathbf{r}, t)]^2 \rangle_T, \quad (10.47)$$

where now the averaging is just a time average over one cycle.

The important conclusion here is that photoelectric transition rates are proportional to the average of the square of the electric field. Basically the same

conclusion was reached quantum-mechanically, but there the square of the field is an operator, and the average must be interpreted as the expectation in a quantum state describing the incident light. Semiclassically, the square of the field has its natural interpretation, and the average is over time. In both cases, the important quantity is a mean-square field.

The great utility of the semiclassical result is that one can do completely classical calculations of electrical fields and, at the end, simply compute a classical mean-square field. This quantity then gives directly the rate of photoelectric transitions.

In almost all cases of importance in imaging, the semiclassical procedure will give essentially the same result as a fully quantum-electrodynamical calculation, but with much less effort. If one works very hard, it is possible to devise experiments in which the semiclassical and quantum approaches predict different results, and in those cases QED invariably turns out to be correct. We shall pursue these issues further in Chap. 11.

Who needs localized photons? The discussion above shows that calculation of photon-counting rates, either semiclassically or quantum-electrodynamically, boils down to computation of a mean-square field. There is never any need to think of photons falling on a detector. Indeed, the quantum purist would insist that such a statement is meaningless since photons are single-mode quanta and hence extend throughout all space. The localized event, in this view, is the photoelectric interaction, which involves the collapse of the wavefunction; the wavefunction itself is not localized, and does not have to be.

In practice, however, computation of a mean-square field may be very difficult. Consider, for example, a small source of short-wavelength radiation such as x rays or gamma rays and a small detector some distance away. We know from practical experience that if we place an opaque obstacle, such as a piece of lead, between the source and detector, we get no photocounts, but it is not straightforward to reach this obvious conclusion by computing a mean-square field. We might, for example, model the source as an ideal point, say it emits a spherical wave and compute the field classically behind the obstacle at the detector location. If this field is zero, there will be no counts on the semiclassical detection model. The problem is that the conclusion — no counts — is far more general than the point-source calculation would suggest. It holds for any spatial and temporal distribution of the source and any state of coherence, so long as the line of sight is blocked and diffraction around the obstacle can be neglected. We may not know these details of the source, and we probably do not care. All we know, or need to know, is that the line of sight is blocked.

In this problem, and many others of practical importance in imaging, it serves our computational needs better to think of the source as emitting localized wavepackets, which we shall call photons for want of a better term, and to think of these packets as travelling in a straight line from the source to the detector. If all relevant dimensions in the problem are large compared to a wavelength, then we can ignore diffraction in the classical perspective, and we can ignore the mathematical issues, raised in Sec. 10.1.3, associated with defining localized photon states.

This approach has much in common with the usual description of electron transport in semiconductors. Elementary solid-state physics tells us that an electron wavefunction in an ideal crystal is a modulated plane wave (called a *Bloch*

function), so the electron, like the photon, extends throughout the medium. To think clearly about diodes and transistors, however, it is essential to assign a degree of localization to the electron and to imagine a fuzzy bundle of charge being swept through a P-N junction. The bundle is formed, as in (10.31), by superimposing pure electron wavefunctions with different wavevectors. So long as all states in the superposition respond to external forces in essentially the same way, it is legitimate to think of the localized packet as responding this way.

Another way to think about the issue of localization is to inquire why the plane-wave descriptions of electrons or photons are used in the first place. Why, for example, did we start in (10.12) with a Fourier series or plane-wave expansion for the field? The answer was given in Chap. 7, where we emphasized the role of Fourier analysis in analyzing linear shift-invariant (LSIV) systems. An electric field in free space, or in a cavity that will be allowed to become infinite, is governed by linear equations with no preferred origin of coordinates, so these equations describe an LSIV system. Similarly, the Schrödinger equation for an electron in an ideal crystal has discrete translational symmetry. In both cases, the eigenfunctions (normal modes) are essentially plane waves.

When we break the translational symmetry, for example with a P-N junction or an opaque obstacle, the normal modes are no longer plane waves, and we probably cannot calculate exactly what they are. Instead, in the localized approach, we use the plane waves as basis functions to construct approximate normal modes in much the same way as we used local Fourier transforms to analyze weakly shift-variant systems in Sec. 7.2.8. So long as we do not attempt to localize too finely and we can neglect interference effects, no significant error results.

10.1.5 What do real detectors detect?

The results in Sec. 10.1.4 were obtained by considering an isolated single atom as the detector. Real detectors consist of many atoms, and the processes that occur after the initial photoelectric interaction can be quite complicated.

One complication is that the response of the detector to a photon will usually depend to some degree on where in the detector material the photoelectron is produced. For example, photoelectrons generated at different depths within the photocathode of a photomultiplier will have different probabilities of escaping the cathode and starting a cascade of secondary electrons. Similarly, in a photodiode, there is a region of high electric field (the *depletion region*, for readers familiar with P-N junctions), and photoelectrons produced in this region are much more likely to contribute to the external current than those produced outside the region.

In addition, the squared electric field itself can vary over the volume of the detector, and it can depend in a complicated way on the time t . Moreover, the response produced by radiation of frequency ω is a complicated function of ω ; this latter issue is discussed at the end of this section, but initially we consider quasimonochromatic radiation.

The mean detector output for quasimonochromatic radiation can be defined as

$$g_{out}(\omega_0) = n_{at} C(\omega_0) \int_0^\tau dt \int_{det} d^3\mathbf{r} S(\mathbf{r}) \langle |\mathbf{e}(\mathbf{r}, t)|^2 \rangle, \quad (10.48)$$

where n_{at} is the number of absorbing atoms per unit volume in the detector, $\mathbf{e}(\mathbf{r}, t)$ is the electric field at point \mathbf{r} inside the detector at time t , τ is the exposure time,

and $S(\mathbf{r})$ is the probability that an interaction at point \mathbf{r} will contribute to the detector output. Thus $g_{out}(\omega_0)$ is the mean number of contributing interactions within the detector volume during the exposure time τ .

Note that (10.48) works equally well from a classical or quantum-mechanical perspective, depending on how we interpret the field and the average. Various special cases of this formula will now be discussed.

Fig. 10.1 Illustration of a photodetector illuminated with a plane wave. Note that the coordinate system is fixed to the detector.

Response to a plane wave Consider a photodetector of dimensions $L \times L \times d$ illuminated with a monochromatic plane wave tipped at angle θ as shown in Fig. 10.1. For simplicity, we imagine that the detector is immersed in an index-matching fluid so we do not have to consider Snell's law. We assume for now that $S(\mathbf{r})$ is a constant and focus attention on the \mathbf{r} dependence of the electric field.

Since the radiation is absorbed, the wave is exponentially attenuated in the detector, but because of the tip angle the beam has traversed a thickness $z/\cos\theta$ when it is at depth z in the detector (see Fig. 10.1). Thus, in a coordinate system fixed to the detector, (10.48) becomes

$$\begin{aligned} g_{out}(\omega_0) &= n_{at}C(\omega_0)|E_0|^2\tau \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dy \int_0^d dz \exp\left(-\frac{\mu z}{\cos\theta}\right) \\ &= n_{at}C(\omega_0)|E_0|^2\tau L^2 \frac{\cos\theta}{\mu} \left[1 - \exp\left(-\frac{\mu d}{\cos\theta}\right)\right], \end{aligned} \quad (10.49)$$

where μ is the attenuation coefficient of the light in the detector material and E_0 is the field amplitude just inside the detector. Note that E_0 is nonrandom for now, so $\langle \cdot \rangle$ is not required.

An important limit of (10.49) is when $\mu d \gg 1$. In the optical wavelength range, μ is about 10^6 m^{-1} in typical semiconductor detector materials, so this limit prevails when d is at least a few μm . In this case,⁴

$$g_{out}(\omega_0) = n_{at}C(\omega_0)|E_0|^2\tau L^2 \frac{\cos\theta}{\mu}. \quad (10.50)$$

⁴The factor of $1/\mu$ in (10.50) may be puzzling since it seems to imply that we get a smaller response by using a more absorbing material, even though all of the energy is absorbed when $\mu d \gg 1$, but in fact $C(\omega_0)$ is also proportional to μ . This issue is discussed further below under the heading Broadband polychromatic radiation.

Comparing (10.50) with (10.4) and (10.11) and noting that $\cos \theta = \hat{\mathbf{k}} \cdot \hat{\mathbf{n}}$, we see that

$$g_{out}(\omega_0) \propto \int_S da \hat{\mathbf{n}} \cdot \mathbf{\Pi}(\mathbf{r}, t). \quad (10.51)$$

The integral in this limit is the energy flux (total power transmitted across the detector face) or, equivalently, the integral of the irradiance over the detector face. Because of the factor of τ , the detector senses the total energy transmitted across the face in the measurement time.

In the limit of an optically thin detector, however, where $\mu d / \cos \theta \ll 1$, (10.49) becomes

$$g_{out}(\omega_0) = n_{at} C(\omega_0) |E_0|^2 \tau L^2 d. \quad (10.52)$$

In this case the detector senses the square of the field, not the energy flux. The power intercepted by the detector varies as $\cos \theta$ but the fraction absorbed is $\mu d / \cos \theta$, so the total absorbed power is independent of θ . An optically thick detector absorbs all of the energy of a beam and gives a response proportional to the energy flux, while an optically thin detector measures the square of the field. For normal incidence, the difference is only in the constant of proportionality, but thin and thick detectors behave differently as the angle of incidence is changed.

Photocathodes In a popular type of photomultiplier, light is incident on one side of the photocathode and electrons are emitted from the opposite side. These photocathodes cannot be made optically thick since then the electrons would have to traverse a large thickness of the material, and their probability of escape would be reduced. To develop a simplified model of such cathodes, assume that the electrons are exponentially attenuated with an attenuation coefficient μ_e , so that an electron produced at depth z has a probability $\exp[-\mu_e(d-z)]$ of escaping. This probability is the factor $S(\mathbf{r})$ in (10.48), so (10.49) is modified to

$$\begin{aligned} g_{out}(\omega_0) &= n_{at} C(\omega_0) |E_0|^2 \tau \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dy \int_0^d dz \exp \left[-\frac{\mu z}{\cos \theta} - \mu_e(d-z) \right] \\ &= n_{at} C(\omega_0) |E_0|^2 \tau L^2 e^{-\mu_e d} \left[\frac{\mu}{\cos \theta} - \mu_e \right]^{-1} \left\{ 1 - \exp \left[-\left(\frac{\mu}{\cos \theta} - \mu_e \right) d \right] \right\}. \end{aligned} \quad (10.53)$$

This expression approaches zero as either $d \rightarrow 0$ or $d \rightarrow \infty$, so some intermediate thickness must be chosen. Then the detector is neither optically thin nor optically thick, so it measures neither field squared nor energy flux.

Multiple plane waves Now consider two plane waves of the same frequency and phase, with parallel electric field amplitudes \mathbf{E}_1 and \mathbf{E}_2 . For simplicity we again assume that the detector is immersed in an index-matching fluid so there is no need to worry about reflection or refraction effects. We assume also that $\mu d \gg 1$ and that $S(\mathbf{r})$ is constant.

With these assumptions, the total amplitude \mathbf{E} at an arbitrary point \mathbf{r} is

$$E^2 = E_1^2 + E_2^2 + 2E_1 E_2 \cos[(\mathbf{k}_2 - \mathbf{k}_1) \cdot \mathbf{r}], \quad (10.54)$$

and (10.48) becomes

$$\begin{aligned} g_{out}(\omega_0) &= n_{at} C(\omega_0) \frac{\tau L^2}{\mu} [|E_1|^2 + |E_2|^2] + \frac{\tau}{\mu} 2E_1 E_2 \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dx \int_{-\frac{1}{2}L}^{\frac{1}{2}L} dy \cos[(\mathbf{k}_2 - \mathbf{k}_1) \cdot \mathbf{r}] \\ &= n_{at} C(\omega_0) \frac{\tau L^2}{\mu} [|E_1|^2 + |E_2|^2 + 2E_1 E_2 \operatorname{sinc} L\Delta\xi \operatorname{sinc} L\Delta\eta] , \end{aligned} \quad (10.55)$$

where $\Delta\xi$ is the x component of $(\mathbf{k}_2 - \mathbf{k}_1)/2\pi$ and $\Delta\eta$ is the y component. The sinc functions are small if $L\Delta\xi$ or $L\Delta\eta$ is greater than about one. From the discussion in Sec. 9.2.1, we can relate these conditions to the angle $\Delta\theta$ between the two waves. From (9.45), we can see that $L\Delta\xi > 1$ or $L\Delta\eta > 1$ is equivalent to $L\Delta\theta/\lambda > 1$, and the term proportional to $E_1 E_2$ can be neglected if this condition is satisfied. Since L/λ is usually $\gg 1$ with practical detectors, this condition can be satisfied even if $\Delta\theta$ is quite small. Physically, the interference term does not contribute to the mean detector response if there are one or more fringes across the width of the detector. Under these conditions, the detector again measures total flux, proportional to $|E_1|^2 + |E_2|^2$. The fact that the waves can interfere with each other does not affect the detector reading unless the detector is smaller than a fringe.

This argument extends to any number of plane waves and hence to general noncollimated radiation. We can ignore interference fringes that are not spatially resolved by the detector.

Narrowband polychromatic radiation Now consider two plane waves of slightly different frequencies but parallel \mathbf{E} . At time t there is an instantaneous phase difference between the waves given by $\Delta\phi = 2\pi\Delta\nu t$, where $\Delta\nu$ is the difference in frequencies. For simplicity assume that the two wave vectors are parallel to each other and to the z axis. Then the interesting part of (10.48) is the time integral, and we find

$$g_{out}(\omega_0) = n_{at} C(\omega_0) \frac{L^2}{\mu} \int_0^\tau dt \{E_1^2 + E_2^2 + 2E_1 E_2 \cos(2\pi\Delta\nu t)\} . \quad (10.56)$$

The cosine term integrates to approximately zero if $\Delta\nu\tau \gg 1$, a condition that is quite easy to satisfy. For example, the frequency difference $\Delta\nu$ between the two sodium D lines is about 5×10^{11} Hz, and between two adjacent modes in a typical helium-neon laser, $\Delta\nu$ is about 5×10^7 Hz. With a 1 μ sec integration time, the cosine would make no significant contribution to the response in either of these cases.

The conclusion is that the response is proportional to the total flux in the two beams, and once again the interference effects can be safely ignored. Instantaneous fringes are indeed produced, but many fringes move through the detector volume in the measurement time τ , so they have no measurable effect. As in the spatial case, we can extend the argument to many different frequencies. Any two frequencies ν and ν' for which $(\nu - \nu')\tau \gg 1$ are detected independently.

Broadband polychromatic radiation To extend the discussion above to broadband radiation, one obvious factor that must be considered is $C(\omega)$, defined in (10.42). Most detectors have a threshold photon energy below which there is no response, simply because there are no energy-conserving transitions. In semiconductor detectors, this minimum energy is the bandgap energy, and in photomultipliers, it is the

workfunction of the photocathode. Thus $C(\omega) = 0$ for $\omega < \omega_{thr}$, where $\hbar\omega_{thr}$ is the minimum or threshold energy.

For $\omega > \omega_{thr}$, $C(\omega)$ has two effects: it relates the photoelectric transition rate to field squared [see (10.46) and (10.47)], and it controls the absorption coefficient μ of the radiation in the detector material. Suppose we increase $C(\omega)$, either by changing ω or by changing the material properties. Then the transition rate is increased and more energy per unit time is extracted from the beam as it propagates, and μ is increased proportionally. Thus the factor $C(\omega)/\mu$ in (10.50) is a constant, independent of both frequency and material properties.

The only residual effect of $C(\omega)$ is that it determines the field distribution within the detector through the factor $\exp[-\mu z/\cos\theta]$ in (10.49) or (10.53). For optically thick detectors, this factor influences the response only when $S(\mathbf{r})$ varies over the detector volume, as it does in (10.53) but not in (10.49).

One other issue that we need to discuss with broadband radiation is the precise meaning of the word response. As defined in (10.48), the response has units of total observable photoelectric transitions during the exposure time. In many detectors, each interaction yields either zero or one observable electron in an external circuit, with probability $S(\mathbf{r})$. In that case the total charge produced by narrowband radiation in time τ is just $e g_{out}(\omega_0)$, where e is the charge on the electron. To get the corresponding expression for broadband radiation, we must integrate against a radiation spectrum defined in terms of the photon flux per unit energy; precise ways of defining such spectra are given in Sec. 10.2. To the extent that $g_{out}(\omega)$ is a slowly varying function of ω , the detector output is then proportional to the total number of photons with energy above $\hbar\omega_{thr}$.

Some detectors, on the other hand, have a response that depends on the energy of each photon, not just on the number of photons absorbed. Consider, for example, an x-ray scintillation detector where the initial photoelectric interaction produces a high-energy electron, but the electron energy is quickly converted into optical photons. Each photoelectron in this case can produce many optical photons, and the mean number of optical photons is approximately proportional to the energy of the original x ray.

A similar situation occurs with certain infrared detectors in which the initial photoelectric interaction excites a free electron from an impurity atom. If the photon energy is larger than the binding energy of the impurity electron, then the photoelectron will have sufficient energy to excite lattice vibrations called *phonons*. Since lattice vibrations are basically the same thing as thermal energy, the photoelectron heats the medium, and the amount of heating is proportional to the photon energy. If we observe the heating with a temperature sensor or through its effect on the conductivity of the medium, then the observed response is related to the total absorbed energy, not the total number of photons.

When the response to an individual photon is proportional to the energy of the photon, as in the x-ray and infrared examples, then the response must be integrated against a spectrum defined in terms of energy flux per unit energy to get the total response to broadband radiation. When the response to an individual photon is approximately independent of its energy (at least above the threshold), as in photodiodes and photomultipliers, then the relevant spectrum involves the photon flux per unit energy.

In the remainder of this chapter we shall learn how these fluxes are specified precisely and how they move about in an imaging system.

10.2 RADIOMETRIC QUANTITIES AND UNITS

Classical radiometry describes the energy in a radiation field but ignores many other characteristics, including coherence, the wave nature of light, the fact that light is a vector field and all aspects of quantum electrodynamics. The main justification for this seemingly egregious oversimplification is the point made at the end of Sec. 10.1: practical detectors often respond rather simply to the energy deposited in them. Hence the most important thing we need to know is how much energy gets to the detector.

In this section we focus on ways of describing the energy content of a radiation field as a function of spatial and angular coordinates. The culmination of the discussion will be the definition of a quantity called the *distribution function* from which many other radiometric quantities can be derived. In defining this function, we use the language of photons, regarded as localized particles, but there is nothing quantum mechanical about the treatment. In Sec. 10.2.7, however, we shall return to the foundations of radiometry and explore further how the quantities defined in this section relate to both classical and quantum electrodynamics.

10.2.1 Self-luminous surface objects

We begin with self-luminous or emissive objects, but we need to distinguish surface emitters, considered here, from volume emitters, to be considered in Sec. 10.2.2. A surface emitter is one where the radiation originates on or very near the surface, and structures within the volume of the object do not substantially influence the radiation received by the imaging system. In a volume emitter, by contrast, the internal structure does influence the radiation received by the imaging system, and it is usually the goal of the system to image this internal, three-dimensional, structure.

If a surface emitter is planar, we can choose the coordinate system so that the surface lies in the plane $z = 0$. Hence, any measure of the strength of the emitted radiation will be a 2D function $f(x, y)$. Small deviations from a planar surface can often be accommodated by writing the z coordinate of a point on the surface as a function of x and y , so that the object function becomes $f(x, y, z(x, y))$, which is still a 2D function. This quasiplanar description is useful only in situations such as that illustrated in Fig. 10.2a where, from the vantage point of the imaging system, two coordinates are sufficient to determine uniquely a point on the surface; more convoluted surfaces as in Fig. 10.2b cannot be described fully this way. Most of the optics literature implicitly assumes a planar or quasiplanar surface object, and we shall also adopt that assumption for the remainder of Sec. 10.2.1. Points in the plane $z = 0$ will be denoted by a 2D vector $\mathbf{r} = (x, y)$.

Basic radiometric quantities We still have to specify just what physical entity is described by the function $f(\mathbf{r})$. Intuitively, $f(\mathbf{r})$ corresponds to the strength of the object, but we need a more precise definition. To arrive at such a definition, we begin with the concept of *radiant energy*.

Radiant energy Q is simply the total energy emitted by a source (over some specified time). The SI units of radiant energy are joules, abbreviated J. In many imaging applications, radiant energy per unit area is an important quantity. In photography, this quantity is called the *exposure*, and in radiological imaging it is called the *energy fluence*. We shall use the latter terminology and define the

energy fluence Ψ by

$$\Psi = \frac{\partial Q}{\partial A}, \quad (10.57)$$

where A denotes area. SI units of Ψ are J/m^2 .

There is still an ambiguity in this definition since it depends on how the area is specified. In radiology, fluence is defined by using a small sphere of cross-sectional area ΔA and dividing the energy intercepted by this sphere by ΔA . Though this device has some advantages when considering energy flow in a volume, we do not adopt it here; instead the area should be regarded as a small portion of a surface, so the fluence can, in general, depend on the orientation of the surface.

Fig. 10.2 (a) Illustration of a quasiplanar self-luminous object and an imaging system for viewing it. (b) Illustration of a more convoluted surface that, for the imaging system shown, cannot be described as quasiplanar.

The radiant flux Φ was already introduced in Sec. 10.1.1; it is the power, or rate of emission of radiant energy, with SI units of J/sec or watts, W . Thus

$$\Phi = \frac{\partial Q}{\partial t}. \quad (10.58)$$

A simple and broadly applicable description of a surface emitter is the *radiant exitance* M , defined as the radiant flux per unit area emitted by a surface, or

$$M = \frac{\partial \Phi}{\partial A} = \frac{\partial \Psi}{\partial t} = \frac{\partial^2 Q}{\partial t \partial A}. \quad (10.59)$$

SI units of radiant exitance are W/m^2 . If the object is time varying, the energy emission can be expressed by $M(\mathbf{r}, t)$.

A radiometric quantity closely related to radiant exitance is the irradiance I , which we discussed in some detail in Sec. 10.1. In the notation of the present section, $I = \partial \Phi / \partial A$, which is (10.59) except that the flux in question is incident on a surface rather than emitted by it. Thus irradiance is flux per unit area in an image and exitance is flux per unit area emitted from a self-luminous object.

Directional properties of the energy flux can be expressed by the *radiant intensity*⁵ Υ , defined as the radiant flux per unit solid angle, or

$$\Upsilon = \frac{\partial \Phi}{\partial \Omega} = \frac{\partial^2 Q}{\partial t \partial \Omega}. \quad (10.60)$$

⁵The letter Υ (upsilon) for radiant intensity is definitely not standard in the literature, but perhaps it suggests an angular spreading.

Solid angle is measured in steradians (ster), so the SI units of radiant intensity are W/ster. (Strictly speaking, angles are dimensionless, but it is handy to carry along the units of radians or steradians in order to check the consistency of various formulas.)

Fig. 10.3 Apparatus for measuring the radiant intensity of a small source. The solid angle $\Delta\Omega$, determined by the distance \mathbf{r} and the detector area, is constant for all detector positions.

Radiant intensity is particularly useful when a source is observed from distances large compared to its size. Then the source is effectively a point, but it does not necessarily radiate uniformly in all directions. A practical measurement setup for observing the radiant intensity is shown in Fig. 10.3, where the directionality of the source is observed by swinging a detector on an arc about the source. As we shall see in Sec. 10.2.7, this directionality is related to the correlation properties of the source considered as a random process, so the intensity Υ cannot, in general, be determined from knowledge of the exitance M .

Fig. 10.4 Geometry for interpreting the concept of radiance. An infinitesimal area dA on a surface emits power $d\Phi$ into a differential solid angle $d\Omega$ in a direction making an angle θ to the surface normal. The radiance is the power per unit solid angle per unit *projected* area, where the projected area $dA_{proj} = \cos\theta dA$.

Radiance If we wish to specify both the spatial and angular dependence of energy flux, we can use the *radiance* L , which gives the radiant flux per unit area per unit solid angle. SI units of L are $W/(m^2 \cdot \text{ster})$. One quirk in the definition of radiance is that the area involved is not the actual area of an element of the source but rather that area projected onto the direction of the flux as shown in Fig. 10.4. An element

of projected area dA_{proj} is related to an element of actual area by

$$dA_{proj} = \cos \theta dA = \hat{\mathbf{s}} \cdot d\mathbf{A}, \quad (10.61)$$

where θ is the angle between the direction of interest $\hat{\mathbf{s}}$ and the surface normal, and $d\mathbf{A}$ is a vector surface element with magnitude dA and orientation parallel to the surface normal. The definition of radiance is thus

$$L = \frac{\partial^2 \Phi}{\partial \Omega \partial A_{proj}} = \frac{1}{\cos \theta} \frac{\partial^2 \Phi}{\partial \Omega \partial A}. \quad (10.62)$$

Radiance can depend on position on the surface \mathbf{r} and direction of the flux as specified by the unit vector $\hat{\mathbf{s}}$, so it will be denoted $L(\mathbf{r}, \hat{\mathbf{s}})$. A time argument will also be included when needed.

Radiance is equally applicable to flux incident on a surface or emitted from it; all that changes is the direction $\hat{\mathbf{s}}$. The irradiance/exitance dichotomy does not arise.

Lambertian surfaces One advantage of using projected area in the definition of radiance is that many natural surfaces then have a radiance that is approximately independent of θ . A surface emitter or reflector with L completely independent of direction $\hat{\mathbf{s}}$ is called a *Lambertian* surface. Another common term applied to a Lambertian emitter is *isotropic* (Chandrasekhar, 1960), implying that the radiance is independent of direction. We shall explore this designation further in Sec. 10.2.6.

A semantic confusion often arises because a Lambertian surface is said to obey *Lambert's cosine law of emission*. This statement does not imply a cosine dependence of radiance; rather, it refers to the radiant intensity. Comparison of (10.60) and (10.62) shows that a Lambertian surface has a radiant intensity that varies as $\cos \theta$.

For a Lambertian surface emitter, the relation between exitance and radiance is simple. Integrating $L \cos \theta$ (where the cosine comes from converting projected area to actual area) over 2π ster, we find (for a Lambertian)

$$M = \int_{2\pi} L \cos \theta d\Omega = \int_0^{2\pi} d\phi \int_0^{\pi/2} \sin \theta d\theta L \cos \theta = \pi L, \quad (10.63)$$

where θ and ϕ are the polar angles of the unit vector $\hat{\mathbf{s}}$, with θ measured from the surface normal.

Spectral dependence To specify the radiation completely, it may also be necessary to give its spectral distribution. If the source emits a range of wavelengths λ , each of the radiometric quantities defined above can be generalized to a function of λ . For example, the *spectral exitance* M_λ , defined by

$$M_\lambda = \frac{\partial^2 \Phi}{\partial A \partial \lambda}, \quad (10.64)$$

gives the emitted power per unit area per unit wavelength. If λ is measured in nanometers (nm), units of M_λ are $\text{W}/(\text{m}^2 \cdot \text{nm})$. Similarly, *spectral radiance* L_λ has units of units of $\text{W}/(\text{m}^2 \cdot \text{ster} \cdot \text{nm})$, being defined by

$$L_\lambda = \frac{1}{\cos \theta} \frac{\partial^3 \Phi}{\partial \Omega \partial A \partial \lambda}. \quad (10.65)$$

Spectral quantities can also be specified in energy or frequency units. For quantized electromagnetic radiation in some medium, the energy per photon is $\mathcal{E} = h\nu = hc_m/\lambda$, where h is Planck's constant, ν is the frequency of the radiation and c_m is the speed of light at frequency ν in the medium. Spectral radiance in frequency units (*i.e.*, radiance per unit frequency) is given by

$$L_\nu = \frac{1}{\cos\theta} \frac{\partial^3\Phi}{\partial\Omega\partial A\partial\nu} = L_\lambda \left| \frac{d\lambda}{d\nu} \right| = L_\lambda \frac{c_m}{\nu^2}, \quad (10.66)$$

with SI units $\text{W}/(\text{m}^2 \cdot \text{ster} \cdot \text{Hz})$. In the older literature, *e.g.*, Chandrasekhar (1960), L_ν is called the *specific intensity* or often just *intensity*, but this risks confusion with the radiant intensity Υ or even with the irradiance, which is called intensity in many parts of the optics literature.

Spectral radiance per unit energy is defined by

$$L_\mathcal{E} = \frac{1}{\cos\theta} \frac{\partial^3\Phi}{\partial\Omega\partial A\partial\mathcal{E}} = L_\nu \left| \frac{d\nu}{d\mathcal{E}} \right| = \frac{1}{h} L_\nu. \quad (10.67)$$

Units of $L_\mathcal{E}$ depend, of course, on the units chosen for \mathcal{E} . The SI units would be joules, but photon energy is virtually never expressed in joules. If electron volts (eV) are used, units of $L_\mathcal{E}$ are $\text{W}/(\text{m}^2 \cdot \text{ster} \cdot \text{eV})$.

The spectral descriptions are more complete than the original functions. From spectral exitance, for example, we can compute exitance via

$$M = \int_0^\infty d\lambda M_\lambda, \quad (10.68)$$

but without additional knowledge we cannot go in the opposite direction.

Photon radiometry Sometimes it is more convenient to describe the radiation in terms of photon flux rather than energy flux. If we consider a monochromatic source emitting photons of energy \mathcal{E} (see Secs. 10.1.3. and 10.1.4), the photon flux Φ_p is related to the energy flux Φ by

$$\Phi_p = \frac{\Phi}{\mathcal{E}}. \quad (10.69)$$

Units of photon flux are photons per second or simply sec^{-1} . Similarly, photon exitance and photon radiance are defined by $M_p = M/\mathcal{E}$ and $L_p = L/\mathcal{E}$, with SI units $\text{sec}^{-1}\text{m}^{-2}$ and $\text{sec}^{-1}\text{m}^{-2} \cdot \text{ster}^{-1}$, respectively. If the radiation consists of particles, such as neutrons, the word 'particle' can be substituted for 'photon' throughout.

Spectral counterparts of these photon quantities can also be defined. For example, the *spectral photon radiance* (per unit wavelength) is given by

$$L_{p,\lambda} = \frac{\lambda}{hc \cos\theta} \frac{\partial^3\Phi}{\partial\Omega\partial A\partial\lambda}. \quad (10.70)$$

Spectral photon radiance is closely related to *brightness* (sometimes called *brilliance*) as used in the laser and synchrotron communities. Papers in those fields may omit the factor of $1/\cos\theta$ in defining brightness, and they may mean spectral photon radiance per unit energy rather than per unit wavelength depending on the application. We prefer to avoid the term brightness.

All of these source-strength functions can depend on the 2D position vector \mathbf{r} and on the time t . Radiance and spectral radiance also depend on direction $\hat{\mathbf{s}}$, and the spectral quantities depend on wavelength or energy. The most complete description we have discussed so far is thus $L_\lambda(\mathbf{r}, \hat{\mathbf{s}}, \lambda, t)$. If needed, further arguments for state of polarization of the radiation can be added.

It is not necessary to specify all of these attributes of the source in all circumstances. We need only include those attributes that influence the response of the imaging system. For example, if the system is insensitive to wavelength, the spectral functions are not needed.

10.2.2 Self-luminous volume objects

Next we consider objects where the radiant energy is produced throughout a 3D volume. Position in the volume is specified by a 3D vector \mathbf{r} with components (x, y, z) . Initially we assume that the object is transparent to its own radiation; the effects of internal absorption and scattering will be taken up later.

As with surface emitters, the discussion begins with radiant energy Q or radiant flux Φ . The volumetric counterpart of radiant exitance is the emitted radiant flux per unit volume, denoted S and defined by

$$S = \frac{\partial \Phi}{\partial V}, \quad (10.71)$$

with units of W/m^3 . There is no generally accepted term for S ; we shall call it simply the *emission density*.

If the radiation consists of photons of energy \mathcal{E} , the emitted photon flux per unit volume, denoted S_p , is given by

$$S_p = \frac{S}{\mathcal{E}} = \frac{1}{\mathcal{E}} \frac{\partial \Phi}{\partial V}. \quad (10.72)$$

We shall refer to S_p as the *photon emission density*. Units are photons/(sec \cdot m³) or equivalently sec⁻¹m⁻³.

If the volume emitter is a radioactive source, a conventional descriptor is its *activity*, which is the total number of radioactive decays per second. SI units of activity are *Becquerels*,⁶ abbreviated Bq, and 1 Bq = 1 sec⁻¹. The number of decays per second per unit volume of the source is its *specific activity*. If every radioactive decay resulted in exactly one photon, specific activity would be identical to S_p , but that is not usually the case.

Directional and spectral dependence To specify the directional dependence of the emitted radiation, we need to know the emitted flux per unit volume per unit solid angle (or, equivalently, emitted radiance per unit path length). We shall denote this quantity as Ξ and define it by

$$\Xi = \frac{\partial^2 \Phi}{\partial \Omega \partial V}. \quad (10.73)$$

⁶In the older literature activity was specified in *curies*, abbreviated Ci and defined as the activity of one gram of radium-226. The SI system abolished the curie, the only common unit named for a woman, and replaced it with one named for Henri Becquerel, Marie Curie's mentor.

Again, there is no accepted name for this quantity, though a few books use the obscure and nondescriptive term *steriscent* (Spiro *et al.*, 1965). We shall call Ξ simply the *source distribution*.

Many natural volume emitters are isotropic, emitting radiation uniformly into 4π ster. For such sources, $\partial/\partial\Omega$ can be replaced by $1/4\pi$ wherever it occurs, so

$$\Xi = \frac{1}{4\pi} \frac{\partial\Phi}{\partial V} = \frac{S}{4\pi}. \quad (10.74)$$

If the source emits radiation with a range of wavelengths or energies, spectral source distributions Ξ_λ and $\Xi_\mathcal{E}$ can be defined by

$$\Xi_\lambda = \frac{\partial^3\Phi}{\partial\Omega\partial V\partial\lambda}, \quad \Xi_\mathcal{E} = \frac{\partial^3\Phi}{\partial\Omega\partial V\partial\mathcal{E}}. \quad (10.75)$$

Photon counterparts of these functions are given by

$$\Xi_{p,\lambda} = \left(\frac{\lambda}{hc_m}\right) \Xi_\lambda, \quad \Xi_{p,\mathcal{E}} = \frac{1}{\mathcal{E}} \Xi_\mathcal{E}. \quad (10.76)$$

10.2.3 Surface reflection and scattering

Objects to be imaged need not generate their own radiation; they can also reflect or scatter radiation from external sources. Though etymologically distinct,⁷ the terms reflection and scattering as used in optics are virtually synonymous, both referring to a redirection of incident radiation. In practice, scattering is more likely to be used for interaction of radiation with small particles within a volume, while reflection is used for surfaces.

The directionality of the redirected radiation is not the crucial determinant of which word is used. Surface reflection can be either *specular* or *diffuse*. Specular reflection (from Latin *speculum*, mirror) occurs when the surface is smooth on the scale of the wavelength of the radiation. In that case a highly directional beam of radiation remains highly directional, and the angle of reflection (measured from the surface normal) equals the angle of incidence. If the surface is rough, however, each element of the surface redirects radiation in a different direction, a phenomenon that can be called either diffuse reflection or surface scattering.

In fact, both specular and diffuse scattering are just manifestations of diffraction. As we saw in Sec. 9.5.4, the diffracted radiation from different surface elements on a smooth surface adds coherently to produce a highly directional reflected/scattered beam. In this view surface roughness imparts a random phase shift to the radiation, destroying its directionality.

Throughout this section we shall assume that the reflective object is planar and lies in the plane $z = 0$. Small deviations from the plane are easily accommodated if the surface can be approximated as locally planar. Very convoluted surfaces as in Fig. 10.2b are more difficult to analyze since one portion of the surface can obstruct either the radiation incident on or reflected from another portion. Analysis of such obstructions is central to computer graphics, image understanding and scene analysis, but will not be treated further here.

⁷Reflect comes from Latin *flectere*, to bend, and scatter comes from Middle English *scatere* (related to the Dutch *schateren*), to burst out laughing.

Reflectance and BRDF The officially sanctioned measure of strength of reflection from a surface is the *reflectance*, defined fundamentally as the ratio of reflected radiant flux to incident radiant flux (Palmer, 1995). We shall call this quantity R_{tot} . For imaging purposes, however, R_{tot} conveys little information since it refers to the total flux and not its spatial variation. A more useful quantity is the position-dependent reflectance $R(\mathbf{r})$, defined as the ratio of radiant exitance to irradiance. The two definitions coincide for a uniform surface where $R(\mathbf{r})$ is independent of position, but such objects are rather uninteresting from an imaging perspective.

We can quantify the diffusive properties of a reflective surface by use of the *bidirectional reflectivity distribution function* or BRDF, defined as the ratio of reflected radiance to *radiant incidence* (Palmer, 1995; Nicodemus, 1963*a, b*, 1973). Radiant incidence, with units of W/m^2 , is the irradiance of a highly collimated beam travelling in direction $\hat{\mathbf{s}}$, and hence BRDF specifies the reflected radiance produced by such a beam.

By its definition, BRDF has units ster^{-1} , suggesting that it can be used in an integral over solid angle. In fact, BRDF is the kernel in an integral transform relating reflected radiance to incident radiance. Since BRDF can depend on position \mathbf{r} on the surface as well as the two directions, we write

$$L_{refl}(\mathbf{r}, \hat{\mathbf{s}}) = \int_{2\pi} d\Omega' \text{BRDF}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') L_{inc}(\mathbf{r}, \hat{\mathbf{s}}') \cos \theta', \quad (10.77)$$

where the angular integral covers the hemisphere of unit vectors $\hat{\mathbf{s}}'$ directed towards the surface, and $\hat{\mathbf{s}}$ lies in the opposite hemisphere. The factor of $\cos \theta'$ in the integrand is necessary since BRDF is defined in terms of radiant incidence, which depends on the actual surface area illuminated by a beam, not the projected area.

For a Lambertian surface, the reflected radiance must be independent of both $\hat{\mathbf{s}}$ and the details of incident radiance; only the total irradiance matters. Conservation of energy requires (for a Lambertian) that

$$L_{refl}(\mathbf{r}, \hat{\mathbf{s}}) = \frac{1}{\pi} R(\mathbf{r}) I(\mathbf{r}), \quad (10.78)$$

where $I(\mathbf{r})$ is the surface irradiance, $R(\mathbf{r})I(\mathbf{r})$ is thus the radiant exitance, and the factor $1/\pi$ converts exitance to radiance according to (10.63). The irradiance $I(\mathbf{r})$ is obtained by integrating $L_{inc} \cos \theta$ over solid angle, so

$$I(\mathbf{r}) = \int_{2\pi} d\Omega' L_{inc}(\mathbf{r}, \hat{\mathbf{s}}') \cos \theta'. \quad (10.79)$$

Inserting (10.79) into (10.78) and comparing the result to (10.77) shows that the BRDF of a Lambertian surface is

$$\text{BRDF}_{Lamb}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') = \frac{1}{\pi} R(\mathbf{r}). \quad (10.80)$$

A *perfect Lambertian* surface is one that absorbs no energy, so that $R(\mathbf{r}) = 1$ and $\text{BRDF} = 1/\pi$.

Spectral dependence None of the reflectance descriptors used so far takes any account of the spectral distribution of the radiation. If there is no wavelength shift on reflection, we can still use (10.77) but with a spectral BRDF defined as the ratio of

reflected spectral radiance to spectral radiant incidence. This new BRDF($\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}', \lambda$) still has units of ster^{-1} . The original BRDF($\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}'$) is not obtained by integrating BRDF($\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}', \lambda$) over λ . Instead,

$$\text{BRDF}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') = \frac{\int_0^\infty L_\lambda(\mathbf{r}, \hat{\mathbf{s}}, \lambda) d\lambda}{\int_0^\infty I_\lambda(\mathbf{r}, \hat{\mathbf{s}}', \lambda) d\lambda}, \quad (10.81)$$

where $I_\lambda(\mathbf{r}, \hat{\mathbf{s}}, \lambda)$ is the spectral radiant incidence of a beam in direction $\hat{\mathbf{s}}$.

If inelastic processes such as Raman or Compton scattering can occur (see Sec. 10.2.5), BRDF has to be generalized to a function of $\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}', \lambda$ and λ' , with units of $\text{ster}^{-1}\text{nm}^{-1}$ if λ is measured in nm. Equation (10.77) then generalizes to

$$L_{\lambda, \text{refl}}(\mathbf{r}, \hat{\mathbf{s}}, \lambda) = \int_0^\infty d\lambda' \int_{2\pi} d\Omega' \text{BRDF}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}', \lambda, \lambda') L_{\lambda, \text{inc}}(\mathbf{r}, \hat{\mathbf{s}}', \lambda') \cos \theta'. \quad (10.82)$$

10.2.4 Transmissive objects

For transmissive objects, we must distinguish between thin objects and thick ones. A thin object is one in which there is little lateral spread of the radiation as it passes through the object. If a transmissive object is a slab of thickness L with flat, parallel faces, it can be placed so that light is incident on it in the plane $z = 0$ and emerges from the plane $z = L$. Position on both the input face and the output face can be specified by the 2D vector $\mathbf{r} = (x, y)$. The object is considered thin if the exitance M at point \mathbf{r} in the exit plane is determined to a good approximation by the irradiance I at that same 2D point in the entrance plane. By direct analogy with the reflectance, the *transmittance* of such an object is a dimensionless quantity defined by

$$T(\mathbf{r}) = \frac{M(\mathbf{r})}{I(\mathbf{r})}. \quad (10.83)$$

Another common measure of transmission, especially for photographic film, is the *optical density* $D(\mathbf{r})$, defined by

$$D(\mathbf{r}) = -\log_{10}[T(\mathbf{r})]. \quad (10.84)$$

With either T or D , we can express the radiant exitance from a thin object as a simple multiplicative factor times the irradiance. For a thick object, by contrast, an integral is required, so we write

$$M(\mathbf{r}) = \int_\infty d^2r' T(\mathbf{r}, \mathbf{r}') I(\mathbf{r}'), \quad (10.85)$$

where $T(\mathbf{r}, \mathbf{r}')$ has SI units of m^{-2} .

Directional properties Transmission, like reflection, can be either diffuse or specular. A general descriptor of the directional properties of thin transmissive objects is the *bidirectional transmission distribution function* or BTDF, defined by analogy to BRDF as the ratio of transmitted radiance L_{trans} to radiant incidence. The counterpart of (10.77) is

$$L_{\text{trans}}(\mathbf{r}, \hat{\mathbf{s}}) = \int_{2\pi} d\Omega' \text{BTDF}(\mathbf{r}, \hat{\mathbf{s}}, \hat{\mathbf{s}}') L_{\text{inc}}(\mathbf{r}, \hat{\mathbf{s}}') \cos \theta'. \quad (10.86)$$

For thick transmissive objects, we can construct two parallel reference planes $z = 0$ and $z = L$ and specify two coordinates and two angles on each plane. The general linear input-output relation between these planes is

$$L_{trans}(\mathbf{r}, \hat{\mathbf{s}}) = \int_{\infty} d^2 r' \int_{2\pi} d\Omega' T(\mathbf{r}, \hat{\mathbf{s}}; \mathbf{r}', \hat{\mathbf{s}}') L_{inc}(\mathbf{r}', \hat{\mathbf{s}}'), \quad (10.87)$$

where L_{inc} is measured in the plane $z = 0$, L_{trans} is measured in the plane $z = L$, and $T(\mathbf{r}, \hat{\mathbf{s}}; \mathbf{r}', \hat{\mathbf{s}}')$ is a generalized transmittance function.

10.2.5 Cross sections

BRDF and BTDF describe absorption and scattering on a macroscopic scale, but often it is useful to relate these functions to elementary interaction processes on a microscopic scale. These processes are conveniently discussed in terms of *cross sections*, quantities with dimensions of area that specify the relative strengths of various physical interactions. As we shall see, cross sections can be defined for both absorption and scattering.

Scattering Scattering can be either *elastic* or *inelastic*. In terms of photons, elastic scattering is when the scattered photon has the same energy as the incident photon, while inelastic scattering involves a change in energy (usually a loss).

A classical view of elastic scattering is that an incident electric field of frequency ν induces dipole oscillations in the scattering object, and the dipoles then radiate at the same frequency. When this kind of scattering occurs in an atom or molecule, it is referred to as *Thomson* or *Rayleigh scattering*, and if it occurs in a larger object, such as a dielectric sphere, it is called *Mie scattering*.

Another form of elastic scattering is *resonant fluorescence* where an atom absorbs a photon of energy $h\nu$ from the field by a resonant transition and then emits a photon of the same energy by spontaneous emission.

Inelastic scattering involves a transfer of energy to some other particle or elementary excitation. In *Compton scattering*, important for x rays and gamma rays, the incident photon transfers part of its energy (and momentum) to an electron, producing a scattered photon of lower energy in a different direction.

Raman scattering is similar to Compton scattering except that the energy is transferred to a vibrational mode in a molecule or solid. One difference in practice between the Compton and Raman effects is that the vibrational modes have relatively low energy and hence have appreciable thermal excitation at room temperature. In addition to imparting energy to the molecule or solid, the photon can also absorb energy from these thermal vibrations, so the scattered photon can have either higher or lower energy than the incident photon. *Brillouin scattering* is a form of Raman scattering where the energy exchange is with vibrational waves called *acoustic phonons* in a solid.

Definitions of cross sections Scattering cross sections are defined for discrete entities such as atoms, molecules or dielectric spheres. In the radar literature, cross sections are even defined for airplanes and missiles. In all of these cases, a beam of radiation incident on the entity yields a certain scattered flux, and the scattering cross section

σ_{sc} is a measure of flux per unit irradiance. Specifically, for elastic processes,

$$\sigma_{sc} = \frac{\Phi}{I_0} = \frac{\text{scattered flux}}{\text{normal irradiance}}. \quad (10.88)$$

The term *normal irradiance* was introduced and explained in Sec. 10.1.2.

For inelastic scattering, we must recognize that the incident and scattered photons have different energies. We can define the scattering cross section by

$$\sigma_{sc} = \frac{\Phi_p}{I_{0,p}} = \frac{\text{scattered photon flux}}{\text{normal photon irradiance}}, \quad (10.89)$$

where normal photon irradiance is normal irradiance divided by the *incident* photon energy, while scattered photon flux is scattered flux divided by the *scattered* photon energy.

A cross section for absorption can be defined similarly, except that it makes little sense to talk about absorbed flux; after the absorption, there is no flux. Instead we back up to a basic definition, (10.58), and relate the rate of energy absorption by the atom (which, by conservation of energy, is also the rate of energy loss from the field) to the normal irradiance. We saw in (10.46) and (10.47) that the transition rate is linear in field squared or normal irradiance, so we can write

$$\frac{\partial Q_{atom}}{\partial t} = \sigma_{abs} I_0, \quad (10.90)$$

where σ_{abs} is the *absorption cross section*. Thus the basic definition is

$$\sigma_{abs} = \frac{\partial Q_{atom}/\partial t}{I_0} = \frac{\text{rate of energy absorption}}{\text{normal irradiance}}. \quad (10.91)$$

As the term implies, a cross section is dimensionally an area. Since flux is measured in watts and irradiance in watts per m², SI units of cross section are m². A common unit for cross section is the *barn*, defined as 10⁻²⁴m². The implication of this designation is that 1 barn is a very large cross section, a statement that is true in nuclear physics but not in optics. If an optical beam induces a resonant transition between energy levels in an atom, the cross section is⁸ $\lambda_0^2/2\pi$, where λ_0 is the resonant wavelength (Loudon, 1973). In the visible region, λ_0 is around 500 nm, so optical absorption cross sections are of order 4×10^{-14} m².

If we think in terms of photons, the cross section has a simple geometric interpretation. The normal photon irradiance is the mean number of incident photons per second per unit area (where area is measured in a plane normal to the beam direction), and the mean number of photons per second scattered or absorbed is given by the average number per second passing through area σ .

⁸This formula holds when the incident radiation is exactly resonant and the only energy broadening of the transition results from the natural lifetime. It may be surprising that no dipole moment, oscillator strength or other quantity related to strength of the interaction between the atom and the radiation field enters into the cross section. Basically, this comes about since the linewidth (reciprocal of the lifetime) and the integral of the absorption over the line both scale as oscillator strength; thus the peak value exactly on resonance is independent of oscillator strength.

Differential scattering cross section Often we need to know not only the total scattered flux but also its angular distribution. For this purpose we use the *differential scattering cross section* $\partial\sigma_{sc}/\partial\Omega$, defined as the ratio of scattered photon intensity to the normal photon irradiance, so

$$\Upsilon_p = \frac{\partial\sigma_{sc}}{\partial\Omega} I_{0,p}, \quad (10.92)$$

where the photon intensity Υ_p is the photon flux per unit solid angle.

For elastic scattering, we can multiply both sides of this equation by the common photon energy and get

$$\Upsilon = \frac{\partial\Phi}{\partial\Omega} = \frac{\partial\sigma_{sc}}{\partial\Omega} I_0. \quad (10.93)$$

This expression does not work for inelastic scattering where I_0 refers to a stream of photons of one energy, and Υ refers to a stream of photons of a different (usually lower) energy.

It is evident from the definition that the solid angle Ω that appears in $\partial\sigma_{sc}/\partial\Omega$ refers to the direction of the scattered radiation, but the differential cross section can also depend on the incident direction. In fact, unless we take heroic measures, the scattering centers will have random orientation. Averaged over orientations, $\partial\sigma_{sc}/\partial\Omega$ can be a function of only the deflection angle θ , defined by

$$\cos\theta = \hat{\mathbf{s}} \cdot \hat{\mathbf{s}}', \quad (10.94)$$

where $\hat{\mathbf{s}}'$ is the direction of the incident radiation and $\hat{\mathbf{s}}$ is the direction of the scattered radiation. Therefore we can fully specify the directional character of the scattering by fixing the incident direction, say along the z axis in polar coordinates, and plotting the radiant intensity as a function of the polar angle θ . We shall denote this function as $[\partial\sigma_{sc}/\partial\Omega](\theta)$.

Differential scattering cross sections often depend strongly on the energy of the incident radiation. To describe this dependence, we need the *differential scattering cross section per unit energy*, $\partial^2\sigma/\partial\Omega\partial\mathcal{E}$, where \mathcal{E} here refers to the incident energy.

10.2.6 Distribution function

Radiometric quantities such as exitance, irradiance and radiant intensity are defined in two-dimensional terms, but often we need to consider in more detail the three-dimensional structure of an object being imaged. For example, if an imaging system is viewing a self-luminous object and the emitted radiation can be scattered or absorbed within the object, knowledge of the emission density is not sufficient to compute the image. Regions of the object that contain no emitter can scatter radiation and act as secondary sources, and radiation from the main source can be absorbed and not get out of the object. Similarly, if we want to compute the BTDF or the generalized transmittance of a transmissive object, we must account for the internal scattering and absorption.

To describe these effects more fully, we can use the *phase-space distribution function* (or simply *distribution function* for short). This function is denoted $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$ and defined by

$$w = \frac{1}{\mathcal{E}} \frac{\partial^3 Q}{\partial V \partial \Omega \partial \mathcal{E}}. \quad (10.95)$$

In terms of localized photons, $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) \Delta V \Delta \Omega \Delta \mathcal{E}$ can be interpreted loosely as the number of photons contained in volume ΔV centered on point \mathbf{r} , travelling in solid angle $\Delta \Omega$ about direction $\hat{\mathbf{s}}$, and having energies between \mathcal{E} and $\mathcal{E} + \Delta \mathcal{E}$ at time t . All of the other radiometric quantities can be derived from the distribution function.

Units of w are $\text{m}^{-3}(\text{ster})^{-1}(\text{eV})^{-1}$ if energies are expressed in eV. If the emission density and the absorption and scattering properties of the medium are known, the distribution function can be found (inside and outside the medium) by solving the *Boltzmann transport equation*, as discussed in detail in Sec. 10.3.

Fig. 10.5 Geometry for computing the radiance at an arbitrary plane when the distribution function $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$ is known. Photons within the shaded parallelepiped and travelling in the direction $\hat{\mathbf{s}}$ will pass through the area element ΔA in time Δt .

Relation to radiance The distribution function w differs from the other radiometric quantities defined above in that it is a derivative of the radiant energy rather than of the radiant flux. In other words, w is not defined on a per-unit-time basis. There is, however, a simple relation between the distribution function and the flux-based quantities such as radiance. To deduce this relation, consider Fig. 10.5. A small area ΔA on an arbitrary plane inside or outside the object forms one face of a parallelepiped. The sides of the parallelepiped are parallel to $\hat{\mathbf{s}}$, and the length of these sides is $c_m \Delta t$ as shown, where c_m is the speed of light in the medium (possibly a function of \mathbf{r}) and Δt is some small time interval. During this interval, all photons within the parallelepiped and travelling in a small solid angle $\Delta \Omega$ around direction $\hat{\mathbf{s}}$ will pass through the area ΔA . By the definition of w , the number of such photons is $w \Delta V \Delta \Omega \Delta \mathcal{E}$. Here ΔV is the volume of the parallelepiped, given by

$$\Delta V = c_m \Delta t \Delta A \cos \theta = c_m \Delta t \Delta A_{proj}, \quad (10.96)$$

where θ is the angle between $\hat{\mathbf{s}}$ and the surface normal, and we have used (10.62) to relate area to projected area. The photon flux through the face ΔA in solid angle $\Delta \Omega$ and energy range $\Delta \mathcal{E}$ is thus

$$\Delta \Phi_p = w \Delta V \Delta \Omega \Delta \mathcal{E} / \Delta t = c_m w \Delta \Omega \Delta \mathcal{E} \Delta A_{proj}. \quad (10.97)$$

From the definition of spectral photon radiance (per unit energy), we now have

$$L_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = \frac{\Delta \Phi_p}{\Delta \Omega \Delta \mathcal{E} \Delta A_{proj}} = c_m(\mathbf{r}) w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t). \quad (10.98)$$

Thus the distribution function times the photon speed is identically the spectral photon radiance.

One subtlety here is that radiance, originally defined for a 2D emitter, is now related to the distribution function, which has a 3D vector \mathbf{r} in its argument. The 2D vector \mathbf{r} in L specifies a point on a plane passing through the point \mathbf{r} in the 3D volume. The above derivation shows that it is quite irrelevant just how the plane is chosen; the flux per unit projected area is independent of the orientation of the surface through which the flux passes. Radiance is a property of the position \mathbf{r} in the volume and the direction of the radiation.

The directional dependence of the radiance is determined entirely by the directional properties of $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$. If $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$ is independent of $\hat{\mathbf{s}}$, the radiance on any plane passing through point \mathbf{r} is independent of $\hat{\mathbf{s}}$ also. This observation explains why Lambertian surfaces are so common; all that is required to obtain a Lambertian is a physical mechanism that thoroughly randomizes the photon directions. Strong scattering as in a thick layer of paint or opal glass is one such mechanism. Also, a blackbody cavity in thermal equilibrium necessarily has $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$ independent of $\hat{\mathbf{s}}$, so both of these situations give rise to a radiance that is independent of direction. For this reason, *isotropic* and *Lambertian* are often used synonymously in radiometric parlance.

10.2.7 Radiance in physical optics and quantum optics

As presented above, the distribution function rests heavily on the corpuscular view of light; neither the classical vector-wave characteristics nor the quantum properties of light were considered. For completeness, we now look briefly at the meaning of the distribution function and radiance in classical scalar wave theory, electromagnetic theory and quantum electrodynamics.

Walther's generalized radiance In a pioneering paper, Adriaan Walther (1968) suggested a connection between radiance and the correlation structure of a scalar optical field. His general approach starts with the spatio-temporal autocorrelation function of the field (see Sec. 9.7.4), performs a temporal Fourier transform to get a correlation function involving the spatial variables and the temporal frequency ν , and then uses this quantity to define radiance. We can see the essential features of the problem, however, by assuming quasimonochromatic light at the outset.

For quasimonochromatic light of wavelength λ , Walther (1968) defined the *generalized spectral radiance* at a point \mathbf{r}' on plane P by

$$L_\nu(\mathbf{r}', \hat{\mathbf{s}}, \nu) = \frac{\cos \theta}{\lambda^2} \int_P d^2 r'' \langle u(\mathbf{r}' + \frac{1}{2}\mathbf{r}'') u^*(\mathbf{r}' - \frac{1}{2}\mathbf{r}'') \rangle \exp(-ik \hat{\mathbf{s}} \cdot \mathbf{r}''), \quad (10.99)$$

where θ is the angle between $\hat{\mathbf{s}}$ and the normal to the plane, $k = 2\pi/\lambda = 2\pi\nu/c_m$, $u(\mathbf{r})$ is any suitable scalar field (see Chap. 9) and \mathbf{r}' and \mathbf{r}'' are 3D position vectors (but confined to the plane). If we take plane P to be $z = 0$, then $\mathbf{r}' = (x', y', 0)$, $\mathbf{r}'' = (x'', y'', 0)$ and $d^2 r'' = dx'' dy''$.

As Walther noted, this definition is closely related to the Wigner distribution function. In fact, the integral in (10.99) is identical to the expectation value of the Wigner distribution function of the field [*cf.* (5.54)]. This expectation, called the *stochastic Wigner distribution function*, was introduced in Sec. 8.2.5. The

connection between radiance and the Wigner distribution was explored in detail by Bastiaans (1978, 1979a, 1979b).

Generalized radiance and wavefronts There are many situations where it is convenient to represent a monochromatic optical field in the form

$$u(\mathbf{r}) = A(\mathbf{r}) \exp[ik W(\mathbf{r})], \quad (10.100)$$

where $W(\mathbf{r})$ is real and $A(\mathbf{r})$ might be slowly varying compared to the exponential factor. In an imaging context, the function $W(\mathbf{r})$ is called the eikonal (see Sec. 9.8.2), and the surface $W(\mathbf{r}) = \text{constant}$ is called the wavefront.

Plane waves and spherical waves fit the description in (10.100), as do many of the coherent point response functions discussed in Sec. 9.6. In Sec. 9.8.2 we derived the eikonal equation from (10.100) with the assumption that k is very large (or λ very small). We shall now investigate the generalized radiance with (10.100).

If we assume that the wave is perfectly monochromatic and nonrandom, then the expectation in (10.99) is not needed, and we have

$$\begin{aligned} & L_\nu(\mathbf{r}', \hat{\mathbf{s}}, \nu) \\ &= \frac{\cos \theta}{\lambda^2} \int_P d^2 r'' A(\mathbf{r}' + \frac{1}{2} \mathbf{r}'') A^*(\mathbf{r}' - \frac{1}{2} \mathbf{r}'') \exp\{ik[W(\mathbf{r}' + \frac{1}{2} \mathbf{r}'') - W(\mathbf{r}' - \frac{1}{2} \mathbf{r}'') - \hat{\mathbf{s}} \cdot \mathbf{r}'']\}. \end{aligned} \quad (10.101)$$

If $W(\mathbf{r})$ is sufficiently slowly varying in the vicinity of the point \mathbf{r}' , then we can expand $W(\mathbf{r}' \pm \frac{1}{2} \mathbf{r}'')$ in a Taylor series about this point and retain only terms up to second order in \mathbf{r}'' (*i.e.*, make the Fresnel approximation). The constant and second-order terms cancel, and we have

$$W(\mathbf{r}' + \frac{1}{2} \mathbf{r}'') - W(\mathbf{r}' - \frac{1}{2} \mathbf{r}'') \simeq \mathbf{r}'' \cdot \nabla W(\mathbf{r}'). \quad (10.102)$$

If, in addition, k is large, then the exponential factor is rapidly varying, and only the vicinity of the point $\mathbf{r}'' = 0$ contributes significantly to the integral. To a good approximation, then,

$$L_\nu(\mathbf{r}', \hat{\mathbf{s}}, \nu) = \frac{\cos \theta}{\lambda^2} |A(\mathbf{r}')|^2 \int_P d^2 r'' \exp\{ik[\mathbf{r}'' \cdot \nabla W(\mathbf{r}') - \hat{\mathbf{s}} \cdot \mathbf{r}'']\}. \quad (10.103)$$

To evaluate this integral, we must relate the 3D vectors in the integrand to their 2D counterparts needed for the integration. Taking the plane of integration as $z = 0$ as usual, we write \mathbf{r} as $(\mathbf{r}'', 0) = (x'', y'', 0)$. Similarly, if $\hat{\mathbf{s}} = (\alpha, \beta, \gamma)$, then we can define a 2D vector \mathbf{s}_\perp as (α, β) . Since $\hat{\mathbf{s}}$ is a unit vector, $\alpha^2 + \beta^2 + \gamma^2 = 1$, but $\alpha^2 + \beta^2 \neq 1$ in general, and \mathbf{s}_\perp is not a unit vector. Since $\nabla = (\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z})$, we define a transverse gradient operator by $\nabla_\perp = (\frac{\partial}{\partial x}, \frac{\partial}{\partial y})$. Finally, we denote $W(\mathbf{r})$ on the plane $z = 0$ as $W_0(\mathbf{r})$.

With this notation and (3.217), we have

$$\begin{aligned} L_\nu(\mathbf{r}', \hat{\mathbf{s}}, \nu) &= \frac{\cos \theta}{\lambda^2} |A(\mathbf{r}')|^2 \int_\infty d^2 r'' \exp\{ik[\mathbf{r}'' \cdot \nabla_\perp W_0(\mathbf{r}') - \mathbf{s}_\perp \cdot \mathbf{r}'']\} \\ &= \frac{\cos \theta}{\lambda^2} |A(\mathbf{r}')|^2 \delta \left\{ \frac{k}{2\pi} [\nabla_\perp W_0(\mathbf{r}') - \mathbf{s}_\perp] \right\}, \end{aligned} \quad (10.104)$$

where the delta function is 2D. Since $k = 2\pi/\lambda$, the scaling property of the delta function, (2.1201), allows us to write

$$L_\nu(\mathbf{r}', \hat{\mathbf{s}}, \nu) = \cos \theta |A(\mathbf{r}')|^2 \delta[\nabla_\perp W_0(\mathbf{r}') - \mathbf{s}_\perp]. \quad (10.105)$$

The delta function is zero except where $\nabla_\perp W_0(\mathbf{r}') = \mathbf{s}_\perp$. If we consider the short-wavelength limit ($k \rightarrow \infty$), however, we know from the eikonal equation (9.348) that $|\nabla W(\mathbf{r}')| = 1$ in free space, so $\nabla W(\mathbf{r}')$ is a 3D unit vector and $\nabla_\perp W_0(\mathbf{r}')$ is its component in plane P . Thus the 2D vector relation $\nabla_\perp W_0(\mathbf{r}') = \mathbf{s}_\perp$ implies the 3D one, $\nabla W(\mathbf{r}') = \hat{\mathbf{s}}$. It is an interesting exercise in delta functions to show that $\cos \theta \delta[\nabla_\perp W_0(\mathbf{r}') - \mathbf{s}_\perp] = \delta[\nabla W(\mathbf{r}') - \hat{\mathbf{s}}]$, where the latter is the angular delta function discussed in Sec. 2.4.7.

With this observation, we have, finally,

$$L_\nu(\mathbf{r}', \hat{\mathbf{s}}, \nu) = |A(\mathbf{r}')|^2 \delta[\nabla W(\mathbf{r}') - \hat{\mathbf{s}}], \quad (10.106)$$

so the radiance is zero (in the short-wavelength limit) except in the direction normal to the wavefront. Note that (10.106) is a pure vector relation, with no reference to the plane P remaining. This is as it should be, since radiance is defined at a point. The quantity $|A(\mathbf{r}')|^2$ is then the normal irradiance (a property of the field alone) and not the irradiance (which depends also on the plane chosen).

Radiant intensity and generalized radiance To further motivate Walther's definition, we shall now compute the radiant intensity from the generalized radiance and then compare the result to what would be obtained from scalar diffraction theory. A more complete treatment of this problem is given by Marchand and Wolf (1974a).

It follows from (10.60) and (10.62) that the radiant intensity is related to radiance by

$$\Upsilon(\hat{\mathbf{s}}) = \cos \theta \int_\infty d^2 r' L(\mathbf{r}', \hat{\mathbf{s}}), \quad (10.107)$$

where θ is the angle between $\hat{\mathbf{s}}$ and the normal to the plane of integration. We noted earlier that radiant intensity is particularly useful when a source is observed from distances large compared to its size as in Fig. 10.3. In that case, $\hat{\mathbf{s}}$ is the unit vector from anywhere on the source to a small, distant detector.

If the radiance is given by (10.99), then the intensity is

$$\Upsilon(\hat{\mathbf{s}}) = \frac{\cos^2 \theta}{\lambda^2} \int_\infty d^2 r' \int_\infty d^2 r'' \langle u(\mathbf{r}' + \frac{1}{2}\mathbf{r}'') u^*(\mathbf{r}' - \frac{1}{2}\mathbf{r}'') \rangle \exp(-ik \hat{\mathbf{s}} \cdot \mathbf{r}''). \quad (10.108)$$

The radiant flux on the detector in Fig. 10.3 is $\Upsilon(\hat{\mathbf{s}})$ times the solid angle subtended by the detector, or $\Upsilon(\hat{\mathbf{s}})A_d/\mathbf{r}^2$, where A_d is the detector area and \mathbf{r} is its distance from the small source. Thus the detector response will be determined by $\Upsilon(\hat{\mathbf{s}})$, which in turn is determined by the stochastic Wigner distribution function of the field.

The experimental arrangement in Fig. 10.3 was analyzed in Sec. 9.4.7 by Fraunhofer diffraction theory, and we shall now show how that theory also predicts (10.108). If we identify $\langle |u(\mathbf{r})|^2 \rangle$ as the irradiance on the detector, then the radiant flux $\Upsilon(\hat{\mathbf{s}})A_d/\mathbf{r}^2$ is equal to $\langle |u(\mathbf{r})|^2 \rangle A_d$. By use of (9.102) we can write

$$\begin{aligned} \Upsilon(\hat{\mathbf{s}}) &= \mathbf{r}^2 \langle |u(\mathbf{r})|^2 \rangle \\ &= \frac{\cos^2 \theta}{\lambda^2} \int_{-\infty}^{\infty} d^2 r_0 \int_{-\infty}^{\infty} d^2 r_1 \langle u(\mathbf{r}_0) u^*(\mathbf{r}_1) \rangle \exp \left[-ik \frac{(\mathbf{r}_0 - \mathbf{r}_1) \cdot \mathbf{r}}{\mathbf{r}} \right]. \end{aligned} \quad (10.109)$$

A change of variables and the recognition that $\mathbf{r}/\mathbf{r} = \hat{\mathbf{s}}$ then reproduces (10.108).

Lambertians We know from Sec. 10.2.1 that a Lambertian source has a radiant intensity that varies as $\cos \theta$, but (10.108) has a leading factor of $\cos^2 \theta$, so the integral in that equation must somehow provide a factor of $1/\cos \theta$ for a Lambertian.

As noted by Walther (1968), the correlation function of a quasimonochromatic Lambertian source must have the form

$$\langle u(\mathbf{r} + \frac{1}{2}\mathbf{r}') u^*(\mathbf{r} - \frac{1}{2}\mathbf{r}') \rangle \propto \text{sinc}(k\mathbf{r}'), \quad (10.110)$$

whenever $\mathbf{r} + \frac{1}{2}\mathbf{r}'$ and $\mathbf{r} - \frac{1}{2}\mathbf{r}'$ both lie within the source region. Since $k = 2\pi/\lambda$, the sinc function in (10.110) has a width of approximately λ . If the source region is large compared to λ , so that we need not fret much over limits, then the integral in (10.108) is approximately

$$\begin{aligned} &\int_{-\infty}^{\infty} d^2 r \int_{-\infty}^{\infty} d^2 r' \langle u(\mathbf{r} + \frac{1}{2}\mathbf{r}') u^*(\mathbf{r} - \frac{1}{2}\mathbf{r}') \rangle \exp(-ik \hat{\mathbf{s}} \cdot \mathbf{r}') \\ &\simeq A_s \int_{-\infty}^{\infty} d^2 r' \frac{\text{sinc}(k\mathbf{r}')}{k\mathbf{r}'} \exp(-ik \hat{\mathbf{s}} \cdot \mathbf{r}'), \end{aligned} \quad (10.111)$$

where A_s is the area of the source.

Since the integral is over the plane $z = 0$, we can replace \mathbf{r}' with its 2D counterpart \mathbf{r}' and write the scalar product $\hat{\mathbf{s}} \cdot \mathbf{r}'$ as $\mathbf{s}_{\perp} \cdot \mathbf{r}'$, where \mathbf{s}_{\perp} is the projection of $\hat{\mathbf{s}}$ onto the plane. Specifically, if θ and ϕ are the spherical polar coordinates of $\hat{\mathbf{s}}$ (with the z axis being the polar axis), then $\mathbf{s}_{\perp} = (\sin \theta \cos \phi, \sin \theta \sin \phi)$. Hence \mathbf{s}_{\perp} is not a unit vector.

With these notational changes, the integral is the 2D Fourier transform of a rotationally symmetric function, so it can be written with the aid of (3.248) as

$$\int_{-\infty}^{\infty} d^2 r' \frac{\text{sinc}(k\mathbf{r}')}{k\mathbf{r}'} \exp(-ik \hat{\mathbf{s}} \cdot \mathbf{r}') = 2\pi \int_0^{\infty} r' dr' \frac{\text{sinc}(kr')}{kr'} J_0(kr' s_{\perp}), \quad (10.112)$$

where $s_{\perp} = |\mathbf{s}_{\perp}| = \sin \theta$. A tabulated integral (6.671(7) in Gradshteyn and Ryzhik, 1980) then shows that

$$\int_0^{\infty} r' dr' \frac{\text{sinc}(kr')}{kr'} J_0(kr' s_{\perp}) = \frac{1}{k^2 \sqrt{1 - s_{\perp}^2}} = \frac{1}{k^2 \cos \theta}. \quad (10.113)$$

Thus the sinc-function correlation of (10.110) indeed implies a Lambertian character. Sarfatt (1963) showed that (10.110) is applicable to blackbodies, so blackbodies are Lambertian (see also Mandel and Wolf, 1976).

In fact, the sinc correlation is equivalent to saying that the radiation is completely randomized in direction. As an exercise, the reader can start with the mode expansion (10.12) and assume that the amplitudes are uncorrelated random variables and that every direction $\hat{\mathbf{k}}_j$ is equally probable. If it is assumed further that the source is observed through a narrowband filter so that only a small range of values for k_j contribute, then the sinc form (10.110) will be obtained.

Propagation through paraxial optical systems In Sec. 9.7.3 we discussed the Fresnel propagation of the scalar wave field through optical systems that can be described in geometrical optics by a 2×2 or 4×4 matrix. The key results cited there are the generalized Fresnel diffraction integral (9.255) and its special case, (9.250), which holds for systems with rotational symmetry.

Friberg (1991) computed the generalized radiance associated with the output field as given in (9.250), and the theory can be extended to make use of (9.255). The result is most neatly stated if we use 2D vectors as the arguments of the radiance and write

$$L_\nu(\mathbf{r}, \hat{\mathbf{s}}, \nu) = L \left(\begin{bmatrix} \mathbf{r} \\ \mathbf{s}_\perp \end{bmatrix} \right), \quad (10.114)$$

where we have dropped the ν argument and subscript, but a spectral radiance is still implied. With this notation, we can now append subscripts to distinguish the radiances associated with input and output fields for some optical system described by an **ABCD** matrix denoted **M**. As Friberg showed, these radiances are related by

$$L_{out} \left(\begin{bmatrix} \mathbf{r} \\ \mathbf{s}_\perp \end{bmatrix} \right) = L_{in} \left(\mathbf{M} \begin{bmatrix} \mathbf{r} \\ \mathbf{s}_\perp \end{bmatrix} \right). \quad (10.115)$$

Thus the radiance is constant along the ray defined by geometrical optics. The same conclusion was reached by Walther (1978) by a stationary-phase approximation, valid asymptotically in the limit of zero wavelength. Friberg's derivation does not require this limit (though it does use the Fresnel approximation), and it is valid for any state of coherence of the fields. Moreover, since it holds for all ν , (10.115) works for the overall radiance as well as the spectral radiance.

Some mathematical issues As noted in Sec. 5.2.1, the Wigner distribution function can take on negative values. Radiance, however, is defined in (10.62) in terms of nonnegative quantities, so the negative values of the generalized radiance are unphysical.

On the other hand, we know from (5.57) and (5.59) that an integral of the Wigner distribution function over either variable is nonnegative. In a radiometric context, the integral of $L(\mathbf{r}, \hat{\mathbf{s}}) \cos \theta$ over angles in a hemisphere is the radiant exitance (or irradiance), and the integral of the same quantity over area is radiant intensity. Fortunately, both of these integrals can be shown to be nonnegative, so the negative values of the generalized radiance do not affect the more directly measurable radiometric quantities (Marchand and Wolf, 1974*b*). In addition, Mandel and Wolf (1995) demonstrate that the generalized radiance itself turns out to be nonnegative for *quasistationary*⁹ sources, as defined in Sec. 8.2.4. This category includes thermal sources, diffuse reflectors and many other sources with short-range correlations.

Just as a bivariate probability density function (PDF) is not determined uniquely by its two marginals, neither is the radiance fully determined by the exitance and radiant intensity. As a result, several different definitions of generalized radiance have been proposed. Walther himself noted some conceptual problems with the Wigner definition and proposed an alternative (Walther, 1973; Baltes *et*

⁹The term *quasihomogeneous*, often used in the literature on radiometry and coherence, is synonymous with quasistationary, at least when spatial stationarity is being discussed.

al., 1978; Marchand and Wolf, 1974*b*). Since all of these definitions lead to the same expressions for exitance and intensity, and none avoids the negativity problem inherent in Walther's original approach, there is little reason to choose an alternative. Moreover, for quasistationary sources, the various definitions are equivalent (Mandel and Wolf, 1995).

Radiometry and Maxwell's equations Emil Wolf and his co-workers have developed an extensive and rigorous electromagnetic theory of radiative transfer in free space. (See Wolf, 1976; Wolf, 1978; Zubairy and Wolf, 1977; and Mandel and Wolf, 1995.) Fante (1981) extended the theory to inhomogeneous dielectric media and discussed the connection between Maxwell's equations and classical radiometry. Fante concludes that the generalized radiance, though it can go negative, satisfies the other postulates of classical radiative transfer if the source is either quasistationary or highly directional; the fluctuations in index of refraction are small and nearly stationary, and the longitudinal components of the field (components of \mathbf{E} parallel to \mathbf{k}) are small.

Quantum electrodynamics A fully quantum-mechanical definition of radiance can be given by an extension of ideas introduced in Sec. 10.1.3. A straightforward generalization of (10.99) is

$$L_\nu(\mathbf{r}, \hat{\mathbf{s}}, \nu) = \frac{\cos \theta}{\lambda^2} \int_{-\infty}^{\infty} d^2 r' \langle \hat{\mathbf{e}}^-(\mathbf{r} + \frac{1}{2}\mathbf{r}') \cdot \hat{\mathbf{e}}^+(\mathbf{r}' - \frac{1}{2}\mathbf{r}') \rangle \exp(-ik \hat{\mathbf{s}} \cdot \mathbf{r}'), \quad (10.116)$$

where the operators are defined below (10.22) and the angle brackets now denote a quantum-mechanical expectation. The other radiometric quantities can then be computed just as in the classical case. *E.g.*, radiant intensity is given by (10.107).

In most imaging applications, neither the classical electromagnetic approach nor the fully quantum-mechanical approach adds much to the more intuitive concept of photon, which we shall use throughout the remainder of this chapter.

10.3 BOLTZMANN TRANSPORT EQUATION

In Sec. 10.2 we introduced a menagerie of radiometric quantities, including the distribution function from which all of the other quantities can be derived. Now we shall derive an important equation that governs the spatio-temporal behavior of the distribution function.

This equation is known by various names in the literature. In statistical mechanics and neutron-transport theory, it is called the *Boltzmann equation*, and we shall adopt that terminology here. In optics, it is often called the *radiative transport equation*, or simply, the *transport equation*. In the quantum-optics literature, one often encounters the term *Fokker-Planck equation*, which describes a wide variety of equations for various distribution functions (Risken, 1984). For example, if we focus on the distribution of photon directions and energies, then we need the distribution function that is obtained from $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$ by integrating out the spatial dependence. The resulting reduced distribution function satisfies a certain Fokker-Planck equation. In this sense, the Boltzmann equation is the most general Fokker-Planck equation. Finally, one form of the *Liouville equation* is the Boltzmann equation without absorption or scattering terms.

We shall stick with the name Boltzmann equation in honor of the seminal contributions of Ludwig Boltzmann (1844–1906) in mechanics, statistics, radiation and thermodynamics. Boltzmann’s scientific vision had a large impact not only on these many fields but also on his own mental health, leading eventually to his tragic suicide; for a fascinating biography, see Cercignani (1998) .

The Boltzmann equation has many applications in imaging. In medical imaging it can be used to analyze the distribution of x rays in chest radiography and computed tomography, gamma rays in nuclear medicine, or infrared photons in breast imaging. In optical imaging it can be used to discuss scattering by the atmosphere or ocean.

Though a useful tool in all of these areas, the Boltzmann equation is not a complete description since it ignores the wave aspects of the radiation. When applied to optics, the Boltzmann equation treats light as if it were made up of localized photons. Interference and diffraction effects are not accounted for, and the photons are assumed to travel in straight lines in homogeneous media. In this sense, transport theory and the Boltzmann equation make the same approximations as in geometric optics.

10.3.1 Derivation of the Boltzmann equation

The Boltzmann equation is an equation for the time derivative of $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$, or w for short. This derivative has contributions from the physical processes of absorption, emission, propagation and scattering of radiation, so we have

$$\frac{dw}{dt} = \left[\frac{\partial w}{\partial t} \right]_{abs} + \left[\frac{\partial w}{\partial t} \right]_{em} + \left[\frac{\partial w}{\partial t} \right]_{prop} + \left[\frac{\partial w}{\partial t} \right]_{sc}, \quad (10.117)$$

where the subscripts have the obvious meanings. We examine each of these terms in succession.

Absorption Suppose we have ΔN identical atoms in a small volume ΔV in a medium where the distribution function is w . If we consider only photons travelling in a small solid angle $\Delta\Omega$ around direction $\hat{\mathbf{s}}$ and having energies in a narrow range $(\mathcal{E}, \mathcal{E} + \Delta\mathcal{E})$, then the irradiance on the atoms in a plane normal to $\hat{\mathbf{s}}$ is $I_0 = c_m \mathcal{E} w \Delta\mathcal{E} \Delta\Omega$. We assume that the atoms absorb radiation independently of each other.

From (10.91), the total energy absorbed by this group of atoms in time Δt is $\Delta N \sigma_{abs} I_0 \Delta t = c_m \mathcal{E} \Delta N \sigma_{abs} w \Delta\mathcal{E} \Delta\Omega \Delta t$. From the definition of w , (10.95), the corresponding change in w is given by

$$\Delta w = - \frac{c_m \mathcal{E} \Delta N \sigma_{abs} w \Delta\mathcal{E} \Delta\Omega \Delta t}{\mathcal{E} \Delta\mathcal{E} \Delta V \Delta\Omega} = - \frac{\Delta N c_m \sigma_{abs} w \Delta t}{\Delta V}. \quad (10.118)$$

If we divide through by Δt and let all small quantities tend to zero, we find

$$\left[\frac{\partial w}{\partial t} \right]_{abs} = -c_m \mu_{abs} w, \quad (10.119)$$

where μ_{abs} is the *absorption coefficient*, defined by

$$\mu_{abs} = n_{abs} \sigma_{abs}, \quad (10.120)$$

and $n_{abs} = \Delta N/\Delta V$ is the number of absorbing atoms per unit volume. Since n_{abs} has units of reciprocal volume and σ_{abs} is an area, μ_{abs} has units of reciprocal length. The interpretation of that length will be seen in Sec. 10.3.3.

If there are several different kinds of atoms or other absorbing particles interspersed in the same volume, then we define

$$\mu_{abs} = \sum_j n_{abs,j} \sigma_{abs,j}, \quad (10.121)$$

where subscript j identifies a particular species. With this definition, (10.119) still holds if each species absorbs radiation independently of the others, a valid assumption for x-ray or gamma-ray absorption and for optical absorption by isolated impurities in solids.

Note that both μ_{abs} and c_m can depend on wavelength or energy of the radiation, position in the medium and time. In addition, c_m depends on direction of propagation in anisotropic media. (Anisotropic absorption can also occur, but is rare.)

Emission To determine the effect of emission of radiation on w , we need the quantities $\Xi_{p,\mathcal{E}}$ and $S_{p,\mathcal{E}}$ defined in Sec. 10.2.2. It follows immediately from these definitions, along with the definition of w in (10.95), that

$$\left[\frac{\partial w}{\partial t} \right]_{em} = \Xi_{p,\mathcal{E}} = \frac{1}{4\pi} S_{p,\mathcal{E}}, \quad (10.122)$$

where the second form holds for an isotropic emitter. Recall that $S_{p,\mathcal{E}}(\mathbf{r}, \mathcal{E})\Delta V\Delta\mathcal{E}$ is the total number of photons per second emitted from volume ΔV in energy range $\Delta\mathcal{E}$, while $\Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})\Delta V\Delta\mathcal{E}\Delta\Omega$ is the total number of photons per second emitted from volume ΔV in energy range $\Delta\mathcal{E}$ and solid angle $\Delta\Omega$ about direction $\hat{\mathbf{s}}$. The dimensions in (10.122) are consistent if the factor of $1/4\pi$ is assigned dimensions of inverse steradians.

If the emission is monoenergetic at photon energy \mathcal{E}_0 , we have

$$\left[\frac{\partial w}{\partial t} \right]_{em} = \Xi_p \delta(\mathcal{E} - \mathcal{E}_0) = \frac{1}{4\pi} S_p \delta(\mathcal{E} - \mathcal{E}_0). \quad (10.123)$$

Again, the second form is only for an isotropic emitter; it applies, for example, to a radioactive source.

Propagation in a homogeneous medium In a homogeneous medium where the speed of light c_m is a constant, it is straightforward to compute the propagation term in the Boltzmann equation. In a short time interval Δt , photons at point \mathbf{r} travelling in direction $\hat{\mathbf{s}}$ move to point $\mathbf{r} + c_m\Delta t\hat{\mathbf{s}}$, so

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = w(\mathbf{r} + c_m\Delta t\hat{\mathbf{s}}, \hat{\mathbf{s}}, \mathcal{E}, t + \Delta t). \quad (10.124)$$

Expanding the right-hand side in a Taylor series yields

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) + c_m\Delta t\hat{\mathbf{s}} \cdot \nabla w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) + \Delta t \left[\frac{\partial}{\partial t} w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) \right]_{prop}. \quad (10.125)$$

The time derivative in the last term is the desired $[\partial w/\partial t]_{prop}$, so we have

$$\left[\frac{\partial w}{\partial t} \right]_{prop} = -c_m \hat{\mathbf{s}} \cdot \nabla w. \quad (10.126)$$

Propagation in inhomogeneous media The form of the propagation term in (10.126) assumes that the speed of light in the medium, c_m , is a constant, but there are many situations where we need to consider a variable speed of light. We saw in Sec. 9.1.4 that $c_m = c/n$, where n is the index of refraction of the medium, and in general we should write the index as a function of position $n(\mathbf{r})$. We need to distinguish three distinct kinds of spatial variations of the refractive index: slow variations, point variations and abrupt changes at interfaces.

The index variations can be considered slow if $n(\mathbf{r})$ is approximately the same at two points one wavelength apart. Mathematically, the condition is $k|\nabla n(\mathbf{r})| \ll 1$, where, as usual, $k = 2\pi/\lambda$. Slow variations may be introduced deliberately as in gradient-index (GRIN) optics in order to focus the light, or they may be random as in propagation of light through the atmosphere. The effect of such variations is that the light follows a complicated curved path, which can be determined by solving the eikonal equation (9.348) or by including an additional term in the Boltzmann equation (Ferwerda, 1999).

Point variations are ones for which $n(\mathbf{r})$ is a constant except over a discrete set of regions which are all small compared to a wavelength. For example, small (subwavelength) bubbles in glass or dust particles in the atmosphere might be well modeled as point variations. The effect of point variations is to scatter the radiation, so these effects are best described by a scattering cross section (see Sec. 10.2.5) rather than in terms of a position-dependent refractive index. Point scatterers can be treated by including a scattering term in the Boltzmann equation.

An important kind of inhomogeneity occurs at the interface between two different homogeneous media, for example at a glass-air interface on the surface of a lens. We do not need a separate term in the Boltzmann equation to account for such interfaces since we can solve the equation separately in each homogeneous medium and then match boundary conditions to get the full solution. Interfaces are discussed in more detail in Sec. 10.3.2.

Scattering Scattering has two effects on the distribution function. Consider photons in a small volume element ΔV travelling in a small solid angle $\Delta\Omega$ and having energies in a narrow range $(\mathcal{E}, \mathcal{E} + \Delta\mathcal{E})$. The mean number of photons in this group is $w\Delta\Omega\Delta\mathcal{E}\Delta V$. Scattering processes occurring in the volume element can either increase or decrease the number of photons in this group. The decrease comes about because photons in the group can change direction, energy or both as a result of scattering. On the other hand, photons not in the group under consideration can scatter *into* the angular range $\Delta\Omega$ and the energy band $\Delta\mathcal{E}$.

Scattering out of the group is described by exactly the same mathematics as in the absorption case; as far as removal from the group is concerned, there is no distinction between absorption and scattering. Thus we can write at once, by analogy to (10.119),

$$\left[\frac{\partial w}{\partial t} \right]_{out} = -c_m \mu_{sc} w, \quad (10.127)$$

where μ_{sc} , called the *scattering coefficient* or *linear attenuation coefficient for scattering*, is defined by

$$\mu_{sc} = n_{sc}\sigma_{sc}, \quad (10.128)$$

and n_{sc} is the number of scatterers per unit volume. As in the absorption term, μ_{sc} can depend on position, time, photon energy and possibly direction $\hat{\mathbf{s}}$.

Scattering into the group under consideration is more complicated. It has to involve integrals over energy and direction since photons of any energy or direction can, in principle, scatter into the group. On the other hand, no integral over position or time is needed since the scattering processes occur at a definite location and definite time. Thus we are looking for an integral transform that connects $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$ to $w(\mathbf{r}, \hat{\mathbf{s}}', \mathcal{E}', t)$ for all other $\hat{\mathbf{s}}'$ and \mathcal{E}' .

At this point an important distinction between optics and statistical mechanics arises. In the latter field, the dominant scattering occurs between molecules, so the probability of scattering depends on a product of the form $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)w(\mathbf{r}, \hat{\mathbf{s}}', \mathcal{E}', t)$, which makes the scattering term in the Boltzmann equation a nonlinear function of w . In optics and radiology, however, the distribution of scattering centers has nothing to do with w ; the scattering characteristics are determined by electrons, atoms and molecules in the medium, while w relates to the distribution of photons. Since photons do not scatter off other *photons*, the Boltzmann equation is linear.¹⁰

The general form of the term that describes scattering into the group of interest is thus

$$\left[\frac{\partial}{\partial t} w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) \right]_{in} = \int_{4\pi} d\Omega' \int_0^\infty d\mathcal{E}' K(\hat{\mathbf{s}}, \mathcal{E}; \hat{\mathbf{s}}', \mathcal{E}' | \mathbf{r}, t) w(\mathbf{r}, \hat{\mathbf{s}}', \mathcal{E}', t). \quad (10.129)$$

The kernel $K(\hat{\mathbf{s}}, \mathcal{E}; \hat{\mathbf{s}}', \mathcal{E}' | \mathbf{r}, t)$ can depend on both the initial and final energy and direction, and it can also depend on position \mathbf{r} in the medium and, for time-varying media, on the time t . Since it is reasonable to assume that the scatterers are randomly oriented, the dependence on $\hat{\mathbf{s}}$ and $\hat{\mathbf{s}}'$ is through the scalar product $\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}'$.

If we think of the scattering centers as mathematical points, then the kernel $K(\hat{\mathbf{s}}, \mathcal{E}; \hat{\mathbf{s}}', \mathcal{E}' | \mathbf{r}, t)$ should be written as a sum of spatial delta functions with weights dependent on the other variables. This kind of description, called a *point process*, is discussed in detail in Chap. 11. In practice, however, we would rarely have enough knowledge of the medium to specify the location of these points. Usually the best we can do is specify an average density of scatterers $n_{sc}(\mathbf{r})$, defined such that $n_{sc}(\mathbf{r})\Delta V$ is the mean number of scattering centers in a small (but not infinitesimal) volume ΔV centered on \mathbf{r} .

We can assume that each scatterer is described by a differential scattering cross section per unit energy $\partial^2\sigma_{sc}/\partial\Omega\partial\mathcal{E}$ as discussed in Sec. 10.2.5. Then, by arguments similar to those used earlier (really little more than dimensional analysis), we find that

$$K(\hat{\mathbf{s}}, \mathcal{E}; \hat{\mathbf{s}}', \mathcal{E}' | \mathbf{r}, t) = c_m n_{sc} \frac{\partial^2\sigma_{sc}}{\partial\Omega\partial\mathcal{E}}. \quad (10.130)$$

¹⁰Nonlinear optical processes do, of course, occur, but only at high intensities and in carefully controlled experimental geometries. Unless one sets out to do a nonlinear optical experiment, it is probably safe to ignore nonlinear effects.

To simplify the notation, we denote the operator defined by (10.129) and (10.130) as \mathcal{K} and write

$$\left[\frac{\partial w}{\partial t} \right]_{scat} = \left[\frac{\partial w}{\partial t} \right]_{in} + \left[\frac{\partial w}{\partial t} \right]_{out} = \mathcal{K}w - c_m \mu_{sc} w. \quad (10.131)$$

Complete equation Collecting together (10.119), (10.122), (10.126) and (10.131), we get the following form for the Boltzmann equation:

$$\frac{dw}{dt} = -c_m \mu_{tot} w + \Xi_{p,\mathcal{E}} + \mathcal{K}w - c_m \hat{\mathbf{s}} \cdot \nabla w, \quad (10.132)$$

where μ_{tot} is the total attenuation coefficient, given by

$$\mu_{tot} = \mu_{sc} + \mu_{abs} = n_{sc} \sigma_{sc} + n_{abs} \sigma_{abs}. \quad (10.133)$$

In (10.132), w , $\Xi_{p,\mathcal{E}}$ and μ_{tot} can depend, in general, on \mathbf{r} , \mathcal{E} , $\hat{\mathbf{s}}$ and t . Similarly, the kernel of the operator \mathcal{K} can depend on \mathbf{r} and t , and it couples w at one $\hat{\mathbf{s}}$ and \mathcal{E} , in general, to w at all other $\hat{\mathbf{s}}$ and \mathcal{E} . On the other hand, our derivations considered the speed of light c_m just to be a constant; point variations in refractive index are included in the scattering term, but we postpone any discussion of slow variations in index or interfaces between media with different indices.

10.3.2 Steady-state solutions in non-absorbing media

In many problems we are interested in steady-state solutions to the Boltzmann equation, where $dw/dt = 0$. For example, in medical applications with either light or x rays, the transit time of photons across the body is only a few nanoseconds. If the radiation source is independent of time, or at least slowly varying on the nanosecond scale, then the distribution function reaches its steady-state value very quickly. Only when the source or the medium is varying rapidly do we need the full time-dependent Boltzmann equation. When it is necessary to include the arguments, we shall denote a steady-state solution by $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$, without a time argument.

Emission and propagation terms In a medium with no absorption or scattering, the Boltzmann equation consists of just the source term and the propagation term; the steady-state equation is then

$$c_m \hat{\mathbf{s}} \cdot \nabla w = \Xi_{p,\mathcal{E}}. \quad (10.134)$$

To solve this equation, we choose a Cartesian coordinate system such that the z axis is parallel to $\hat{\mathbf{s}}$. Then $\hat{\mathbf{s}} \cdot \nabla = \frac{\partial}{\partial z}$, and (10.134) reduces to an ordinary differential equation in z , which integrates to

$$w(x, y, z, \hat{\mathbf{s}}, \mathcal{E}) = \frac{1}{c_m} \int_{-\infty}^z dz' \Xi_{p,\mathcal{E}}(x, y, z', \hat{\mathbf{s}}, \mathcal{E}). \quad (10.135)$$

No constant of integration is needed if there is no radiation source other than $\Xi_{p,\mathcal{E}}$.

Defining $\ell = z - z'$ and reverting to a general vector notation, we have

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = \frac{1}{c_m} \int_0^{\infty} d\ell \Xi_{p,\mathcal{E}}(\mathbf{r} - \hat{\mathbf{s}}\ell, \hat{\mathbf{s}}, \mathcal{E}). \quad (10.136)$$

The interpretation of this equation is that $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ is obtained by integrating the source distribution along a line parallel to $\hat{\mathbf{s}}$ and passing through the point \mathbf{r} . Only photons originating along this line can contribute to the distribution function with the specified \mathbf{r} and $\hat{\mathbf{s}}$, and of those originating along the line, only those travelling in direction $\hat{\mathbf{s}}$ contribute. Only positive values of ℓ are needed since photons originating at a point $\mathbf{r} + \hat{\mathbf{s}}|\ell|$ propagate away from the observation point \mathbf{r} .

Equation (10.136) defines an integral transform, known as the *x-ray transform*,¹¹ which maps a function of \mathbf{r} and $\hat{\mathbf{s}}$ to another function of \mathbf{r} and $\hat{\mathbf{s}}$. We shall denote this operator as \mathcal{X} and write (10.136) symbolically as

$$w = \mathcal{X}\Xi_{p,\mathcal{E}}. \quad (10.137)$$

Note that we are now including the factor $1/c_m$ in the definition of \mathcal{X} , so the operator is dimensionally a time. This factor will be dropped in Chap. 16 when we discuss actual x-ray applications of the x-ray transform.

Optical case Many problems in optics involve propagation of radiation in a homogeneous, source-free medium with no absorption or scattering. In that case, the steady-state Boltzmann equation is just

$$\hat{\mathbf{s}} \cdot \nabla w = 0. \quad (10.138)$$

This form implies that w is constant in direction $\hat{\mathbf{s}}$.

Recall from (10.98) that $L_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = c_m(\mathbf{r}) w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$. Since c_m is a constant in a homogeneous medium, (10.138) shows that $L_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)$ is also constant along $\hat{\mathbf{s}}$. This conclusion is true for all \mathcal{E} , and we can drop the t dependence in steady-state situations, so the total radiance $L(\mathbf{r}, \hat{\mathbf{s}})$ is constant. We can move an arbitrary distance in direction $\hat{\mathbf{s}}$ and $L(\mathbf{r}, \hat{\mathbf{s}})$ does not change. In the optics literature, this result is often capsulized by saying that radiance is constant along the ray.

Constant radiance, however, does not imply constant irradiance on a detector or other surface. To illustrate this point, we consider a uniform volume radiator in the form of a disc of diameter D and thickness a (see Fig. 10.6). At a point along the positive z axis (which is the axis of the disc), the spectral photon radiance in the z direction is given by (10.98) and (10.136) as

$$L_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{z}}) = \frac{a}{4\pi} S_0, \quad (10.139)$$

where the factor of a results from the line integral through the disc and S_0 is the value of $S_{p,\mathcal{E}}(\mathbf{r})$ inside the disc. Thus $L_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{z}})$ remains constant as we move along the z axis, in direction $\hat{\mathbf{z}}$. If we consider a general direction $\hat{\mathbf{s}}$, however, $L_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}})$ will be zero unless we can draw a line from point \mathbf{r} backwards in the direction $-\hat{\mathbf{s}}$ to the source. If this line misses the source, the line integral in (10.136) is zero. Thus, the radiance at point \mathbf{r} is zero except for a range of directions $\hat{\mathbf{s}}$ defined by the angular subtense of the source at the point.

¹¹The name of this transform comes about since it was originally defined in the radiology literature, but there is nothing in the mathematics specific to x rays. Moreover, some authors in radiology would call (10.136) the *cone-beam transform* in general, reserving the term *x-ray transform* for the special case where all rays are parallel. For more details on cone-beam tomography, see Chap. 17.

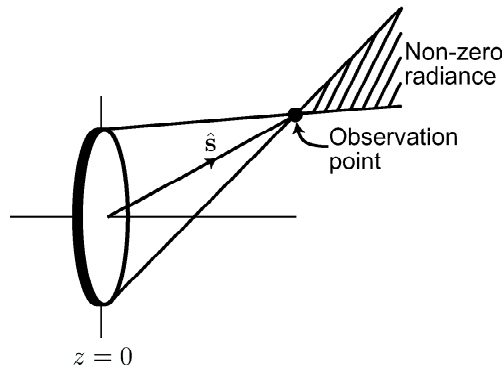

Fig. 10.6 Diagram for illustrating the relation between radiance and irradiance.

The spectral photon irradiance is obtained by integrating the corresponding radiance over angles [cf. (10.79)]:

$$I_{p,\varepsilon} = \int_{2\pi} d\Omega L_{p,\varepsilon}(\mathbf{r}, \hat{\mathbf{s}}) \cos \theta. \tag{10.140}$$

If the point \mathbf{r} is on the z axis and $z \gg D$, then the source subtends a solid angle of $\Delta\Omega = \pi D^2/4z^2$, and the radiance is given by (10.139) for all $\hat{\mathbf{s}}$ in this range. Since $\cos \theta \simeq 1$ with these assumptions, we have

$$I_{p,\varepsilon} = \frac{D^2}{16z^2} aS_0. \tag{10.141}$$

Now we see the familiar inverse-square law; the irradiance varies inversely as the square of the distance from the source, so long as that distance is sufficiently large that all cosine factors can be approximated by unity. The radiance, on the other hand, is power per unit (projected) area per unit solid angle, so it varies as $I/\Delta\Omega$, and both I and $\Delta\Omega$ vary as $1/z^2$, leaving the radiance independent of z .

Fig. 10.7 Diagram illustrating the change of radiance at a smooth interface. (a) Normal incidence. (b) Oblique incidence.

Interfaces From the discussion of Snell’s law in Chap. 9, we know what happens to light at a smooth interface between media with different refractive indices. In particular, (9.148) gives an explicit expression for the direction $\hat{\mathbf{s}}_{tr}$ of the transmitted light when the incident direction $\hat{\mathbf{s}}_{inc}$ and the indices are known, and (9.149) is a

similar expression for the reflected direction. Now we need to determine what happens to the radiance across this interface.

The interface plane is defined as $z = 0$, and the index of refraction is n for $z < 0$ and n' for $z > 0$. As in Sec. 9.2.1, the projection of $\hat{\mathbf{s}}_{inc}$ onto the x - z plane makes an angle θ_x with the z axis and the projection onto the y - z plane makes an angle θ_y with the z axis. Similarly, $\hat{\mathbf{s}}_{tr}$ is defined by angles θ'_x and θ'_y . Snell's law shows that

$$n \sin \theta_x = n' \sin \theta'_x; \quad n \sin \theta_y = n' \sin \theta'_y. \quad (10.142)$$

As seen in Fig. 10.7, Snell's law causes the light to diverge at the interface upon entering a medium with smaller index. Differentiating (10.142), we find

$$n \Delta \theta_x \cos \theta_x = n' \Delta \theta'_x \cos \theta'_x; \quad n \Delta \theta_y \cos \theta_y = n' \Delta \theta'_y \cos \theta'_y. \quad (10.143)$$

At normal incidence, all of the cosines are one, so $n^2 \Delta \Omega = n'^2 \Delta \Omega'$, where $\Delta \Omega = \Delta \theta_x \Delta \theta_y$ and $\Delta \Omega' = \Delta \theta'_x \Delta \theta'_y$. In this case, the total flux incident on a small area ΔA on the interface is given by $L \Delta A \Delta \Omega$. By conservation of energy, exactly the same flux must emerge from the area, part of it in the reflected beam and part in the transmitted beam. Therefore, at normal incidence, we must have

$$L_{inc} \Delta \Omega = L_{refl} \Delta \Omega + L_{tr} \Delta \Omega'. \quad (10.144)$$

If we denote by R the fraction of the energy reflected and by $T \equiv 1 - R$ the fraction transmitted, then the transmitted radiance must satisfy

$$\frac{1}{n'^2} L_{tr} = \frac{T}{n^2} L_{inc}. \quad (10.145)$$

For a glass-air interface, $R \simeq 0.04$ and $T \simeq 0.96$, and it is common to approximate T as unity. With that approximation, (10.145) shows that L/n^2 is conserved across the interface. To be explicit, L here refers to $L(\mathbf{r}, \hat{\mathbf{n}})$, where $\hat{\mathbf{n}}$ is normal to the interface and \mathbf{r} is any point on the interface.

The calculation is similar for oblique incidence, but we must remember that radiance is defined in terms of projected area. If we consider $\hat{\mathbf{s}}_{inc}$ in the x - z plane, then we can still take $\cos \theta_y \simeq \cos \theta'_y \simeq 1$, but we must retain the cosines in the x direction. Now the projected area is $\Delta A \cos \theta_x$ and the total flux incident on ΔA is given by $L \Delta A \Delta \Omega \cos \theta_x$. The solid angle $\Delta \Omega$ is still $\Delta \theta_x \Delta \theta_y$, and a little algebra shows that (10.145) still holds. Explicitly,

$$\frac{1}{n'^2} L_{tr}(\mathbf{r}, \hat{\mathbf{s}}_{tr}) = \frac{T}{n^2} L_{inc}(\mathbf{r}, \hat{\mathbf{s}}_{inc}), \quad (10.146)$$

where $\hat{\mathbf{s}}_{tr}$ is related to $\hat{\mathbf{s}}_{inc}$ and $\hat{\mathbf{n}}$ by (9.148). Up to reflection losses, then, L/n^2 is conserved along a ray direction defined by Snell's law.

10.3.3 Steady-state solutions in absorbing media

Now we can add absorption to the treatment above. With the absorption term and a general volume source, the steady-state Boltzmann equation is

$$\hat{\mathbf{s}} \cdot \nabla w = \frac{1}{c_m} \Xi_{p,\varepsilon} - \mu_{abs} w. \quad (10.147)$$

In a Cartesian coordinate system with the z axis parallel to $\hat{\mathbf{s}}$, (10.147) is again an ordinary differential equation in z , as it was in Sec. 10.3.2, but now the coefficients are not constant. In particular, μ_{abs} is a function of z , in general, so we incorporate an integrating factor by defining

$$\tilde{w}(z) = w(x, y, z, \hat{\mathbf{s}}, \mathcal{E}) \exp \left[\int_{-\infty}^z dz'' \mu_{abs}(x, y, z'', \mathcal{E}) \right], \quad (10.148)$$

where we show all of the arguments on the right for clarity but focus on the z dependence on the left. Of course, \tilde{w} is still a function of the other variables.

With this substitution, the equation for \tilde{w} is

$$\frac{\partial \tilde{w}}{\partial z} = \frac{1}{c_m} \Xi_{p, \mathcal{E}}(z) \exp \left[\int_{-\infty}^z dz'' \mu_{abs}(z'') \right]. \quad (10.149)$$

The solution for \tilde{w} is obtained by simple integration, and then the original w is given by

$$\begin{aligned} w &= \exp \left[- \int_{-\infty}^z dz'' \mu_{abs}(z'') \right] \frac{1}{c_m} \int_{-\infty}^z dz' \Xi_{p, \mathcal{E}}(z') \exp \left[\int_{-\infty}^{z'} dz'' \mu_{abs}(z'') \right] \\ &= \frac{1}{c_m} \int_{-\infty}^z dz' \Xi_{p, \mathcal{E}}(z') \exp \left[- \int_{z'}^z dz'' \mu_{abs}(z'') \right]. \end{aligned} \quad (10.150)$$

In a vector notation analogous to (10.136) (and with all of the variables reinstated), we can write

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = \frac{1}{c_m} \int_0^{\infty} dl \Xi_{p, \mathcal{E}}(\mathbf{r} - \hat{\mathbf{s}}l, \hat{\mathbf{s}}, \mathcal{E}) \exp \left[- \int_0^l dl' \mu_{abs}(\mathbf{r} - \hat{\mathbf{s}}l', \mathcal{E}) \right]. \quad (10.151)$$

As in (10.136), $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ is still found by integrating the source distribution along a line parallel to $\hat{\mathbf{s}}$ and passing through the point \mathbf{r} , but more distant points along this line contribute less because of the exponential attenuation factor.

We can now see the interpretation of μ_{abs} ; if it is independent of \mathbf{r} , then radiation traversing a distance ℓ is attenuated by a factor of $\exp(-\mu_{abs}\ell)$, so μ_{abs} is the reciprocal of the distance required for attenuation by $1/e$. If μ_{abs} depends on position, however, the attenuation is determined by a line integral of μ_{abs} .

The integral in (10.151) defines the *attenuated x-ray transform* \mathcal{X}_μ . Like the x-ray transform, \mathcal{X}_μ maps a function of \mathbf{r} and $\hat{\mathbf{s}}$ to another function of \mathbf{r} and $\hat{\mathbf{s}}$. In terms of this operator, (10.151) is

$$w = \mathcal{X}_\mu \Xi_{p, \mathcal{E}}. \quad (10.152)$$

As we shall see in Chap. 16, this transform is fundamental to emission-imaging modalities such as nuclear medicine and fluorescence microscopy in which the object is the radiation source but there is significant self-absorption of the radiation in the object.

Point sources In many kinds of imaging, including transmission microscopy and radiography with x rays, we are interested in the attenuating properties of the medium rather than the properties of the source. In these cases we can choose the

form of the source in order to facilitate probing of the attenuation distribution. A common choice is a very small source, approximating a mathematical point. In radiography, for example, x rays are generated by focusing a beam of electrons on a metal target, and it is desirable to make the focal spot as small as possible.

An ideal point source at point \mathbf{r}_0 is described by

$$\Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = A \delta(\mathbf{r} - \mathbf{r}_0). \quad (10.153)$$

The strength A of the delta function can, in general, depend on energy \mathcal{E} , but to focus on the spatial structure we treat A as a constant and drop the \mathcal{E} argument in μ_{abs} .

When we insert (10.153) into (10.151), the result is

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = \frac{A}{c_m} \int_0^\infty d\ell \delta(\mathbf{r} - \mathbf{r}_0 - \hat{\mathbf{s}}\ell) \exp \left[- \int_0^\ell d\ell' \mu_{abs}(\mathbf{r} - \hat{\mathbf{s}}\ell') \right]. \quad (10.154)$$

The argument of the delta function vanishes when $\mathbf{r} - \mathbf{r}_0 = \hat{\mathbf{s}}\ell$, which requires that

$$\hat{\mathbf{s}} = \frac{\mathbf{r} - \mathbf{r}_0}{|\mathbf{r} - \mathbf{r}_0|} \quad (10.155)$$

and

$$\ell = |\mathbf{r} - \mathbf{r}_0|. \quad (10.156)$$

If we substitute (10.156) for ℓ in the upper limit of the integral over ℓ' in (10.154), we can write

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = \frac{A}{c_m} \exp \left[- \int_0^{|\mathbf{r} - \mathbf{r}_0|} d\ell' \mu_{abs}(\mathbf{r} - \hat{\mathbf{s}}\ell') \right] \int_0^\infty d\ell \delta(\mathbf{r} - \mathbf{r}_0 - \hat{\mathbf{s}}\ell). \quad (10.157)$$

The remaining integral is a representation of an angular delta function, enforcing the condition (10.155). Before continuing with the discussion of (10.157), we must derive a new representation of such delta functions.

Digression: Angular delta functions An angular delta function was defined in Sec. 2.4.7 by requiring that

$$\int_{4\pi} d\Omega_s \delta(\hat{\mathbf{s}} - \hat{\mathbf{s}}_0) t(\hat{\mathbf{s}}) = t(\hat{\mathbf{s}}_0), \quad (10.158)$$

where $d\Omega_s$ is the element of solid angle associated with $\hat{\mathbf{s}}$, and $t(\hat{\mathbf{s}})$ is a test function in the angular variables.

With this notation, we shall now show that

$$|\mathbf{r} - \mathbf{r}_0|^2 \int_0^\infty d\ell \delta(\mathbf{r} - \mathbf{r}_0 - \hat{\mathbf{s}}\ell) = \delta \left(\hat{\mathbf{s}} - \frac{\mathbf{r} - \mathbf{r}_0}{|\mathbf{r} - \mathbf{r}_0|} \right). \quad (10.159)$$

To demonstrate that this equation is correct, we multiply both sides by an arbitrary angular test function $t(\hat{\mathbf{s}})$ and integrate over solid angle. The integral on the left-hand side becomes

$$|\mathbf{r} - \mathbf{r}_0|^2 \int_{4\pi} d\Omega_s t(\hat{\mathbf{s}}) \int_0^\infty d\ell \delta(\mathbf{r} - \mathbf{r}_0 - \hat{\mathbf{s}}\ell) = \int_{4\pi} d\Omega_s \int_0^\infty \ell^2 d\ell t(\hat{\mathbf{s}}) \delta(\mathbf{r} - \mathbf{r}_0 - \hat{\mathbf{s}}\ell), \quad (10.160)$$

where we have moved $|\mathbf{r} - \mathbf{r}_0|^2$ inside the integral and replaced it with ℓ^2 by use of (10.156). Now we can define a 3D vector $\mathbf{r}_s = \hat{\mathbf{s}}\ell$ and recognize that $d^3\mathbf{r}_s = \ell^2 d\ell d\Omega_s$. This substitution puts the integral into the correct form for applying the familiar 3D sifting property, and we obtain

$$|\mathbf{r} - \mathbf{r}_0|^2 \int_{4\pi} d\Omega_s t(\hat{\mathbf{s}}) \int_0^\infty d\ell \delta(\mathbf{r} - \mathbf{r}_0 - \hat{\mathbf{s}}\ell) = \int_\infty d^3\mathbf{r}_s t(\hat{\mathbf{s}}) \delta(\mathbf{r} - \mathbf{r}_0 - \mathbf{r}_s) = t\left(\frac{\mathbf{r} - \mathbf{r}_0}{|\mathbf{r} - \mathbf{r}_0|}\right). \quad (10.161)$$

Exactly the same result would be obtained with the right-hand side of (10.159) and the angular sifting property (10.158), so (10.161) proves the validity of (10.159).

Return With (10.159), (10.157) becomes

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = \frac{A}{c_m} \exp\left[-\int_0^{|\mathbf{r} - \mathbf{r}_0|} d\ell' \mu_{abs}(\mathbf{r} - \hat{\mathbf{s}}\ell')\right] \frac{\delta\left(\hat{\mathbf{s}} - \frac{\mathbf{r} - \mathbf{r}_0}{|\mathbf{r} - \mathbf{r}_0|}\right)}{|\mathbf{r} - \mathbf{r}_0|^2}. \quad (10.162)$$

The inverse-square factor might surprise the reader, but it is consistent with our previous conclusions. In the absence of attenuation, we showed that the radiance (and hence w) was constant along the direction $\hat{\mathbf{s}}$, with no inverse-square factor. From (10.162), we see only that w is infinite for all distances when $\hat{\mathbf{s}}$ is directed precisely away from the source, and it is zero for all distances for any other $\hat{\mathbf{s}}$. The inverse-square factor is evident only when one performs an angular integral as in (10.140) to get irradiance. This integral can be performed via (10.158), and the resulting spectral photon irradiance (measured at point \mathbf{r} on a surface normal to the line of sight to the source) is

$$I_{p,\mathcal{E}} = \frac{A}{|\mathbf{r} - \mathbf{r}_0|^2} \exp\left[-\int_0^{|\mathbf{r} - \mathbf{r}_0|} d\ell' \mu_{abs}\left(\mathbf{r} - \frac{\mathbf{r} - \mathbf{r}_0}{|\mathbf{r} - \mathbf{r}_0|}\ell'\right)\right]. \quad (10.163)$$

As expected, the irradiance diminishes as the inverse square of the distance from the source, and it is further attenuated by an exponential factor involving the integral of the total attenuation coefficient along the path.

For fixed locations of the source and observation point, (10.163) shows that the log of the irradiance is linearly related to the line integral of the attenuation coefficient. We shall have much more to say about this relation in Chap. 16 when we discuss x-ray imaging.

10.3.4 Scattering effects

Now we consider the full steady-state Boltzmann equation with the scattering term:

$$\hat{\mathbf{s}} \cdot \nabla w = \frac{1}{c_m} \Xi_{p,\mathcal{E}} - \mu_{tot} w + \frac{1}{c_m} \mathcal{K} w. \quad (10.164)$$

Because of the scattering term, this equation cannot be solved by simple integration, but an integral along $\hat{\mathbf{s}}$ is nevertheless useful. It transforms (10.164) to

$$\begin{aligned}
 w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) &= \frac{1}{c_m} \int_0^\infty d\ell \Xi_{p,\mathcal{E}}(\mathbf{r} - \hat{\mathbf{s}}\ell, \hat{\mathbf{s}}, \mathcal{E}) \exp \left[- \int_0^\ell d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell') \right] \\
 &+ \frac{1}{c_m} \int_0^\infty d\ell [\mathcal{K}w](\mathbf{r} - \hat{\mathbf{s}}\ell, \hat{\mathbf{s}}, \mathcal{E}) \exp \left[- \int_0^\ell d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell') \right]. \quad (10.165)
 \end{aligned}$$

This equation is not a solution since the unknown w still appears in the second integral. With the operators defined above, (10.165) can be written as

$$w = \mathcal{X}_\mu \Xi_{p,\mathcal{E}} + \mathcal{X}_\mu \mathcal{K}w, \quad (10.166)$$

or

$$[\mathbf{I} - \mathcal{X}_\mu \mathcal{K}]w = \mathcal{X}_\mu \Xi_{p,\mathcal{E}}, \quad (10.167)$$

where \mathbf{I} is the identity operator. Since \mathcal{X}_μ and \mathcal{K} are integral operators, (10.167) is really an integral equation for w .

A formal solution of (10.167) is given by the Neumann series (introduced in App. A and discussed in more detail in Chap. 1). From (A.59) and (10.167), we can write

$$\begin{aligned}
 w &= [\mathbf{I} - \mathcal{X}_\mu \mathcal{K}]^{-1} \mathcal{X}_\mu \Xi_{p,\mathcal{E}} \\
 &= \mathcal{X}_\mu \Xi_{p,\mathcal{E}} + \mathcal{X}_\mu \mathcal{K} \mathcal{X}_\mu \Xi_{p,\mathcal{E}} + \mathcal{X}_\mu \mathcal{K} \mathcal{X}_\mu \mathcal{K} \mathcal{X}_\mu \Xi_{p,\mathcal{E}} + \dots \quad (10.168)
 \end{aligned}$$

Convergence conditions for this series are discussed in Sec. 1.7.6.

The series in (10.168) can be interpreted as the attenuated x-ray transform of an effective source distribution Ξ_{eff} , *i.e.*,

$$w = \mathcal{X}_\mu \Xi_{eff}, \quad (10.169)$$

where

$$\Xi_{eff} = \Xi_{p,\mathcal{E}} + \mathcal{K} \mathcal{X}_\mu \Xi_{p,\mathcal{E}} + \mathcal{K} \mathcal{X}_\mu \mathcal{K} \mathcal{X}_\mu \Xi_{p,\mathcal{E}} + \dots \quad (10.170)$$

Successive terms in this series represent successively more scattering; photons that have scattered n times contribute the term $[\mathcal{K} \mathcal{X}_\mu]^n \Xi_{p,\mathcal{E}}$ to Ξ_{eff} .

A useful tool for dealing with scatter problems is an expansion in spherical harmonics, as discussed immediately below. Other useful techniques are treated in Secs. 10.3.6 and 10.3.7.

10.3.5 Spherical harmonics

Most scatter problems have an important symmetry that we can exploit. For randomly oriented scatterers, as noted below (10.129), the scatter kernel $K(\hat{\mathbf{s}}, \mathcal{E}; \hat{\mathbf{s}}', \mathcal{E}' | \mathbf{r}, t)$ depends on $\hat{\mathbf{s}}$ and $\hat{\mathbf{s}}'$ only through the scalar product $\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}'$. That means that the operator \mathcal{K} is invariant to arbitrary rotations of the coordinate system used to express the directions $\hat{\mathbf{s}}$ and $\hat{\mathbf{s}}'$. In the language of group theory (see Sec. 6.7), the symmetry group of \mathcal{K} is $\mathbf{SO}(3)$. As we discussed in Sec. 6.7.7, the spherical harmonics are basis functions for irreducible representations of $\mathbf{SO}(3)$. Since \mathcal{K} is invariant to this group, the scatter kernel will take a simple diagonal form in this basis.

Transformation of the distribution function We can expand the angular dependence of the distribution function in spherical harmonics as

$$w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} W_{\ell m}(\mathbf{r}, \mathcal{E}, t) Y_{\ell m}(\hat{\mathbf{s}}), \quad (10.171)$$

where $Y_{\ell m}(\hat{\mathbf{s}})$ means the same thing as $Y_{\ell m}(\theta, \phi)$. Note carefully that θ and ϕ are the spherical coordinates of $\hat{\mathbf{s}}$, not \mathbf{r} .

From the orthogonality relation (4.37), the coefficients are given by

$$W_{\ell m}(\mathbf{r}, \mathcal{E}, t) = \int_{4\pi} d\Omega Y_{\ell m}^*(\hat{\mathbf{s}}) w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t). \quad (10.172)$$

This equation defines a CD operator \mathcal{Y} that maps a function of direction $\hat{\mathbf{s}}$ (or equivalently, polar angles θ and ϕ) to its spherical-harmonic coefficients, *i.e.*,

$$[\mathcal{Y}w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t)]_{\ell m} = W_{\ell m}(\mathbf{r}, \mathcal{E}, t). \quad (10.173)$$

If we consider the coefficients to be components of an infinite-dimensional vector \mathbf{W} , then we can express this operator relation even more abstractly as

$$\mathcal{Y}\mathbf{w} = \mathbf{W}, \quad (10.174)$$

where the boldface is used since we now want to think of \mathbf{w} as a vector in a Hilbert space. Since the spherical harmonics are orthonormal [see (4.37)], the operator \mathcal{Y} is unitary.

Transformation of the source Like the distribution function w , the source distribution $\Xi_{p,\mathcal{E}}$ is a function of \mathbf{r} , $\hat{\mathbf{s}}$, \mathcal{E} and t , and its angular dependence (if any) can also be transformed to spherical harmonics. That is, we can define an infinite vector $\boldsymbol{\xi} = \mathcal{Y}\Xi_{p,\mathcal{E}}$, with components $\xi_{\ell m}$ given by

$$\xi_{\ell m}(\mathbf{r}, \mathcal{E}, t) = \int_{4\pi} d\Omega Y_{\ell m}(\hat{\mathbf{s}}) \Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t). \quad (10.175)$$

For an isotropic source this vector has just one nonzero element (ξ_{00}), but it is useful to be more general.

Steady-state Boltzmann equation We now assume steady-state conditions, so that the source and distribution function are independent of time. To get the steady-state Boltzmann equation in spherical-harmonic form, we make the substitutions $\mathbf{w} = \mathcal{Y}^{-1}\mathbf{W}$ and $\Xi_{p,\mathcal{E}} = \mathcal{Y}^{-1}\boldsymbol{\xi}$ in (10.132) and then operate from the left with \mathcal{Y} , obtaining

$$\mu_{tot}\mathbf{W} - \frac{1}{c_m}\boldsymbol{\xi} - \frac{1}{c_m}\mathcal{Y}\mathcal{K}\mathcal{Y}^{-1}\mathbf{W} + \mathcal{Y}(\hat{\mathbf{s}} \cdot \nabla)\mathcal{Y}^{-1}\mathbf{W}. \quad (10.176)$$

This equation, where the unknown is the infinite vector \mathbf{W} , is equivalent to the steady-state Boltzmann equation. To solve it, we need to learn how to compute the scatter term $\mathcal{Y}\mathcal{K}\mathcal{Y}^{-1}\mathbf{W}$ and the propagation term $\mathcal{Y}(\hat{\mathbf{s}} \cdot \nabla)\mathcal{Y}^{-1}\mathbf{W}$. It will turn out that the scatter term is diagonal, but the propagation term is complicated. We shall discuss both terms below.

Another way of expressing the steady-state Boltzmann equation is by the integral equation (10.166), and it is useful to transform this equation to spherical-harmonic form also. By applying \mathcal{Y} to (10.166) and inserting $\mathcal{Y}^{-1}\mathcal{Y}$ judiciously, we find

$$\mathbf{W} = \mathcal{Y}\mathcal{X}_\mu\mathcal{Y}^{-1} [\boldsymbol{\xi} + \mathcal{Y}\mathcal{K}\mathcal{Y}^{-1}\mathbf{W}] . \quad (10.177)$$

The scatter term $\mathcal{Y}(\hat{\mathbf{s}} \cdot \nabla)\mathcal{Y}^{-1}\mathbf{W}$ from (10.176) appears here as an effective source term. The overall source is then operated on by the attenuated x-ray transform, expressed in the spherical-harmonic representation as $\mathcal{Y}\mathcal{X}_\mu\mathcal{Y}^{-1}$. Ways of implementing this operator are discussed below.

Transformation of the scatter operator We look first at the scattering term $\mathcal{Y}\mathcal{K}\mathcal{Y}^{-1}\mathbf{W}$ which appears in (10.176) and (10.177). In component form, this term is

$$[\mathcal{Y}\mathcal{K}\mathcal{Y}^{-1}\mathbf{W}]_{\ell m} = \sum_{\ell'=0}^{\infty} \sum_{m'=-\ell'}^{\ell'} [\mathcal{Y}\mathcal{K}\mathcal{Y}^{-1}]_{\ell m, \ell' m'} W_{\ell' m'} . \quad (10.178)$$

Now we make use of the fact that the scatter kernel is a function of $\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}'$, which is just the cosine of the angle between the incoming and scattered photons. As we noted in Sec. 4.1.4, Legendre polynomials are particularly useful for expanding functions of the cosine of an angle, so we expand the scatter kernel as

$$K(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') = \sum_{\ell''=0}^{\infty} k_{\ell''} P_{\ell''}(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') = \sum_{\ell''=0}^{\infty} k_{\ell''} \frac{4\pi}{2\ell''+1} \sum_{m''=-\ell''}^{\ell''} Y_{\ell'' m''}(\hat{\mathbf{s}}) Y_{\ell'' m''}^*(\hat{\mathbf{s}}') , \quad (10.179)$$

where we have used the addition theorem (4.38) to get the second form. The notation here may be somewhat misleading since $k_{\ell''}$ looks like a constant but can be substantially more complicated. For elastic scattering in an inhomogeneous medium, $k_{\ell''}$ is a function of \mathbf{r} , and for inelastic scattering it is an integral operator with respect to the energy variable; it transforms a function of \mathcal{E}' to a function of \mathcal{E} .

With this expansion, the matrix elements in (10.178) are given by

$$\begin{aligned} & [\mathcal{Y}\mathcal{K}\mathcal{Y}^{-1}]_{\ell m, \ell' m'} \\ &= \sum_{\ell''=0}^{\infty} k_{\ell''} \frac{4\pi}{2\ell''+1} \sum_{m''=-\ell''}^{\ell''} \int_{4\pi} d\Omega Y_{\ell'' m''}(\hat{\mathbf{s}}) Y_{\ell m}^*(\hat{\mathbf{s}}) \int_{4\pi} d\Omega' Y_{\ell'' m''}^*(\hat{\mathbf{s}}') Y_{\ell' m'}(\hat{\mathbf{s}}') \\ &= \frac{4\pi}{2\ell+1} k_{\ell} \delta_{\ell\ell'} \delta_{mm'} , \end{aligned} \quad (10.180)$$

where the final form has made use of the orthogonality of the spherical harmonics, (4.37).

It follows from (10.180) that the spherical harmonics are eigenfunctions of the angular part of \mathcal{K} . (The full operator \mathcal{K} still requires an integral over energy if the scattering is inelastic.) As a practical matter, (10.180) shows that the angular integral in \mathcal{K} can be implemented in the spherical-harmonic domain, where it corresponds to multiplication by a diagonal matrix.

For notational ease, we define

$$\mathcal{D} = \mathcal{Y}\mathcal{K}\mathcal{Y}^{-1} , \quad (10.181)$$

where the letter \mathcal{D} suggests that the operator is diagonal with respect to the spherical-harmonic indices. For inelastic scattering, \mathcal{D} is still an operator on the energy variables, and the matrix elements can depend on both position and energy.

Propagation term Unfortunately, the spherical-harmonic expansion does not diagonalize the full Boltzmann equation. In particular, the propagation term in (10.176) is not diagonalized.

In detail, this term takes the form

$$\begin{aligned} [\mathcal{Y}(\hat{\mathbf{s}} \cdot \nabla) \mathcal{Y}^{-1} \mathbf{W}]_{\ell m}(\mathbf{r}, \mathcal{E}) &= \int_{4\pi} d\Omega Y_{\ell m}^*(\hat{\mathbf{s}}) \hat{\mathbf{s}} \cdot \nabla w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) \\ &= \sum_{\ell' m'} \int_{4\pi} d\Omega Y_{\ell m}^*(\hat{\mathbf{s}}) Y_{\ell' m'}(\hat{\mathbf{s}}) \hat{\mathbf{s}} \cdot \nabla W_{\ell' m'}(\mathbf{r}, \mathcal{E}). \end{aligned} \quad (10.182)$$

Since $\hat{\mathbf{s}} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$ in Cartesian coordinates, we can also write

$$\begin{aligned} [\mathcal{Y}(\hat{\mathbf{s}} \cdot \nabla) \mathcal{Y}^{-1} \mathbf{W}]_{\ell m}(\mathbf{r}, \mathcal{E}) &= \sum_{\ell' m'} \frac{\partial W_{\ell' m'}(\mathbf{r}, \mathcal{E})}{\partial x} \int_{4\pi} d\Omega Y_{\ell m}^*(\hat{\mathbf{s}}) Y_{\ell' m'}(\hat{\mathbf{s}}) \sin \theta \cos \phi \\ &\quad + \sum_{\ell' m'} \frac{\partial W_{\ell' m'}(\mathbf{r}, \mathcal{E})}{\partial y} \int_{4\pi} d\Omega Y_{\ell m}^*(\hat{\mathbf{s}}) Y_{\ell' m'}(\hat{\mathbf{s}}) \sin \theta \sin \phi \\ &\quad + \sum_{\ell' m'} \frac{\partial W_{\ell' m'}(\mathbf{r}, \mathcal{E})}{\partial z} \int_{4\pi} d\Omega Y_{\ell m}^*(\hat{\mathbf{s}}) Y_{\ell' m'}(\hat{\mathbf{s}}) \cos \theta, \end{aligned} \quad (10.183)$$

where we have used (10.171).

This relation can be written more compactly if we define an infinite-dimensional, vector-valued matrix \mathbf{C} , where each element is a 3D vector given by

$$\mathbf{C}_{\ell m, \ell' m'} = \int_{4\pi} d\Omega Y_{\ell m}^*(\hat{\mathbf{s}}) Y_{\ell' m'}(\hat{\mathbf{s}}) \hat{\mathbf{s}}. \quad (10.184)$$

In terms of \mathbf{C} , (10.182) is

$$\left[\frac{\partial \mathbf{W}}{\partial t} \right]_{prop} = -c_m \mathbf{C} \cdot \nabla \mathbf{W}. \quad (10.185)$$

Full equation With the forms derived above for the scattering and propagation terms, the steady-state Boltzmann equation in the spherical-harmonic representation, (10.176), becomes

$$\mathbf{C} \cdot \nabla \mathbf{W} = \frac{1}{c_m} \boldsymbol{\xi} - \mu_{tot} \mathbf{W} - \frac{1}{c_m} \mathcal{D} \mathbf{W}, \quad (10.186)$$

Attenuated x-ray transform Next we look at the operator $\mathcal{Y} \mathcal{X}_\mu \mathcal{Y}^{-1}$ that appears in (10.177). This operator maps an infinite vector in the spherical-harmonic space to another such infinite vector, but the mapping is not local.

To see the nonlocal character, consider a general vector $\mathbf{V}(\mathbf{r})$ with components $V_{\ell m}(\mathbf{r})$. If we let $\mathcal{Y}^{-1}\{\mathbf{V}(\mathbf{r})\} = v(\mathbf{r}, \hat{\mathbf{s}})$, then the equation

$$\mathbf{U} = \mathcal{Y} \mathcal{X}_\mu \mathcal{Y}^{-1} \mathbf{V} \quad (10.187)$$

means that

$$\begin{aligned}
 U_{\ell m}(\mathbf{r}) &= [\mathcal{Y} \mathcal{X}_\mu \mathbf{v}]_{\ell m}(\mathbf{r}) \\
 &= \frac{1}{c_m} \int_{4\pi} d\Omega Y_{\ell m}^*(\hat{\mathbf{s}}) \int_0^\infty dt v(\mathbf{r} - \hat{\mathbf{s}}t, \hat{\mathbf{s}}) \exp \left[- \int_0^t dt' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}t') \right]. \quad (10.188)
 \end{aligned}$$

From (10.171) and the unitarity of \mathcal{Y} , the function $v(\mathbf{r}, \hat{\mathbf{s}})$ is related to the components of $\mathbf{V}(\mathbf{r})$ by

$$v(\mathbf{r}, \hat{\mathbf{s}}) = \sum_{\ell' m'} V_{\ell' m'}(\mathbf{r}) Y_{\ell' m'}(\hat{\mathbf{s}}). \quad (10.189)$$

By a change of variables,

$$v(\mathbf{r} - \hat{\mathbf{s}}t, \hat{\mathbf{s}}) = \sum_{\ell' m'} V_{\ell' m'}(\mathbf{r} - \hat{\mathbf{s}}t) Y_{\ell' m'}(\hat{\mathbf{s}}), \quad (10.190)$$

so (10.188) becomes

$$\begin{aligned}
 U_{\ell m}(\mathbf{r}) &= \\
 &= \frac{1}{c_m} \sum_{\ell' m'} \int_{4\pi} d\Omega Y_{\ell m}^*(\hat{\mathbf{s}}) \int_0^\infty dt V_{\ell' m'}(\mathbf{r} - \hat{\mathbf{s}}t) Y_{\ell' m'}(\hat{\mathbf{s}}) \exp \left[- \int_0^t dt' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}t') \right]. \quad (10.191)
 \end{aligned}$$

If we define $\mathbf{r}' = \mathbf{r} - \hat{\mathbf{s}}t$ and recognize that $t^2 dt d\Omega = d^3 \mathbf{r}'$ and $t = |\mathbf{r} - \mathbf{r}'|$, then

$$\begin{aligned}
 U_{\ell m}(\mathbf{r}) &= \frac{1}{c_m} \sum_{\ell' m'} \int_\infty d^3 \mathbf{r}' \frac{Y_{\ell m}^* \left(\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \right) Y_{\ell' m'} \left(\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \right)}{|\mathbf{r} - \mathbf{r}'|^2} V_{\ell' m'}(\mathbf{r}') \\
 &\quad \times \exp \left[- \int_0^{|\mathbf{r} - \mathbf{r}'|} dt' \mu_{tot} \left(\mathbf{r} - t' \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \right) \right]. \quad (10.192)
 \end{aligned}$$

This equation shows in detail the action of the operator $\mathcal{Y} \mathcal{X}_\mu \mathcal{Y}^{-1}$.

We can simplify the notation by defining

$$\mathcal{A} = \mathcal{Y} \mathcal{X}_\mu \mathcal{Y}^{-1}. \quad (10.193)$$

The letter \mathcal{A} here indicates that the operator is the spherical-harmonic transform of the attenuated x-ray transform. From (10.192) we see that \mathcal{A} is a combination of a matrix operator and an integral operator,

$$[\mathcal{A} \mathbf{V}]_{\ell m}(\mathbf{r}) = \sum_{\ell' m'} \int_\infty d^3 \mathbf{r}' A_{\ell m, \ell' m'}(\mathbf{r}, \mathbf{r}') V_{\ell' m'}(\mathbf{r}'), \quad (10.194)$$

with an element/kernel given by

$$\begin{aligned}
 A_{\ell m, \ell' m'}(\mathbf{r}, \mathbf{r}') &= \frac{1}{c_m} \frac{1}{|\mathbf{r} - \mathbf{r}'|^2} Y_{\ell m}^* \left(\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \right) Y_{\ell' m'} \left(\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \right) \\
 &\quad \times \exp \left[- \int_0^{|\mathbf{r} - \mathbf{r}'|} dt' \mu_{tot} \left(\mathbf{r} - t' \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \right) \right]. \quad (10.195)
 \end{aligned}$$

If the attenuation coefficient is a constant, independent of position, then the exponential factor becomes $\exp[-\mu_{tot}|\mathbf{r} - \mathbf{r}'|]$, and in this case the spatial part of the operator is shift-invariant.

Scattered distribution in spherical harmonics We now know the effect of each of the operators in (10.177), and we can use that equation to construct an equation for the scattered distribution in spherical harmonics. In the present notation, (10.177) reads

$$\mathbf{W} = \mathcal{A}[\boldsymbol{\xi} + \mathcal{D}\mathbf{W}], \quad (10.196)$$

where \mathcal{A} is the attenuated x-ray transform in spherical-harmonic space, and the operator \mathcal{D} , which is a diagonal matrix for elastic scattering, is in general the transform of the scatter operator \mathcal{K} .

It is useful to divide \mathbf{W} into contributions arising from primary (unscattered) and scattered radiation:

$$\mathbf{W} = \mathbf{W}^{pri} + \mathbf{W}^{sc}, \quad (10.197)$$

where

$$\mathbf{W}^{pri} \equiv \mathcal{A}\boldsymbol{\xi}. \quad (10.198)$$

With this division, (10.196) leads to

$$\mathbf{W}^{sc} = \mathcal{A}\mathcal{D}[\mathcal{A}\boldsymbol{\xi} + \mathbf{W}^{sc}], \quad (10.199)$$

or

$$[\mathbf{I} - \mathcal{A}\mathcal{D}]\mathbf{W}^{sc} = \mathcal{A}\mathcal{D}\mathcal{A}\boldsymbol{\xi}. \quad (10.200)$$

The right-hand side of this equation represents an effective source distribution produced by the attenuated primary photons plus singly scattered photons. Nevertheless, because of the operator on the left, the equation still accounts for multiple scatters of all orders. No approximations have yet been made.

Solution methods A formal solution to (10.200) is

$$\mathbf{W}^{sc} = [\mathbf{I} - \mathcal{A}\mathcal{D}]^{-1} \mathcal{A}\mathcal{D}\mathcal{A}\boldsymbol{\xi}, \quad (10.201)$$

and a numerical solution can, in principle, be implemented with a Neumann series like (10.168). As discussed below, three practical ways to solve (10.200) are (1) the weak-scattering approximation, (2) the diffusion approximation (Ishimaru, 1978) and (3) trickle-down theory (Barrett *et al.*, 1998d).

The weak-scattering limit of (10.201), which amounts to neglecting multiple scatters, is

$$\mathbf{W}^{sc} \simeq \mathcal{A}\mathcal{D}\mathcal{A}\boldsymbol{\xi}. \quad (10.202)$$

This approximation is valid if the dimensions of the scattering medium are all small compared to $1/\mu_{sc}$, so that a photon will probably escape the medium before scattering more than once.

The diffusion approximation, discussed in Sec. 10.3.6, is the opposite extreme from the weak-scattering approximation; it is appropriate with strong elastic scattering where the dimensions of the medium are all much greater than $1/\mu_{sc}$.

The trickle-down approach is useful with inelastic scattering, such as Compton scattering, where the photon loses energy in each scatter event. In that case, the distribution at one energy is influenced by the distribution at all higher energies but not that at lower energies. This approach is developed in Sec. 10.3.7.

10.3.6 Elastic scattering and diffusion

Elastic scattering is the dominant scattering mechanism for optical or infrared photons propagating in a turbid medium such as breast tissue or sea water. Even Compton scattering of x rays and gamma rays is approximately elastic if the photon energy is very small compared to the rest-mass energy of the electron (511 keV).

If many elastic scattering events can occur before a photon is absorbed or escapes the medium, the effect of elastic scattering is to thoroughly randomize the photon directions. In that case only a few low-order terms in the spherical-harmonic expansion of the distribution function are needed to describe the scattered radiation. As we shall see, the result of this approximation is to reduce the Boltzmann equation to the diffusion equation.

Since elastic scattering does not change the photon energy, we can consider each energy group individually, or equivalently just drop the energy argument and denote the distribution function as $w(\mathbf{r}, \hat{\mathbf{s}})$.

Diffusion approximation As in (10.197), we split the distribution function into contributions arising from primary and scattered radiation,

$$w(\mathbf{r}, \hat{\mathbf{s}}) = w^{pri}(\mathbf{r}, \hat{\mathbf{s}}) + w^{sc}(\mathbf{r}, \hat{\mathbf{s}}), \quad (10.203)$$

where $w^{pri} = \mathcal{Y}^{-1} \mathbf{W}^{pri}$ and $w^{sc} = \mathcal{Y}^{-1} \mathbf{W}^{sc}$. The Boltzmann equation now splits into two equations,

$$\hat{\mathbf{s}} \cdot \nabla w^{pri} = \frac{1}{c_m} \xi_{p,\mathcal{E}} - \mu_{tot} w^{pri}; \quad (10.204)$$

$$\hat{\mathbf{s}} \cdot \nabla w^{sc} = -\mu_{tot} w^{sc} + \frac{1}{c_m} \mathcal{K}(w^{sc} + w^{pri}). \quad (10.205)$$

These equations are coupled since both w^{pri} and w^{sc} appear in the last term of (10.205).

The diffusion approximation consists of retaining only the terms corresponding to $\ell = 0$ and $\ell = 1$ in the spherical-harmonic expansion of w^{sc} , thus writing

$$w^{sc}(\mathbf{r}, \hat{\mathbf{s}}) \simeq W_{00}^{sc}(\mathbf{r}) Y_{00}(\hat{\mathbf{s}}) + \sum_{m=-1}^1 W_{1m}^{sc}(\mathbf{r}) Y_{1m}(\hat{\mathbf{s}}). \quad (10.206)$$

Since $Y_{00}(\hat{\mathbf{s}})$ is the constant $1/\sqrt{4\pi}$, the first term represents an isotropic distribution of photons. Specifically, with the use of (10.172),

$$W_{00}^{sc}(\mathbf{r}) Y_{00}(\hat{\mathbf{s}}) = \frac{1}{4\pi} \int_{4\pi} d\Omega' w^{sc}(\mathbf{r}, \hat{\mathbf{s}}'). \quad (10.207)$$

From the definition of the distribution function, the integral in (10.207) can be interpreted as a spatial density of scattered photons, which we denote as $u^{sc}(\mathbf{r})$ and define by

$$u^{sc}(\mathbf{r}) \equiv \int_{4\pi} d\Omega' w^{sc}(\mathbf{r}, \hat{\mathbf{s}}'). \quad (10.208)$$

To see the meaning of the second term in (10.206), we use (10.172) again to write

$$\begin{aligned} \sum_{m=-1}^1 W_{1m}^{sc}(\mathbf{r}) Y_{1m}(\hat{\mathbf{s}}) &= \sum_{m=-1}^1 Y_{1m}(\hat{\mathbf{s}}) \int_{4\pi} d\Omega' Y_{1m}^*(\hat{\mathbf{s}}') w^{sc}(\mathbf{r}, \hat{\mathbf{s}}') \\ &= \frac{3}{4\pi} \int_{4\pi} d\Omega' P_1(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') w^{sc}(\mathbf{r}, \hat{\mathbf{s}}') = \frac{3}{4\pi} \hat{\mathbf{s}} \cdot \int_{4\pi} d\Omega' \hat{\mathbf{s}}' w^{sc}(\mathbf{r}, \hat{\mathbf{s}}'), \end{aligned} \quad (10.209)$$

where the second line has used the addition theorem (4.38) and the fact that $P_1(x) = x$. We now define a vector quantity $\mathbf{J}^{sc}(\mathbf{r})$ by

$$\mathbf{J}^{sc}(\mathbf{r}) = c_m \int_{4\pi} d\Omega' \hat{\mathbf{s}}' w^{sc}(\mathbf{r}, \hat{\mathbf{s}}'). \quad (10.210)$$

If $w^{sc}(\mathbf{r}, \hat{\mathbf{s}}')$ is isotropic, then the integral vanishes since the integrand is an odd function of $\hat{\mathbf{s}}$. Thus $\mathbf{J}^{sc}(\mathbf{r})$ measures the magnitude and direction of the residual anisotropy. Moreover, since $c_m \hat{\mathbf{s}}$ is the photon velocity, $\mathbf{J}^{sc}(\mathbf{r})$ can be thought of as the average of the velocity of the photons at point \mathbf{r} times their density. Units of \mathbf{J}^{sc} are photons per second per unit area per unit energy, but for elastic scattering we ignore the energy dependence (we could integrate over energy) and think of \mathbf{J}^{sc} as photons per second per unit area. Then $\mathbf{J}^{sc}(\mathbf{r}) \cdot \hat{\mathbf{n}}$ gives the rate at which photons traverse unit area on a surface normal to $\hat{\mathbf{n}}$, so we can think of \mathbf{J}^{sc} as a *photon current density*. In terms of the radiometric quantities introduced in Sec. 10.2, $\mathbf{J}^{sc}(\mathbf{r}) \cdot \hat{\mathbf{n}}$ is the spectral photon irradiance.

Putting the pieces together, we see that

$$w^{sc}(\mathbf{r}, \hat{\mathbf{s}}) \simeq \frac{1}{4\pi} u^{sc}(\mathbf{r}) + \frac{3}{4\pi c_m} \hat{\mathbf{s}} \cdot \mathbf{J}^{sc}(\mathbf{r}) \quad (10.211)$$

in the diffusion approximation. This equation involves both u^{sc} and \mathbf{J}^{sc} , but these quantities are not independent. As we shall now show, we can eliminate \mathbf{J}^{sc} and derive the diffusion equation, a partial differential equation for u^{sc} alone. The derivation given here follows Ishimaru (1978).

If we integrate both sides of (10.205) over $\hat{\mathbf{s}}$ and use (10.208), the result is

$$\int_{4\pi} d\Omega \hat{\mathbf{s}} \cdot \nabla w^{sc} = -\mu_{tot} u^{sc} + \frac{1}{c_m} \int_{4\pi} d\Omega \mathcal{K}(w^{sc} + w^{pri}). \quad (10.212)$$

Since $\hat{\mathbf{s}}$ is a constant so far as the ∇ operator is concerned,

$$\hat{\mathbf{s}} \cdot \nabla w^{sc} = \nabla \cdot (\hat{\mathbf{s}} w^{sc}), \quad (10.213)$$

which, with (10.210), shows that the left-hand side of (10.212) is $\nabla \cdot \mathbf{J}^{sc}$.

The term in (10.212) involving \mathcal{K} also simplifies considerably. Since the kernel of \mathcal{K} for elastic scattering and randomly oriented scatterers is just $K(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}' | \mathbf{r})$, we have

$$\begin{aligned} \int_{4\pi} d\Omega \mathcal{K} w^{sc} &= \int_{4\pi} d\Omega \int_{4\pi} d\Omega' K(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}' | \mathbf{r}) w^{sc}(\mathbf{r}, \hat{\mathbf{s}}') \\ &= c_m \mu_{sc}(\mathbf{r}) \int_{4\pi} d\Omega' w^{sc}(\mathbf{r}, \hat{\mathbf{s}}') = c_m \mu_{sc}(\mathbf{r}) u^{sc}(\mathbf{r}), \end{aligned} \quad (10.214)$$

where we have used (10.128) and an integral of (10.130) to relate the scatter kernel to the attenuation coefficient. A similar result holds for the term involving $\mathcal{K}w^{pri}$, and (10.212) becomes simply

$$\nabla \cdot \mathbf{J}^{sc} = -c_m \mu_{tot} u^{sc} + c_m \mu_{sc} (u^{sc} + u^{pri}). \quad (10.215)$$

This equation connects the two unknown quantities u^{sc} and \mathbf{J}^{sc} . To get another equation in these unknowns, we substitute (10.211) into (10.205) to yield

$$\begin{aligned} & \frac{1}{4\pi} \hat{\mathbf{s}} \cdot \nabla u^{sc} + \frac{3}{4\pi c_m} \hat{\mathbf{s}} \cdot \nabla (\hat{\mathbf{s}} \cdot \mathbf{J}^{sc}) \\ = & -\mu_{tot} \left(\frac{1}{4\pi} u^{sc} + \frac{3}{4\pi c_m} \hat{\mathbf{s}} \cdot \mathbf{J}^{sc} \right) + \frac{1}{c_m} \mathcal{K} \left(w^{pri} + \frac{1}{4\pi} u^{sc} + \frac{3}{4\pi c_m} \hat{\mathbf{s}} \cdot \mathbf{J}^{sc} \right). \end{aligned} \quad (10.216)$$

The goal now is to find simultaneous solutions for u^{sc} and \mathbf{J}^{sc} satisfying (10.215) and (10.216). The general procedure will be to multiply both sides of (10.216) by $\hat{\mathbf{s}}$, integrate over $\hat{\mathbf{s}}$, use all of the symmetries we can, and plug the result back into (10.215).

The following identities (Dorn, 1997; Ishimaru, 1978) are useful:

- (a) $\int_{4\pi} d\Omega = 4\pi$;
- (b) $\int_{4\pi} d\Omega \hat{\mathbf{s}} = 0$;
- (c) $\int_{4\pi} d\Omega \hat{\mathbf{s}} \cdot \mathbf{A} = 0$;
- (d) $\int_{4\pi} d\Omega \hat{\mathbf{s}} (\hat{\mathbf{s}} \cdot \mathbf{A}) = \frac{4\pi}{3} \mathbf{A}$;
- (e) $\int_{4\pi} d\Omega (\hat{\mathbf{s}} \cdot \mathbf{A}) (\hat{\mathbf{s}} \cdot \mathbf{B}) = \frac{4\pi}{3} \mathbf{A} \cdot \mathbf{B}$;
- (f) $\int_{4\pi} d\Omega \hat{\mathbf{s}} (\hat{\mathbf{s}} \cdot \mathbf{A}) (\hat{\mathbf{s}} \cdot \mathbf{B}) = 0$.

In these relations, \mathbf{A} and \mathbf{B} are any vectors that are independent of $\hat{\mathbf{s}}$, including the vector operator ∇ . The relations with 0 on the right-hand side follow immediately from symmetry since the integrands are odd functions of $\hat{\mathbf{s}}$. The others can be derived by writing out the integrands in component form.

Anisotropic scattering Let us look first at the term $\mathcal{K}(\hat{\mathbf{s}} \cdot \mathbf{J}^{sc})$ in (10.216). This term can be simplified by taking advantage of the form of the kernel of \mathcal{K} as in (10.214); by using polar coordinates with $\hat{\mathbf{s}}$ as the polar axis, we can show that

$$\mathcal{K}(\hat{\mathbf{s}} \cdot \mathbf{J}^{sc}) = \int_{4\pi} d\Omega K(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') \hat{\mathbf{s}}' \cdot \mathbf{J}^{sc} = \hat{\mathbf{s}} \cdot \mathbf{J}^{sc} \int_{4\pi} d\Omega K(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') \hat{\mathbf{s}} \cdot \hat{\mathbf{s}}' \equiv c_m \mu_{sc} \gamma \hat{\mathbf{s}} \cdot \mathbf{J}^{sc}, \quad (10.217)$$

where γ (often called g in the literature) is defined by

$$\gamma \equiv \frac{\int_{4\pi} d\Omega K(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') \hat{\mathbf{s}} \cdot \hat{\mathbf{s}}'}{\int_{4\pi} d\Omega K(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')} = \langle \cos \theta_{sc} \rangle, \quad (10.218)$$

where $\cos \theta_{sc} = \hat{\mathbf{s}} \cdot \hat{\mathbf{s}}'$ is the cosine of the scattering angle. Note that the denominator here equals $c_m \mu_{sc}$ as in (10.214).

The integral in the numerator of (10.218) is a measure of the difference in cross section for forward and backward scattering. In many situations, including optical scattering from small (subwavelength) particles and Compton scattering of low-energy x rays, forward and backward scattering are almost equally probable and $\gamma \approx 0$. For optical scattering in biological tissue, however, it turns out that $\gamma \approx 0.8 - 0.9$, so the scattering is forward-peaked.

Messy manipulations, minimally mentioned As advertised, we now multiply both sides of (10.216) by $\hat{\mathbf{s}}$ and integrate over $\hat{\mathbf{s}}$. The result is

$$\begin{aligned} & \frac{1}{3} \nabla u^{sc} + \frac{3}{4\pi c_m} \int_{4\pi} d\Omega (\hat{\mathbf{s}} \cdot \nabla) (\hat{\mathbf{s}} \cdot \mathbf{J}^{sc}) \hat{\mathbf{s}} \\ &= -\frac{\mu_{tot}}{c_m} \int_{4\pi} d\Omega \hat{\mathbf{s}} u^{sc} - \frac{\mu_{abs} + (1-\gamma)\mu_{sc}}{c_m} \mathbf{J}^{sc} + \frac{1}{c_m} \int_{4\pi} d\Omega \hat{\mathbf{s}} \mathcal{K} \left(w^{pri} + \frac{1}{4\pi} u^{sc} \right), \end{aligned} \quad (10.219)$$

where we have used identity (d) above.

Several of the integrals in (10.219) vanish by symmetry. The integral $\int_{4\pi} d\Omega \hat{\mathbf{s}} u^{sc}$ vanishes by identity (b) since u^{sc} is independent of $\hat{\mathbf{s}}$. Similarly, $\int_{4\pi} d\Omega \hat{\mathbf{s}} \mathcal{K} u^{sc}$ vanishes, again by identity (b), since $\mathcal{K} u^{sc}$ is also independent of $\hat{\mathbf{s}}$. Finally, the first integral in (10.218) vanishes by identity (f) with $\mathbf{A} = \nabla$. We are left with

$$\frac{1}{3} \nabla u^{sc} = -\frac{\mu_{abs} + (1-\gamma)\mu_{sc}}{c_m} \mathbf{J}^{sc} + \frac{1}{c_m} \int_{4\pi} d\Omega \hat{\mathbf{s}} \mathcal{K} w^{pri}. \quad (10.220)$$

Fick's law and diffusion coefficient In a very strongly scattering medium, the primary flux may make a small contribution to w , so we can approximate w^{pri} by 0. In that case, (10.220) expresses *Fick's law* (Fick, 1855), which says that the photon current is proportional to the gradient of the photon density:

$$\mathbf{J}^{sc} = -D \nabla u^{sc}, \quad (10.221)$$

where D is the *diffusion coefficient*,

$$D \equiv \frac{c_m}{3[\mu_{abs} + (1-\gamma)\mu_{sc}]} \equiv \frac{c_m}{3\mu_{tr}}. \quad (10.222)$$

The quantity $\mu_{tr} \equiv \mu_{abs} + (1-\gamma)\mu_{sc}$ is an effective total attenuation coefficient for transport problems; it reduces to μ_{tot} for isotropic scattering. Though we have suppressed the arguments in our shorthand notation, D and μ_{tr} depend in general on position \mathbf{r} and energy \mathcal{E} .

Slightly different forms for D are also found in the literature. If $\gamma \approx 0$, we see that $D \approx c_m/(3\mu_{tot})$, a form often used for scattering from subwavelength particles. In the context of neutron transport, Weinberg and Wigner (1958) give $D = c_m \mu_{sc}/(3\mu_{tot}^2)$, but diffusion theory depends on the assumption that the particle undergoes many scatter events before it is absorbed, so $\mu_{abs} \ll \mu_{sc}$, $\mu_{sc} \approx \mu_{tot}$, and $c_m \mu_{sc}/(3\mu_{tot}^2) \approx c_m/(3\mu_{tot})$.

More messy manipulations Now we return to (10.220), without approximating the last term by zero. If we multiply that equation by $3D$, take the divergence of both sides, solve for $\nabla \cdot \mathbf{J}^{sc}$ and substitute the result into (10.215), we find

$$\nabla \cdot (D\nabla u^{sc}) - c_m \mu_{abs} u^{sc} = -c_m \mu_{sc} u^{pri} + \frac{3}{c_m} \nabla \cdot \left[D \int_{4\pi} d\Omega \hat{\mathbf{s}} \mathcal{K} w^{pri} \right]. \quad (10.223)$$

If μ_{sc} and μ_{abs} are independent of position, this formula reduces to

$$(\nabla^2 - \kappa^2) u^{sc} = -3\mu_{tr} \mu_{sc} u^{pri} + \frac{3}{c_m} \nabla \cdot \int_{4\pi} d\Omega \hat{\mathbf{s}} \mathcal{K} w^{pri}, \quad (10.224)$$

where

$$\kappa^2 \equiv 3\mu_{tr} \mu_{abs} = 3[\mu_{abs} + (1 - \gamma)\mu_{sc}] \mu_{abs}. \quad (10.225)$$

Discussion The right-hand side of (10.224) is a source term that can be found by solving the scatter-free Boltzmann equation (10.204), using methods developed in Sec. 10.3.3. With that source, u^{sc} can be found by solving (10.224), \mathbf{J}^{sc} can be found from (10.220), and the scatter distribution function in the diffusion approximation follows from (10.211).

An interesting result of this analysis is that κ is $\sqrt{3}$ times the geometric mean of μ_{abs} and μ_{tr} . If there is no absorption, $\kappa = 0$ in spite of the strong attenuation due to scattering. In that case the diffusion equation reduces to the Poisson equation discussed in Sec. 9.1.5. With absorption, the diffusion equation resembles the Helmholtz equation, but $\nabla^2 + k^2$ is replaced by $\nabla^2 - \kappa^2$, where k and κ are both real. Thus the Helmholtz equation admits of wave-like solutions proportional to $\exp(i\mathbf{k} \cdot \mathbf{r})$, but the time-independent diffusion equation has only damped solutions.

10.3.7 Inelastic (Compton) scattering

Compton scattering is often the dominant interaction mechanism for low-energy x rays or gamma rays, especially in media with low atomic number such as air, water or human tissue. In Compton scattering, the incident photon interacts with an electron in the medium. The photon changes direction and the electron recoils, gaining some energy and momentum from the photon in the process.

If we assume that the electron is initially at rest, its energy after the interaction must equal the loss in energy of the photon. By conservation of energy and momentum, it can be shown (see, for example, Krane, 1983) that the scattered photon has an energy \mathcal{E} given by

$$\frac{1}{\mathcal{E}} = \frac{1}{\mathcal{E}_0} + \frac{1}{mc^2} (1 - \cos \theta_s), \quad (10.226)$$

where θ_s is the scattering angle, \mathcal{E}_0 is the energy of the incident photon, m is the rest mass of the electron and c is the speed of light. Thus mc^2 is the rest-mass energy of the electron, numerically equal to 511 keV. For example, 45° scattering of a 140 keV photon gives a scattered photon of energy 129.6 keV, 90° scattering gives 109.9 keV and 180° scattering gives 90.4 keV.

Form of the scattering kernel To get an explicit form for the kernel of \mathcal{K} with Compton scattering, we make use of the differential scattering cross section defined

in Sec. 10.2.5. If the scatterers (electrons in the Compton problem) act independently, the scattering kernel must be proportional to the density of scatterers, n_{sc} , times $\partial\sigma_{sc}/\partial\Omega$. Moreover, since it is reasonable to assume that the scatterers are randomly oriented, the dependence on $\hat{\mathbf{s}}$ and $\hat{\mathbf{s}}'$ is through the scalar product $\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}'$, which is the same as $\cos\theta_s$ in (10.226).

The dependence of the kernel on energy must take account of the conservation rule (10.226) and must therefore involve a delta function. Since (10.226) shows that the initial energy \mathcal{E}' is determined if the final energy \mathcal{E} and $\cos\theta_s$ are specified, we have the choice of including a delta function of the form $\delta[\mathcal{E} - \gamma_1(\mathcal{E}', \cos\theta_s)]$, $\delta[\mathcal{E}' - \gamma_2(\mathcal{E}, \cos\theta_s)]$ or $\delta[\cos\theta_s - \gamma_3(\mathcal{E}, \mathcal{E}')]$, where the functions $\gamma_j(\cdot)$ are determined by solving (10.226). These delta functions all impose the constraint (10.226), but they differ from each other by Jacobians. As we shall demonstrate in a moment, for the first delta function listed, the kernel has the structure,

$$K(\hat{\mathbf{s}}, \mathcal{E}; \hat{\mathbf{s}}', \mathcal{E}' | \mathbf{r}) = cn_{sc} \frac{\partial\sigma_{sc}}{\partial\Omega} \delta \left\{ \mathcal{E} - \left[\frac{1}{\mathcal{E}'} + \frac{1}{mc^2}(1 - \cos\theta_s) \right]^{-1} \right\}. \quad (10.227)$$

By the usual rule for transforming delta functions, an equivalent form is

$$K(\hat{\mathbf{s}}, \mathcal{E}; \hat{\mathbf{s}}', \mathcal{E}' | \mathbf{r}) = cn_{sc} \frac{mc^2}{\mathcal{E}^2} \frac{\partial\sigma_{sc}}{\partial\Omega} \delta \left[\cos\theta_s - 1 + mc^2 \left(\frac{1}{\mathcal{E}} - \frac{1}{\mathcal{E}'} \right) \right]. \quad (10.228)$$

The first form is useful when we wish to use the delta function to perform an integral over energy, while the second form is used in angular integrals.

To show that (10.227) is correct, consider a collimated beam of monoenergetic photons for which

$$w(\mathbf{r}, \hat{\mathbf{s}}', \mathcal{E}') = A \delta(\hat{\mathbf{s}}' - \hat{\mathbf{s}}_0) \delta(\mathcal{E}' - \mathcal{E}_0), \quad (10.229)$$

where A is a constant and $\delta(\hat{\mathbf{s}}' - \hat{\mathbf{s}}_0)$ is an angular delta function, with sifting property given by (10.158). As discussed in Chap. 2, the sifting property can be extended to situations where $t(\hat{\mathbf{s}})$ is a generalized function rather than a test function or a good function by noting that a generalized function can be approximated arbitrarily closely by a sequence of good functions.

With these considerations, (10.227) and (10.229) yield

$$[\mathcal{K}w](\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = cAn_{sc} \frac{\partial\sigma_{sc}}{\partial\Omega} \delta \left\{ \mathcal{E} - \left[\frac{1}{\mathcal{E}_0} + \frac{1}{mc^2}(1 - \cos\theta_{s0}) \right]^{-1} \right\}, \quad (10.230)$$

where $\cos\theta_{s0} = \hat{\mathbf{s}} \cdot \hat{\mathbf{s}}_0$. If $\partial\sigma_{sc}/\partial\Omega$ depends on energy, it must be evaluated at energy \mathcal{E}_0 as a result of the second delta function in (10.229).

The delta function in (10.230) shows that the photons have the correct energy, depending on the scatter angle θ_{s0} from the original beam direction. The right-hand side of (10.230) is also consistent with the definitions of $\partial\sigma_{sc}/\partial\Omega$ and w ; from the definition of w , the incident photon irradiance is cA , so $cA\partial\sigma_{sc}/\partial\Omega$ is the scattered intensity per scatterer. The total scattered intensity can also be obtained by integrating $\mathcal{K}w$ over a volume ΔV and over all energies, so it is given by $cAN_{sc}\partial\sigma_{sc}/\partial\Omega$, where $N_{sc} = n_{sc}\Delta V$ is the total number of scatterers in ΔV . Since this result is just what we would have obtained directly from the definition of $\partial\sigma_{sc}/\partial\Omega$ without going through the integrals, it verifies that the form (10.227) is correct.

Trickle-down theory Since the photon loses energy on each scattering event, the distribution function at energy \mathcal{E} is influenced by higher energies, $\mathcal{E}' > \mathcal{E}$, but it is insensitive to lower energies. If we start with a monoenergetic source, as we usually do in nuclear medicine, we can solve the Boltzmann equation one energy at a time.

To show the trickle-down of photon energy explicitly, we use discrete energy bins and define

$$w_k(\mathbf{r}, \hat{\mathbf{s}}) = w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}_0 - k\Delta\mathcal{E}), \quad k = 0, \dots, k_{max}, \quad (10.231)$$

where $\Delta\mathcal{E} \equiv \mathcal{E}_0/k_{max}$ is the width of the energy bin.

The steady-state Boltzmann equation now takes the form

$$-c\mu_{tot}w_k + \Xi_k + \Delta\mathcal{E} \sum_{j=0}^{k-1} \mathcal{K}_{kj}w_j - c\hat{\mathbf{s}} \cdot \nabla w_k = 0, \quad (10.232)$$

where $\Xi_k(\mathbf{r})$ is the source distribution for the k^{th} energy bin, and \mathcal{K}_{kj} is the angular part of the operator \mathcal{K} with its kernel sampled at $\mathcal{E} = \mathcal{E}_0 - k\Delta\mathcal{E}$ and $\mathcal{E}' = \mathcal{E}_0 - j\Delta\mathcal{E}$, *i.e.*,

$$[\mathcal{K}_{kj}w_j](\mathbf{r}, \hat{\mathbf{s}}) = \int_{4\pi} d\Omega' K(\hat{\mathbf{s}}, \mathcal{E}_0 - k\Delta\mathcal{E}; \hat{\mathbf{s}}', \mathcal{E}_0 - j\Delta\mathcal{E} | \mathbf{r}) w_j(\mathbf{r}, \hat{\mathbf{s}}'). \quad (10.233)$$

Note that the kernel still depends on position \mathbf{r} and that there is still an implicit delta function in it. The trickle-down aspect of (10.232) is contained in the summation limits; with discrete energy bins as we have defined them, the requirement $\mathcal{E}' > \mathcal{E}$ translates to $j < k$.

Consider a monoenergetic source, in which case

$$\Xi_k(\mathbf{r}) = \frac{f(\mathbf{r})}{4\pi\Delta\mathcal{E}} \delta_{k0}. \quad (10.234)$$

We have already obtained the solution to (10.232) for $k = 0$, which is the only bin with a real source in it. For this bin, the scattering term makes no contribution, and (10.152) shows that

$$w_0 = \mathcal{X}_\mu \Xi_0. \quad (10.235)$$

Next look at $k = 1$, where there is no true source term but the summation over j in (10.232) contains the single term $\mathcal{K}_{10}w_0$, which acts as an effective source of photons of energy $\mathcal{E}_0 - \Delta\mathcal{E}$. We then have

$$w_1 = \mathcal{X}_\mu \mathcal{K}_{10}w_0 = \mathcal{X}_\mu \mathcal{K}_{10} \mathcal{X}_\mu \Xi_0. \quad (10.236)$$

In the next bin, $k = 2$, we have two effective source terms since photons of energy $\mathcal{E}_0 - 2\Delta\mathcal{E}$ can be generated by scattering photons of energy \mathcal{E}_0 or $\mathcal{E}_0 - \Delta\mathcal{E}$. Thus,

$$w_2 = \mathcal{X}_\mu [\mathcal{K}_{20}w_0 + \mathcal{K}_{21}w_1]. \quad (10.237)$$

In general, we can compute w_k by the iteration rule,

$$w_k = \mathcal{X}_\mu \sum_{j=0}^{k-1} \mathcal{K}_{kj}w_j. \quad (10.238)$$

Note that this series is fundamentally different from the Neumann series used in (10.168), where each term represents the contribution at all energies from a particular order of scattering. In (10.238), by contrast, each term gives the contribution at a particular energy from all orders of scatter.

10.4 TRANSPORT THEORY AND IMAGING

Transport theory gives us a way of determining the spatial, spectral and angular distribution of energy in any region of space, but we still need to relate this information to what we measure in an imaging system. In this section we treat the imaging system as a continuous-to-discrete (CD) mapping from the source strength, which is a function of spatial position \mathbf{r} , to a set of discrete measurements. The Boltzmann equation maps the source strength to the distribution function, so we must now learn how to map the distribution function to the mean detector outputs.

In Sec. 10.4.1, we begin the discussion of the Boltzmann equation in imaging by deriving a general equation applicable to all linear CD imaging systems in which diffraction and polarization effects can be ignored. As we shall see, all such systems measure linear functionals of the distribution function (or, equivalently, of the radiance). Examples of the use of this equation are given in Secs. 10.4.1, where we discuss pinhole imaging or x rays or gamma rays, and 10.4.3, where we treat optical imaging of a planar source.

Some practical computational issues that arise when the Boltzmann equation is applied to imaging are discussed in Secs. 10.4.4 and 10.4.5. We show in Sec. 10.4.4 how the adjoint of the Boltzmann operator can be put to good use. In Sec. 10.4.5 we introduce the important computational technique of Monte Carlo integration and show how it can be applied to solving the Boltzmann equation.

10.4.1 General imaging equation

To get a general expression for \bar{g}_m , we need only two simple assumptions. First, we assume that the detector responds linearly to the energy incident on it. Second, we assume that the radiation source and the detector are spatially separated so that we can set up a reference plane P somewhere between them. Then, if we know the distribution function on this plane we can compute the mean output¹² of each detector element as a linear functional of w . By the Riesz representation theorem, this functional must have the form,

$$\bar{g}_m = \int_P d^2r \int_0^\infty d\mathcal{E} \int_{2\pi} d\Omega \int_0^\tau dt d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t), \quad (10.239)$$

where τ is the exposure time and \mathbf{r} is a general 3D vector, but the spatial integral is over the two variables needed to specify points in the plane. If we take the plane to be $z = 0$, then $\mathbf{r} = (x, y, z)$ but $d^2r = dxdy$. We shall frequently jump back and forth between 2D and 3D notation in this section, with the convention that \mathbf{r} and \mathbf{r} specify the same point.¹³ Note that the integral over solid angle in (10.239) covers only 2π ster since photons on the plane but directed away from the detector do not contribute to the output. Usually the properties of the detector system will be independent of time, so we can drop the t argument in d_m . If we consider only steady-state sources, w is independent of t also, so the t -integral simply gives a

¹²To be specific, the mean output \bar{g}_m considered in this section is the expectation of g_m conditioned on a particular source. The averaging implied by the overbar is thus over measurement noise, not over object randomness.

¹³A different convention was used in Chap. 9, where \mathbf{r} could refer to the same x - y coordinates in two different planes.

factor of τ . The function $d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ in (10.239) is called the *detector response function* since it specifies how the m^{th} detector element responds to photons at point \mathbf{r} travelling in direction $\hat{\mathbf{s}}$ and having energy \mathcal{E} . The detector system must necessarily include imaging elements such as lenses, collimators or pinholes so that information about the source distribution can be captured in the image, and the effect of these elements is contained in d_m . Specific examples will be given in Secs. 10.4.2 and 10.4.3.

Imaging equation in the absence of scatter In operator form, (10.239) can be written as

$$\bar{\mathbf{g}} = \mathcal{M}\mathbf{w}, \quad (10.240)$$

where \mathcal{M} is called the *measurement operator*. If there is no scatter and the source is isotropic, then \mathbf{w} is given by (10.152), so

$$\bar{\mathbf{g}} = \frac{1}{4\pi} \mathcal{M} \mathcal{X}_\mu \mathbf{S}_{p,\mathcal{E}}. \quad (10.241)$$

We would like to put this expression into the same form as the standard imaging equation in Chap. 7, $\bar{\mathbf{g}} = \mathcal{H}\mathbf{f}$, but to do so we must be more precise about what \mathbf{f} means. If we consider emission imaging, where the object to be imaged is the radiation source, and assume that the emission is isotropic, we might think that \mathbf{f} would be synonymous with $\mathbf{S}_{p,\mathcal{E}}$. Usually, however, we are more interested in the spatial properties of the source than in the spectral properties, so we want \mathbf{f} to correspond to a function of \mathbf{r} alone. On the other hand, the response of a detector system is inevitably a function of \mathcal{E} , so we need the full $S_{p,\mathcal{E}}(\mathbf{r}, \mathcal{E})$ to compute $\bar{\mathbf{g}}$.

In some problems it is valid to assume that the spectral properties of the source are independent of position. This assumption holds, for example, in nuclear medicine if a single isotope is used and in fluorescence microscopy with a single fluorophore. On the other hand, almost any other emissive or reflective optical source would have a spectrum dependent on position, so a full description of the source is necessarily a spatio-spectral function.

When the spectral properties of the source are independent of position, we can write

$$S_{p,\mathcal{E}}(\mathbf{r}, \mathcal{E}) = f(\mathbf{r}) N(\mathcal{E}), \quad (10.242)$$

where $N(\mathcal{E})$ is a normalized source spectrum, defined such that

$$\int_0^\infty d\mathcal{E} N(\mathcal{E}) = 1. \quad (10.243)$$

With this definition, $f(\mathbf{r})$ is identical to the photon emission density S_p . Units of f are thus photons/(sec \cdot m³).

Since $S_{p,\mathcal{E}}$ is linearly related to $f(\mathbf{r})$, it must be possible to find a linear operator \mathcal{H} such that

$$\bar{\mathbf{g}} = \mathcal{H}\mathbf{f}, \quad (10.244)$$

or, as an integral,

$$\bar{g}_m = \int_\infty d^3\mathbf{r}' f(\mathbf{r}') h_m(\mathbf{r}') = [\mathcal{H}\mathbf{f}]_m. \quad (10.245)$$

The remaining problem is to determine the kernel $h_m(\mathbf{r}')$.

Explicit form of the kernel The overall mapping from \mathbf{f} to $\bar{\mathbf{g}}$ is found by substituting (10.151) and (10.242) into (10.239); the result is

$$\begin{aligned} \bar{g}_m &= \frac{\tau}{4\pi c_m} \int_P d^2r \int_0^\infty d\mathcal{E} N(\mathcal{E}) \int_{2\pi} d\Omega d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) \\ &\times \int_0^\infty d\ell f(\mathbf{r} - \hat{\mathbf{s}}\ell) \exp \left[- \int_0^\ell d\ell' \mu_{abs}(\mathbf{r} - \hat{\mathbf{s}}\ell') \right]. \end{aligned} \quad (10.246)$$

To identify the kernel $h_m(\mathbf{r}')$, we use a manipulation similar to the one that led to (10.192): we define $\mathbf{r}' = \mathbf{r} - \hat{\mathbf{s}}\ell$ and recognize that $\ell^2 d\ell d\Omega = d^3\mathbf{r}'$ and $\ell = |\mathbf{r} - \mathbf{r}'|$. Then (10.246) becomes

$$\bar{g}_m = \frac{\tau}{4\pi c_m} \int_\infty d^3\mathbf{r}' f(\mathbf{r}') \int_P d^2r \frac{d_m(\mathbf{r}, \hat{\mathbf{s}})}{|\mathbf{r} - \mathbf{r}'|^2} \exp \left\{ - \int_0^{|\mathbf{r} - \mathbf{r}'|} d\ell' \mu_{abs} \left[\mathbf{r} - \left(\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \right) \ell' \right] \right\}, \quad (10.247)$$

where

$$d_m(\mathbf{r}, \hat{\mathbf{s}}) = \int_0^\infty d\mathcal{E} d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) N(\mathcal{E}). \quad (10.248)$$

By comparing (10.245) and (10.247), we see that

$$h_m(\mathbf{r}') = \frac{\tau}{4\pi c_m} \int_P d^2r \frac{d_m(\mathbf{r}, \hat{\mathbf{s}})}{|\mathbf{r} - \mathbf{r}'|^2} \exp \left\{ - \int_0^{|\mathbf{r} - \mathbf{r}'|} d\ell' \mu_{abs} \left[\mathbf{r} - \left(\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \right) \ell' \right] \right\}. \quad (10.249)$$

The factor $1/|\mathbf{r} - \mathbf{r}'|^2$ arose from the change of variables $\mathbf{r}' = \mathbf{r} - \hat{\mathbf{s}}\ell$, but it has an important physical interpretation; at the source point \mathbf{r} , an area element d^2r subtends a solid angle $\cos\theta d^2r/|\mathbf{r} - \mathbf{r}'|^2$, where θ is the angle between $\hat{\mathbf{s}}$ and the normal to plane P . As we shall see in more detail in Sec. 10.4.2, the cosine is hidden in $d_m(\mathbf{r}, \hat{\mathbf{s}})$, but the inverse-square factor appears explicitly.

Imaging equation with weak scatter If we substitute the Neumann series (10.168) into (10.240), we have

$$\bar{\mathbf{g}} = \mathcal{M}[\mathbf{I} - \boldsymbol{\chi}_\mu \boldsymbol{\mathcal{K}}]^{-1} \boldsymbol{\chi}_\mu \Xi_{p,\mathcal{E}} = \mathcal{M} \boldsymbol{\chi}_\mu \sum_{j=0}^{\infty} (\boldsymbol{\mathcal{K}} \boldsymbol{\chi}_\mu)^j \Xi_{p,\mathcal{E}}. \quad (10.250)$$

If the object being imaged is the source distribution and we assume monoenergetic, isotropic emission, we can write $\Xi_{p,\mathcal{E}}(\mathbf{r}, \mathcal{E}) = f(\mathbf{r}) \delta(\mathcal{E} - \mathcal{E}_0)/4\pi$.

The single-scatter term ($j = 1$) in (10.250) has the same structure as the no-scatter term except that $\mathcal{M} \boldsymbol{\chi}_\mu$ operates on $\boldsymbol{\mathcal{K}} \boldsymbol{\chi}_\mu \mathbf{S}$ rather than on \mathbf{S} directly. We can therefore compute the single-scatter kernel $h_m^{(1)}(\mathbf{r})$ in two steps, considering first the operator $\boldsymbol{\mathcal{K}} \boldsymbol{\chi}_\mu$ and then $\mathcal{M} \boldsymbol{\chi}_\mu$. From (10.129) and (10.151), the first of these operators has the form,

$$\begin{aligned} [\boldsymbol{\mathcal{K}} \boldsymbol{\chi}_\mu \mathbf{S}](\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) &= \int_\infty d^3r' K \left(\hat{\mathbf{s}}, \mathcal{E}; \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|}, \mathcal{E}_0 \mid \mathbf{r} \right) \\ &\times \frac{f(\mathbf{r}')}{4\pi c |\mathbf{r} - \mathbf{r}'|^2} \exp \left\{ - \int_0^{|\mathbf{r} - \mathbf{r}'|} d\ell' \mu_{tot} \left[\mathbf{r} - \left(\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \right) \ell' \right] \right\}, \end{aligned} \quad (10.251)$$

where we have used the delta function in $\Xi_{p,\mathcal{E}}(\mathbf{r}, \mathcal{E})$ to good end, and we have also made a change of variables, $\mathbf{r}' = \mathbf{r} - \hat{\mathbf{s}}\ell'$.

The interpretation of (10.251) is straightforward. Photons of energy \mathcal{E}_0 originate at \mathbf{r}' and travel to \mathbf{r} , diminishing in number per unit area because of the inverse-square factor and the attenuation factor. At \mathbf{r} , they scatter into direction $\hat{\mathbf{s}}$ with energy \mathcal{E} .

Now we can apply the operator $\mathcal{M}\mathcal{X}_\mu$ to propagate these photons to the plane P where they are measured by the imaging system. The operator \mathcal{X}_μ has the effect of replacing \mathbf{r} with $\mathbf{r} - \hat{\mathbf{s}}\ell$ everywhere, inserting another exponential factor and a $1/c$, and integrating over ℓ . The measurement operator \mathcal{M} is implemented by multiplication by d_m and integration over the plane P , energy \mathcal{E} and solid angle Ω . The overall kernel is thus

$$\begin{aligned}
 h_m^{(1)}(\mathbf{r}') &= \tau \int_P d^2r \int_0^\infty d\mathcal{E} \int_{2\pi} d\Omega d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) \int_0^\infty d\ell K\left(\hat{\mathbf{s}}, \mathcal{E}; \frac{\mathbf{r} - \hat{\mathbf{s}}\ell - \mathbf{r}'}{|\mathbf{r} - \hat{\mathbf{s}}\ell - \mathbf{r}'|}, \mathcal{E}_0 |\mathbf{r} - \hat{\mathbf{s}}\ell|\right) \\
 &\times \frac{1}{4\pi c^2 |\mathbf{r} - \hat{\mathbf{s}}\ell - \mathbf{r}'|^2} \exp\left\{-\int_0^{|\mathbf{r} - \hat{\mathbf{s}}\ell - \mathbf{r}'|} d\ell' \mu_{tot}\left[\mathbf{r} - \hat{\mathbf{s}}\ell - \left(\frac{\mathbf{r} - \hat{\mathbf{s}}\ell - \mathbf{r}'}{|\mathbf{r} - \hat{\mathbf{s}}\ell - \mathbf{r}'|}\right)\ell'\right]\right\} \\
 &\times \exp\left[-\int_0^\ell d\ell' \mu_{tot}(\mathbf{r} - \hat{\mathbf{s}}\ell')\right]. \quad (10.252)
 \end{aligned}$$

When integrated against a source distribution, this complicated expression gives the contribution to \bar{g}_m of photons that have scattered exactly once. If patience suffices, higher-order terms can be computed similarly.

10.4.2 Pinhole imaging

To illustrate the formalism developed in Sec. 10.4.1, we consider a circular pinhole imaging system of the kind that might be used to image a gamma-ray source in nuclear medicine. For short-wavelength radiation such as gamma rays, diffraction can be neglected and transport theory should give accurate answers.

The imaging geometry is illustrated in Fig. 10.8. We consider a circular pinhole of diameter D_{ph} in a thin sheet of highly absorbing material such as lead. The origin of coordinates is taken as the center of the pinhole, and the aperture plane is $z = 0$. The detectors are assumed to lie in the plane $z = -s$, hence parallel to the aperture plane and a distance s away. Two different choices for the reference plane P will be discussed below.

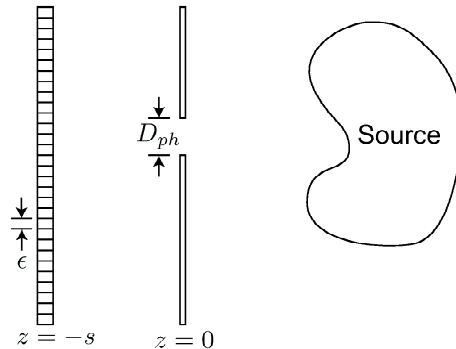

Fig. 10.8 Pinhole imager viewing a volume source.

Source model The source is assumed to be time-independent, monoenergetic and isotropic, so that

$$\Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = \frac{1}{4\pi} f(\mathbf{r}) \delta(\mathcal{E} - \mathcal{E}_0). \quad (10.253)$$

For simplicity, we assume that there is no absorption or scattering in the object itself, but we may still need to consider the absorption term in the Boltzmann equation, depending on where the reference plane P is with respect to the aperture plate.

Detector model The detector system is assumed to be a regular array of square detector elements of size $\epsilon \times \epsilon$, with the m^{th} element centered at position \mathbf{r}_m in the plane $z = -s$. We assume that $\epsilon \ll D_{ph}$ and that the detectors respond uniformly to photons that strike them. That is, the m^{th} detector element measures an integral of the spectral photon irradiance in the detector plane:

$$\bar{g}_m = \tau \int_0^\infty d\mathcal{E} \eta(\mathcal{E}) \int_\infty^\infty d^2r \operatorname{rect} \left[\frac{\mathbf{r} - \mathbf{r}_m}{\epsilon} \right] I_{p,\mathcal{E}}(\mathbf{r}, \mathcal{E}), \quad (10.254)$$

where $\eta(\mathcal{E})$, called the *quantum efficiency* of the detector, is the probability that a photon of energy \mathcal{E} incident on the detector will, in fact, be detected.

The spectral photon irradiance is related to the spectral photon radiance by (10.140), and the radiance is related in turn to the distribution function by a factor of c_m [cf. (10.98)], so

$$\bar{g}_m = \tau c_m \int_0^\infty d\mathcal{E} \eta(\mathcal{E}) \int_\infty^\infty d^2r \operatorname{rect} \left[\frac{\mathbf{r} - \mathbf{r}_m}{\epsilon} \right] \int_{2\pi} d\Omega w(\mathbf{r}, \hat{\mathbf{s}}) \hat{\mathbf{n}} \cdot \hat{\mathbf{s}}, \quad (10.255)$$

where $\hat{\mathbf{n}}$ is the unit vector normal to the detector plane (hence parallel to the z axis).

Reference plane coincident with detector plane Suppose initially that the reference plane coincides with the detector plane. Comparison of (10.255) with (10.239) shows immediately that

$$d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = \tau \eta(\mathcal{E}) c_m \operatorname{rect} \left[\frac{\mathbf{r} - \mathbf{r}_m}{\epsilon} \right] \hat{\mathbf{n}} \cdot \hat{\mathbf{s}}, \quad (10.256)$$

where \mathbf{r} and \mathbf{r}_m are the 2D vectors in the image plane specifying points \mathbf{r} and \mathbf{r}_m , respectively. Since the detector plane is $z = -s$, $\mathbf{r}_m = (\mathbf{r}_m, -s)$.

For small detectors such that $w(\mathbf{r}, \hat{\mathbf{s}}) \simeq w(\mathbf{r}_m, \hat{\mathbf{s}})$ within the m^{th} detector, we can write

$$\bar{g}_m \simeq \epsilon^2 \tau c_m \int_0^\infty d\mathcal{E} \eta(\mathcal{E}) \int_{2\pi} d\Omega w(\mathbf{r}_m, \hat{\mathbf{s}}, \mathcal{E}) \hat{\mathbf{n}} \cdot \hat{\mathbf{s}}. \quad (10.257)$$

Now we can make use of (10.151) along with the source model (10.253) to obtain

$$\bar{g}_m = \frac{\epsilon^2 \tau \eta(\mathcal{E}_0)}{4\pi} \int_{2\pi} d\Omega \int_0^\infty d\ell f(\mathbf{r}_m - \hat{\mathbf{s}}\ell) \hat{\mathbf{n}} \cdot \hat{\mathbf{s}} \exp \left[- \int_0^\ell d\ell' \mu_{abs}(\mathbf{r}_m - \hat{\mathbf{s}}\ell') \right]. \quad (10.258)$$

As we have done several times in this chapter, we make a change of variables by defining $\mathbf{r} = \mathbf{r}_m - \hat{\mathbf{s}}\ell$, noting that the minus sign reverses the direction of the

hemisphere of integration. Whenever $f(\mathbf{r}) = 0$ between the reference plane and the detector, we can extend the integral to the full sphere. In this case the reference plane is the detector plane, so (10.258) becomes

$$\bar{g}_m = \int_{\infty} d^3\mathbf{r} f(\mathbf{r}) h_m(\mathbf{r}), \quad (10.259)$$

where

$$h_m(\mathbf{r}) = \frac{\epsilon^2 \tau \eta(\mathcal{E}_0)}{4\pi} \frac{\hat{\mathbf{n}} \cdot (\mathbf{r}_m - \mathbf{r})}{|\mathbf{r}_m - \mathbf{r}|^3} \exp \left[- \int_0^{|\mathbf{r}_m - \mathbf{r}|} d\ell' \mu_{abs} \left(\mathbf{r}_m - \frac{\mathbf{r}_m - \mathbf{r}}{|\mathbf{r}_m - \mathbf{r}|} \ell' \right) \right]. \quad (10.260)$$

Since we are neglecting attenuation in the object, μ_{abs} refers only to the aperture. If we assume that μ_{abs} is very high for the aperture material, the exponential factor is nearly zero if the line $\mathbf{r}_m - \hat{\mathbf{s}}\ell$ passes through the absorbing portion of the aperture plate. Thus, for a small, point-like detector element, $h_m(\mathbf{r})$ is nearly zero except over a cone-shaped region of object space as shown in Fig. 10.9. If the detector element cannot be approximated by a point, the cone has fuzzy edges.

Fig. 10.9 Illustration of the detector response function for a pinhole imager.

The weighting within this conical region is just what we would calculate by elementary geometrical considerations. If we consider a unit-strength isotropic emitter at point \mathbf{r}_0 , then this source emits, on average, one photon per second or τ photons during the integration time. The m^{th} detector element subtends a solid angle Ω_m given by

$$\Omega_m = \frac{\epsilon^2}{|\mathbf{r}_m - \mathbf{r}_0|^2} \hat{\mathbf{n}} \cdot \frac{\mathbf{r}_m - \mathbf{r}_0}{|\mathbf{r}_m - \mathbf{r}_0|}, \quad (10.261)$$

where the scalar product is simply the cosine of the angle between the detector normal and the line of sight from \mathbf{r}_0 to the detector. If this line of sight passes through the open part of the pinhole, then the exponential is unity, otherwise it is near zero. The interpretation of (10.260) is then straightforward: the mean response of the m^{th} detector to a point equals the mean number of photons emitted by that point times the fractional solid angle $\Omega_m/4\pi$ times the probability $\eta(\mathcal{E}_0)$ that a photon reaching the detector will be detected times a 0–1 function indicating whether the photon is blocked by the aperture.

Reference plane coincident with aperture plane The reference plane P need not coincide with the detector plane; it can be placed anywhere between the source and

the detector. If it is immediately after the aperture plane, then $d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ is near zero unless \mathbf{r} lies in the open portion of the pinhole, so d_m includes a factor of $\text{cyl}(r/D_{ph})$. The cylinder function is defined in (3.257).

For a point within the pinhole, however, the m^{th} detector element responds only to radiation directed from this point to the detector. If the detector size ϵ is small, as we have assumed above, then this angular selectivity can be described by a delta function of the form

$$\epsilon^2 \frac{\cos \theta}{|\mathbf{r}_m - \mathbf{r}|^2} \delta \left(\hat{\mathbf{s}} - \frac{\mathbf{r}_m - \mathbf{r}}{|\mathbf{r}_m - \mathbf{r}|} \right) = \epsilon^2 \frac{\hat{\mathbf{n}} \cdot (\mathbf{r}_m - \mathbf{r})}{|\mathbf{r}_m - \mathbf{r}|^3} \delta \left(\hat{\mathbf{s}} - \frac{\mathbf{r}_m - \mathbf{r}}{|\mathbf{r}_m - \mathbf{r}|} \right), \quad (10.262)$$

where $\epsilon^2 \cos \theta$ is the area of the detector element projected onto the direction from point \mathbf{r} in the open aperture to the detector. The unit vector here looks much like the one in (10.261), but there is an essential difference: the vector \mathbf{r} here specifies a point in the aperture plane, not a point in the object, and the weight of the delta function is independent of location in the object.

The spectral photon radiance at point \mathbf{r} in the aperture plane is $c_m w$, and we recall from Sec. 10.2.1 that radiance is radiant flux per unit solid angle per unit *projected* area [see (10.62)]. To get the total photon flux from an area element $d^2 r$ into the direction defined by (10.262), we must multiply $c_m w$ by the projected area $\cos \theta d^2 r$. With respect to the line from \mathbf{r} to \mathbf{r}_m , both the aperture plane and the detector plane are tipped by an angle θ , so we need two cosine factors. In addition, the response is proportional to the quantum efficiency $\eta(\mathcal{E})$ and the exposure time τ , so we now have

$$d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = \epsilon^2 c_m \tau \eta(\mathcal{E}) \frac{\cos^2 \theta}{|\mathbf{r}_m - \mathbf{r}|^2} \text{cyl} \left(\frac{r}{D_{ph}} \right) \delta \left(\hat{\mathbf{s}} - \frac{\mathbf{r}_m - \mathbf{r}}{|\mathbf{r}_m - \mathbf{r}|} \right). \quad (10.263)$$

With this response function, the detector output is given by

$$\bar{g}_m = \epsilon^2 c_m \tau \int_0^\infty d\mathcal{E} \eta(\mathcal{E}) \int_\infty d^2 r \frac{\cos^2 \theta}{|\mathbf{r}_m - \mathbf{r}|^2} \text{cyl} \left(\frac{r}{D_{ph}} \right) w \left(\mathbf{r}, \frac{\mathbf{r}_m - \mathbf{r}}{|\mathbf{r}_m - \mathbf{r}|}, \mathcal{E} \right). \quad (10.264)$$

With (10.151) and (10.253), we find

$$\bar{g}_m = \frac{\epsilon^2 \tau \eta(\mathcal{E}_0)}{4\pi} \int_0^\infty d\ell \int_\infty d^2 r \frac{\cos^2 \theta}{|\mathbf{r}_m - \mathbf{r}|^2} \text{cyl} \left(\frac{r}{D_{ph}} \right) f \left(\mathbf{r} - \ell \frac{\mathbf{r}_m - \mathbf{r}}{|\mathbf{r}_m - \mathbf{r}|} \right). \quad (10.265)$$

There is now no exponential factor since we are assuming that the object is non-absorbing. Nevertheless, the integral is over the conical region depicted in Fig. 10.9 since the cylinder function selects out lines in that region. Moreover, $d^2 r \cos \theta / |\mathbf{r}_m - \mathbf{r}|^2$ is the solid angle subtended by $d^2 r$ from the detector, so we can replace that expression by $d\Omega$, and (10.258) is then recovered.

Thus the two choices for reference plane lead to the same expression for \bar{g}_m and hence for $h_m(\mathbf{r})$.

10.4.3 Optical imaging of a planar source

In the last section we discussed pinhole imaging of a volume source, such as a radioisotope distribution in nuclear medicine. In optics, however, we are more often concerned with surface emitters, and we can use lenses and mirrors rather than simple apertures such as pinholes. In this section we shall see how the general imaging equation (10.239) can be applied in this case.

Source description Consider a source confined to the plane $z = 0$. If the source is independent of time and if its spectral and directional properties are independent of position, then we can express the source distribution as

$$\Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = A(\hat{\mathbf{s}}) N(\mathcal{E}) f(\mathbf{r}) \delta(z), \quad (10.266)$$

where $A(\hat{\mathbf{s}})$ describes the angular dependence, $f(\mathbf{r})$ describes the dependence on position in the plane, and $N(\mathcal{E})$ gives the spectral dependence. We shall generalize this source description below and allow different points on the object plane to have different spectral characteristics.

When we discussed isotropic volume sources, the angular factor $A(\hat{\mathbf{s}})$ was assumed to be a constant [cf. (10.242)], but in the case of Lambertian surface emitters, it must contain a cosine factor. To see why, let us use (10.136) to compute the distribution function w in the plane $z = 0^+$, just to the right of the source. Since $c_m w$ is the spectral photon radiance, and since a Lambertian source has constant radiance in the source plane, this calculation must give w independent of $\hat{\mathbf{s}}$. With a general $A(\hat{\mathbf{s}})$, however, (10.136) shows that

$$c_m w(\mathbf{r}, z, \hat{\mathbf{s}}, \mathcal{E}) = A(\hat{\mathbf{s}}) N(\mathcal{E}) \int_0^\infty d\ell \cdot f(x - s_x \ell, y - s_y \ell) \delta(z - s_z \ell), \quad (10.267)$$

where $\hat{\mathbf{s}} = (s_x, s_y, s_z)$ and of course $f(x, y) = f(\mathbf{r})$. With the help of (2.28), we find

$$c_m w(\mathbf{r}, z, \hat{\mathbf{s}}, \mathcal{E}) = A(\hat{\mathbf{s}}) N(\mathcal{E}) f\left(x - \frac{s_x}{s_z} z, y - \frac{s_y}{s_z} z\right) \frac{1}{s_z}. \quad (10.268)$$

In order for this expression to be independent of $\hat{\mathbf{s}}$ as $z \rightarrow 0^+$, we must have $A(\hat{\mathbf{s}}) \propto s_z$, which is just the cosine of the angle between $\hat{\mathbf{s}}$ and the z -axis (or surface normal).

To summarize and generalize, a planar Lambertian source lying in the plane $\mathbf{r} \cdot \hat{\mathbf{n}} = p$ is described by the source distribution¹⁴

$$\Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = (\hat{\mathbf{s}} \cdot \hat{\mathbf{n}}) N(\mathcal{E}) f(\mathbf{r}) \delta(p - \mathbf{r} \cdot \hat{\mathbf{n}}), \quad (10.269)$$

provided the spatial and spectral properties are independent. The spectral photon radiance immediately adjacent to this source is given by

$$L_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = c_m w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = N(\mathcal{E}) f(\mathbf{r}). \quad (10.270)$$

Imaging with a simple lens Consider a planar Lambertian source lying in the plane $z = -p$, a thin lens of focal length f and diameter D_{lens} in the plane $z = 0$, and a discrete detector array in the plane $z = q$, where p , q and f are related by the imaging equation $p^{-1} + q^{-1} = f^{-1}$. In terms of paraxial geometrical optics, this system is described by the ABCD matrix (9.247):

$$\mathbf{M} = \begin{bmatrix} m & 0 \\ -\frac{1}{f} & \frac{1}{m} \end{bmatrix}, \quad (10.271)$$

where $m = -p/q$.

¹⁴The reader should not lose sight of our convention that \mathbf{r} and \mathbf{r} refer to the same point on the plane.

We can use this matrix in (10.115) to determine the radiance in the detector plane when the input radiance is specified by (10.270). If there were no aperture on the lens, the result would be $N(\mathcal{E})f(m\mathbf{r})$, but the radiance in the detector plane cannot be independent of angle if only a finite range of ray angles emerges from the lens; radiance is constant along a ray only if that ray is not interrupted by an aperture. If we neglect diffraction from the aperture, we can write

$$L_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}, t) = N(\mathcal{E}) f(m\mathbf{r}) I(\mathbf{r}, \hat{\mathbf{s}}), \quad (z = q), \quad (10.272)$$

where $I(\mathbf{r}, \hat{\mathbf{s}})$ is an indicator function that takes on the value 1 when a ray from point \mathbf{r} in the detector plane extended backward along $\hat{\mathbf{s}}$ passes through the lens aperture, and $I(\mathbf{r}, \hat{\mathbf{s}})$ is 0 otherwise.

Detector response The simplest model for the response of a detector is that it integrates the irradiance over its active area and is independent of incidence angle or photon energy. With this model, the output of the j^{th} detector has the form [cf. (10.257)]

$$\bar{g}_j \propto \int_0^\infty d\mathcal{E} N(\mathcal{E}) \int_P d^2r f(m\mathbf{r}) \text{rect} \left[\frac{\mathbf{r} - \mathbf{r}_j}{\epsilon} \right] \int_{2\pi} d\Omega I(\mathbf{r}, \hat{\mathbf{s}}) \hat{\mathbf{n}} \cdot \hat{\mathbf{s}}, \quad (10.273)$$

where plane P coincides with the detector.

A common approximation at this stage is to consider a lens with a large F -number so that $q \gg D_{\text{lens}}$ and to assume that the pixel size ϵ is much smaller than D_{lens} . Then the factor $\hat{\mathbf{n}} \cdot \hat{\mathbf{s}}$ can be approximated by the cosine of the angle θ_j from the j^{th} detector pixel to the center of the lens and removed from the integral. Similarly, the indicator function $I(\mathbf{r}, \hat{\mathbf{s}})$ can be approximated by $I(\mathbf{r}_j, \hat{\mathbf{s}})$. The integral over $d\Omega$ is then just the solid angle subtended by the lens from the point \mathbf{r}_j ; within the approximation we are making, this solid angle is given explicitly by

$$\Omega_{\text{lens}}(\mathbf{r}_j) \equiv \int_{2\pi} d\Omega I(\mathbf{r}_j, \hat{\mathbf{s}}) \simeq \frac{\pi D_{\text{lens}}^2}{4R_j^2} \cos \theta_j = \frac{\pi D_{\text{lens}}^2}{4q^2} \cos^3 \theta_j, \quad (10.274)$$

where $R_j \equiv q/\cos \theta_j$ is the distance from the detector element to the center of the lens. Thus we have

$$\bar{g}_j \propto \cos^4 \theta_j \int_P d^2r f(m\mathbf{r}) \text{rect} \left[\frac{\mathbf{r} - \mathbf{r}_j}{\epsilon} \right]. \quad (10.275)$$

With the current approximations, therefore, the detector output is the integral of the magnified object weighted with a factor $\cos^4 \theta_j$. (One cosine factor comes from converting projected area to area on the detector, and the other three factors come from the solid angle of the lens.) This result shows that the image of a uniform object (the flood image discussed in Sec. 7.2.1) will not be uniform.

To reiterate the approximations made in deriving (10.275), we assumed that the system could be described by a simple ABCD matrix and that diffraction from the lens aperture could be neglected; that the lens F -number was large and that the detector element was small; that the source was Lambertian with spectral properties independent of position; and that the detector simply integrated the irradiance without regard for spectral or angular properties of the radiation. It is straightfor-

ward to avoid these approximations and to allow more complicated detector models, but numerical evaluation will usually be required.¹⁵

Spatio-spectral sources The source description of (10.266) is seldom valid in optics. It might hold in fluorescence microscopy with a single fluorophore, but most emissive or reflective objects have different spectral properties at different locations. For such objects, a better description for a planar source is

$$\Xi_{p,\mathcal{E}}(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = A(\hat{\mathbf{s}}) f(\mathbf{r}, \mathcal{E}) \delta(z). \quad (10.276)$$

This form allows a general spatio-spectral function but it still assumes that the angular properties are independent of location and energy; for example, this model would hold for Lambertian objects.

Without further assumptions, we would now have to consider $f(\mathbf{r}, \mathcal{E})$ as a 3D object function, even though it is only 2D spatially. If we can assume, however, that the spectral response of the detector is independent of position and angle, then a simplification results. Suppose the detector response can be written as

$$d_j(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) \propto D(\mathcal{E}) \operatorname{rect} \left[\frac{\mathbf{r} - \mathbf{r}_j}{\epsilon} \right], \quad (10.277)$$

where $D(\mathcal{E})$ is a normalized spectral response function. Then retracing the steps leading up to (10.275) shows that

$$\bar{g}_j \propto \cos^4 \theta_j \int_P d^2r f_{eff}(\mathbf{r}) \operatorname{rect} \left[\frac{\mathbf{r} - \mathbf{r}_j}{\epsilon} \right], \quad (10.278)$$

where $f_{eff}(\mathbf{r})$ is an effective 2D object function defined by

$$f_{eff}(\mathbf{r}) = \int_0^\infty d\mathcal{E} D(\mathcal{E}) f(\mathbf{r}, \mathcal{E}). \quad (10.279)$$

Thus the conventional view of the lens system as a 2D-to-2D mapping is preserved with this detector model. If neither the object nor the detector has spectral properties independent of position, however, we have to use a 3D-to-2D mapping, with the third dimension being photon energy or wavelength.

10.4.4 Adjoint methods

So far we have derived a general imaging equation and applied it to pinhole imaging and optical imaging. In these simple problems, we were able to obtain useful results completely analytically. In more complicated problems, however, numerical methods will be needed. This section and the next introduce important practical techniques for the numerical computation of images. In particular, here we show the role of adjoint operators.

¹⁵The reader may well question the consistency of these approximations. Since we used an ABCD matrix derived in the last chapter under paraxial conditions, should we not have set $\cos \theta_j$ to unity throughout? The answer might be yes for a simple lens, but for well-designed lenses with low distortion and low field curvature, the ABCD matrix of (10.271) will be valid at much larger angles than ones for which $\cos^4 \theta_j \simeq 1$.

Linear CD systems To introduce adjoint methods, let us reexamine the discussion in Sec. 7.2.1 on linear CD systems that can be decomposed into a CC system followed by a detector array modeled as a linear CD mapping. From (7.227) and (7.229), we know that the mean image produced by such a system can be described by

$$\bar{\mathbf{g}} = \mathcal{D}_a \mathcal{H}_{CC} \mathbf{f} \equiv \mathcal{H} \mathbf{f}, \quad (10.280)$$

or in component form as

$$\bar{g}_m = \int_{\mathbf{S}_g} d^s r_d a_m(\mathbf{r}_d) \int_{\mathbf{S}_f} d^q r h(\mathbf{r}_d, \mathbf{r}) f(\mathbf{r}), \quad (10.281)$$

where $a_m(\mathbf{r}_d)$ is the response function of the m^{th} detector. This response function can, for example, take the value 1 inside the aperture of the detector and 0 outside. Recall that \mathbf{r} is a position vector of dimensionality q in the object domain, and \mathbf{r}_d is a position vector of dimensionality s on the detector plane, before sampling by the discrete detector array.

This last equation can be rewritten in two equivalent forms,

$$\bar{g}_m = (\mathbf{a}_m, \mathcal{H}_{CC} \mathbf{f}) = (\mathcal{H}_{CC}^\dagger \mathbf{a}_m, \mathbf{f}), \quad (10.282)$$

where \mathbf{a}_m is the Hilbert-space vector corresponding to the function $a_m(\mathbf{r}_d)$. The first scalar product is thus in the continuous data space (variable \mathbf{r}_d), and the second scalar product is in the continuous object space (variable \mathbf{r}). In the first version we map the object through \mathcal{H}_{CC} onto the detector response function, and in the second version we map the detector response function through \mathcal{H}_{CC}^\dagger onto the object.

Though the two versions of (10.282) are mathematically equivalent, the second or adjoint version may have considerable computational benefit in simulation studies. To implement the first version for a particular object, we have to transform the object through the operator \mathcal{H}_{CC} ; if this operator is represented by a matrix with K sample points for each dimension, then altogether it is a $K^s \times K^q$ matrix, and for realistic choices of K , this size may be completely impractical. In the second version, we have a matrix of the same size but need only apply it to a compact vector, most elements of which are zero. For example, it often suffices to use a 3×3 or 5×5 array of sampling points across a 2D detector element, and in that case $a_m(\mathbf{r}_d)$ is represented by just 9 or 25 nonzero samples. The operation $\mathcal{H}_{CC}^\dagger \mathbf{a}_m$ thus becomes feasible, and the result is represented as K^q points in the discretized object space. Many of these points may be near zero, but the scalar product with any given object vector requires at most K^q multiplies. In addition, the calculation of $\mathcal{H}_{CC}^\dagger \mathbf{a}_m$ does not have to be repeated for each new object.

In some problems $\mathcal{H}_{CC}^\dagger \mathbf{a}_m$ can be computed completely analytically without any matrix representations. For example, in diffraction-limited optical systems, $\mathcal{H}_{CC}^\dagger \mathbf{a}_m$ is determined by the diffraction pattern of the detector aperture, which can be expressed analytically in terms of Fresnel integrals for Fresnel diffraction (see Sec. 9.4.6) or as the Fourier transform of $a_m(\mathbf{r}_d)$ for Fraunhofer diffraction (see Sec. 9.4.7).¹⁶ When such analytic calculations are possible, discretization is needed

¹⁶For incoherent optical systems, one must take the squared modulus of the amplitude of these diffraction patterns, but the system is nevertheless linear when the input and output are stated in terms of irradiance.

only for the final scalar product in the second version of (10.282). The first version, on the other hand, is nearly useless for analytic purposes since the object is not expressed analytically in the first place, and even if it was, its analytic diffraction pattern would almost never be calculable.

Adjoint methods for transport calculations Adjoint methods are also useful for the Boltzmann equation. To illustrate, consider the steady-state Boltzmann equation (10.164) for photons, which can be written in simplified form as

$$v \hat{\mathbf{s}} \cdot \nabla w + v \mu_{tot} w - \mathcal{K} w = \Xi, \quad (10.283)$$

where v is the speed of light in the medium (denoted c_m earlier in this chapter, but we now need the subscript m for something else) and Ξ is the spectral photon distribution function of the source (denoted $\Xi_{p,\mathcal{E}}$ earlier), \mathcal{K} is the scattering operator and w denotes the distribution function $w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$. In general, Ξ depends on direction $\hat{\mathbf{s}}$, photon energy \mathcal{E} and 3D position \mathbf{r} , but it may be valid to assume that the directional and energy dependences are independent of position, and then the source description is reduced to a purely spatial function like our familiar $f(\mathbf{r})$ (see Sec. 10.4.2).

We can also regard the distribution function as a vector in a Hilbert space of square-integrable functions of 3D position, direction and energy. We shall call this new Hilbert space *distribution space* and denote it as \mathbb{D} , and the distribution function itself, regarded as a vector in this space, will be denoted as \mathbf{w} . We can then express the Boltzmann equation in operator form as

$$\mathcal{B} \mathbf{w} = \Xi, \quad (10.284)$$

where \mathcal{B} is an operator given by

$$\mathcal{B} = v \hat{\mathbf{s}} \cdot \nabla + v \mu_{tot} - \mathcal{K}. \quad (10.285)$$

In the absence of scattering, \mathcal{B} is a first-order partial differential operator, and in free space where both the absorption and scattering vanish, $\mathcal{B} = v \hat{\mathbf{s}} \cdot \nabla$. In all cases, \mathcal{B} is a local operator; the scattering operator \mathcal{K} mixes angles and energies but maps a distribution function at one spatial location to another distribution function at the *same* location.

If there are no radiation sources outside some volume V , the operator \mathcal{B} has a left inverse, which simply means that the distribution function \mathbf{w} in V is fully determined by the source Ξ within V . Denoting this left inverse as \mathcal{L} , we can write

$$\mathbf{w} = \mathcal{L} \Xi. \quad (10.286)$$

When the source is describable by its spatial dependence alone, we can go a step further and write

$$\mathbf{w} = \mathcal{L}_f \mathbf{f}. \quad (10.287)$$

Expressions for \mathcal{L} and \mathcal{L}_f are given for various cases in Sec. 10.3; with scattering it is difficult to express them analytically except by an infinite series such as (10.168).

Of course, the distribution function \mathbf{w} is not an image, but in many cases a (noise-free) digital image consists of a set of linear functionals of \mathbf{w} (see Sec. 10.4.1). Specifically, if the detector is linear and its response function for the m^{th}

measurement is denoted $d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$, then the mean of the measurement is given under steady-state conditions by [cf. (10.239)]

$$\bar{g}_m = \tau \int_P d^2r \int_0^\infty d\mathcal{E} \int_{2\pi} d\Omega d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}), \quad (10.288)$$

where τ is the exposure time. As we discussed in Sec. 10.4.1, \mathbf{r} is a general 3D vector, but the spatial integral is over the two variables needed to specify a reference plane P somewhere between the source and detector. If we denote that plane as $z = 0$ and assume that only photons with $s_z \geq 0$ are directed towards the detector, we can redefine the detector response function in 3D by letting

$$p_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) \equiv \tau d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) \delta(z) \text{step}(s_z), \quad (10.289)$$

and (10.288) becomes

$$\bar{g}_m = \int_V d^3\mathbf{r} \int_0^\infty d\mathcal{E} \int_{4\pi} d\Omega p_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) w(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}). \quad (10.290)$$

We can regard this expression as a scalar product¹⁷:

$$\bar{g}_m = (\mathbf{p}_m, \mathbf{w})_{\mathbb{D}}. \quad (10.291)$$

We can also define adjoints of the operators \mathcal{B} , \mathcal{L} and \mathcal{L}_f ; note that the first two of these operators map \mathbb{D} to itself, but the third maps $\mathbb{L}_2(\mathbb{R}^q)$ to \mathbb{D} . The usefulness of \mathcal{L}^\dagger and \mathcal{L}_f^\dagger is that we can write, analogously to (10.282),

$$\bar{g}_m = (\mathcal{L}^\dagger \mathbf{p}_m, \Xi)_{\mathbb{D}} = (\mathcal{L}_f^\dagger \mathbf{p}_m, \mathbf{f})_{\mathbb{L}_2(\mathbb{R}^q)}. \quad (10.292)$$

The latter form in particular is useful computationally since \mathcal{L}_f^\dagger maps the detector response from a 6D space to a 2D or 3D one. Also, as in the discussion of adjoint methods above, the difficult calculation $\mathcal{L}_f^\dagger \mathbf{p}_m$ does not need to be repeated for each \mathbf{f} , and in some problems (usually without scatter) it can be performed analytically.

Adjoint Boltzmann equation The adjoint of \mathcal{B} plays a rather different role than the adjoints of \mathcal{L} and \mathcal{L}_f . It is not used with solutions of the Boltzmann equation itself, but rather with solutions of the *adjoint Boltzmann equation*:

$$\mathcal{B}^\dagger \tilde{\mathbf{w}}_m = \mathbf{p}_m. \quad (10.293)$$

In this equation, $\tilde{\mathbf{w}}_m$ is a function in \mathbb{D} but not the photon distribution produced by the actual source. To understand its significance, let us temporarily ignore scatter so that \mathcal{B} becomes a differential operator,

$$\mathcal{B} = v \hat{\mathbf{s}} \cdot \nabla + v \mu_{abs}. \quad (10.294)$$

Adjoint of differential operators were discussed in Sec. 4.1.3. Integration by parts [cf. (4.16)] shows that

$$\mathcal{B}^\dagger = -v \hat{\mathbf{s}} \cdot \nabla + v \mu_{abs}, \quad (10.295)$$

¹⁷A technical difficulty here is that $p_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ is not a square-integrable function because of the factor $\delta(z)$, but this problem can be handled by a limiting argument. The problem would not arise in the first place if we considered the finite thickness of the detector.

provided the boundary terms vanish.¹⁸ Thus the forward operator \mathcal{B} describes particles moving at speed v in direction \hat{s} , while the adjoint \mathcal{B}^\dagger describes particles moving at the same speed in direction $-\hat{s}$. The adjoint distribution function \tilde{w}_m can be viewed as the distribution function in the object domain that would result if the detector response function \mathbf{p}_m were a source of these backward-travelling photons.

Without scatter, the ordinary Boltzmann equation is solved by the attenuated x-ray transform (10.151). For the adjoint Boltzmann equation without scatter, (10.151) is again the solution provided we replace the actual source Ξ with the effective source p_m and also let $\hat{s} \rightarrow -\hat{s}$.

When the scatter term is reinstated, the adjoint operator becomes

$$\mathcal{B}^\dagger = -v \hat{s} \cdot \nabla + v \mu_{tot} - \mathcal{K}^\dagger. \tag{10.296}$$

The kernel for the forward scatter operator \mathcal{K} is defined by (10.129), and the reader should be able to construct the kernel for \mathcal{K}^\dagger by taking a little care with the primes on the energy variables. Actually solving the adjoint Boltzmann equation with scatter usually requires Monte Carlo methods, to be discussed in Sec. 10.4.5.

If we have solved the adjoint Boltzmann equation, the mean image can be computed by combining (10.291) and (10.293) as follows:

$$\bar{g}_m = (\mathbf{p}_m, \mathbf{w}) = (\mathcal{B}^\dagger \tilde{w}_m, \mathbf{w}) = (\tilde{w}_m, \mathcal{B} \mathbf{w}) = (\tilde{w}_m, \Xi), \tag{10.297}$$

where the last step has used (10.284). Thus the scalar product between the adjoint distribution function and the source is the same as that between the actual physical distribution function and the detector response, namely the desired mean data \bar{g}_m .

10.4.5 Monte Carlo methods

The term *stochastic simulation* refers to a broad class of methods in which some quantity is estimated by performing random experiments, either physically or in a computer, in such a way that the mean value of the experimental outcome is the quantity of interest. The quantities being estimated are often naturally interpretable as probabilities, but many applications of stochastic simulation have no relation to probability except as a computational tool.

Historically, stochastic simulation substantially predates computers. For example, the eighteenth-century French polymath Georges-Louis Leclerc De Buffon¹⁹ (1707–1768) posed the question: If a needle of length L is thrown randomly onto a grid of parallel lines of spacing L , what is the probability that the needle will overlap one of the lines? The answer turns out to be $2/\pi$, and throughout the nineteenth and twentieth century many people used either experiments with real needles or simulations as a way of estimating π .

Similarly, W. S. Gosset (“Student”) used numerical experiments to verify his analytic form for the celebrated t distribution. Lord Rayleigh and A. N. Kolmogorov showed the connection between random walks and differential equations.

¹⁸In fact, the boundary terms vanish if it is possible, as we have assumed, to set up a reference plane completely separating the source and detector; see Lewis and Miller (1984).

¹⁹It was also Buffon who in 1748 suggested what we now call Fresnel lenses. Fresnel’s contribution was applying them to the construction of lighthouse lenses (*Encyclopedia Britannica*, 2001).

The real power of stochastic simulation, however, emerged with the advent of computers, and the application that sparked widespread interest was simulation of neutron transport in connection with the Manhattan Project during World War II. Key figures in this development included John von Neumann, Edward Teller, Nicolas Metropolis, Herman Kahn and Stanislaw Ulam.

When one person is singled out as the originator of this method, it is usually Stanislaw Ulam (1909–1984). Ulam obtained his Ph.D. in 1933 from the Polytechnic Institute in Lemberg, Poland (now Lvov, Ukraine), where he studied under Banach and drank coffee at the Scottish Cafe. In 1935 he was invited by von Neumann to spend a few months at the Institute for Advanced Studies of Princeton, and in 1940 he emigrated permanently to the U.S. In 1943 he received a second invitation from von Neumann, this time to participate in secret wartime research. It was apparently Ulam who suggested the colorful term *Monte Carlo* for the general class of methods that relies on computer-generated random numbers. Von Neumann, on the other hand, remained skeptical; in 1951 he said, “Anyone who considers arithmetical methods of producing random digits is, of course, in a state of sin.”

An important practical advantage of Monte Carlo methods in general is that they are inherently well suited to parallel computation (with either many peasants throwing needles or many computers computing particle trajectories). Since the events are independent, the processing speed grows linearly with the number of processing units.

We shall introduce Monte Carlo methods here with a brief discussion of their use in performing definite integrals, but then we shall return to their use in transport calculations and image simulation.

Monte Carlo integration Consider an integral of the form

$$I = \int_a^b dx f(x) p(x), \quad (10.298)$$

where $p(x)$ is a PDF on (a, b) [*i.e.*, $p(x) \geq 0$ and $\int_a^b dx p(x) = 1$]. Thus I is the expectation of $f(x)$ with respect to this PDF. If we can draw a set of samples $\{x_i\}$ from $p(x)$, say by one of the methods discussed in Sec. C.7, then we can construct a random point process $u(x)$ defined by

$$u(x) = \frac{1}{N} \sum_{i=1}^N \delta(x - x_i). \quad (10.299)$$

We can then estimate I by

$$\hat{I}_N \equiv \int_a^b dx f(x) u(x) = \frac{1}{N} \sum_{i=1}^N f(x_i). \quad (10.300)$$

This viewpoint of a Monte Carlo estimate as a scalar product with a random point process will prove useful below.

A full treatment of random point processes will be given in Chap. 11, but we anticipate a few simple results here. As we shall show in (11.81), $\langle u(x) \rangle = p(x)$, so it follows that $\langle \hat{I}_N \rangle = I$. It can also be shown that

$$\lim_{N \rightarrow \infty} \hat{I}_N = I, \quad \text{Var}\{\hat{I}_N\} \propto \frac{1}{N}. \quad (10.301)$$

Thus the estimate of I is unbiased and consistent.

The basic idea of Monte Carlo integration extends readily to multidimensional integrals, and in fact the Monte Carlo approach becomes increasingly advantageous as the dimension increases. If we want to perform a q D integral by sampling on a regular grid with a total of N function evaluations, then we have $N^{\frac{1}{q}}$ samples in each dimension, and the precision of the result (expressed as RMS error) varies as $N^{-\frac{1}{2q}}$. For Monte Carlo estimation, again with N function evaluations, the variance of the estimate varies as $1/N$ for all q , so the precision (standard deviation of the estimate) varies as $N^{-\frac{1}{2}}$. For large q , convergence is therefore much faster with Monte Carlo.

Monte Carlo transport calculations For simulating imaging systems (as opposed to bombs), the essence of a Monte Carlo transport calculation is simply to track photons in a computer from a source towards a detector. The initial photon directions and the locations and outcomes of all scattering and absorption events are assigned by calling suitable random-number generators, mimicking the actual physical processes. Each photon is tracked until it is either absorbed, reaches the reference plane P between the source and the detector, or escapes from the system altogether. We repeat the procedure for a total of N initial photons and denote the number that make it to P as N_P .

At this stage, we know the photon coordinates $\{\mathbf{r}_i, \hat{\mathbf{s}}_i, \mathcal{E}_i, i = 1, \dots, N_P\}$, and we can define a random point process analogous to (10.299) by

$$u(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E}) = \frac{1}{N_P} \sum_{i=1}^{N_P} \delta(\mathbf{r} - \mathbf{r}_i) \delta(\hat{\mathbf{s}} - \hat{\mathbf{s}}_i) \delta(\mathcal{E} - \mathcal{E}_i). \quad (10.302)$$

The mean measurement \bar{g}_m is defined in (10.291), and it can be estimated by analogy to (10.300) as

$$\hat{g}_m = \frac{\bar{N}_{em} N_P}{N\tau} (\mathbf{p}_m, \mathbf{u})_{\mathbb{D}} = \frac{\bar{N}_{em}}{N} \sum_{i=1}^{N_P} d_m(\mathbf{r}_i, \hat{\mathbf{s}}_i, \mathcal{E}_i), \quad (10.303)$$

where N is the number of initial photons used in the Monte Carlo simulation and \bar{N}_{em} is the mean number of photons emitted during the exposure time when an actual physical source is used. (In most Monte Carlo problems, \bar{N}_{em} can be computed directly from the original object description and does not have to be estimated.) The reader may demonstrate her virtuosity with point processes by showing that this estimator is unbiased, at least to the extent that the Monte Carlo simulation accurately models the real physical processes that would occur with the physical source.

Mechanics of Monte Carlo We shall illustrate some of the practical aspects of Monte Carlo simulation by describing how to simulate the image of a self-luminous object that both absorbs and scatters its own radiation. This description is motivated by single-photon emission computed tomography or SPECT (see Chap. 17), but it is applicable also to fluorescence microscopy, solar imaging and studies of flames, for example.

The first step is to choose the emission point for the photon. If the object is specified in a voxel representation, one approach is to step systematically

through the voxels and to let each voxel emit a random number of photons, Poisson-distributed about a mean proportional to the coefficient θ_n associated with that voxel. This approach amounts to assuming that the object is the mean of a Poisson random process (see Sec. 11.3).

When the object is specified geometrically, for example in terms of geometric shapes, a variant on the rejection method of Sec. C.7.1 can be used. First the object is normalized by defining $f_0(\mathbf{r}) \equiv f(\mathbf{r})/\max\{f(\mathbf{r})\}$. Then a point \mathbf{r} is chosen randomly from a PDF that is uniform over the object support, and a photon is assumed to be emitted from this point if $f_0(\mathbf{r}) > t$, where t is a uniform random number on $(0, 1)$. This method amounts to assuming that the object is the mean of a random process but not necessarily a Poisson one.

Having chosen the emission point, the next step is to launch a photon from that point in a random direction, taking care to get the proper angular distribution. For example, if the source is an isotropic emitter, we must ensure that all emission directions are equally probable. If the direction is specified by the usual polar angles θ and ϕ , it is not correct to choose values for these angles by calling a uniform random-number generator. The problem is that the differential solid angle is given by $d\Omega = \sin\theta d\theta d\phi$, so a uniform distribution of θ and ϕ does not correspond to a constant number of photons per unit solid angle (or constant radiant intensity). A simple fix is to choose $\cos\theta$ from a uniform distribution over $(-1, 1)$, then to compute θ itself by taking an arccosine. Since $d\Omega = d(\cos\theta) d\phi$, this procedure gives a source radiant intensity independent of direction. On the other hand, if we wish to simulate a Lambertian surface emitter, we must make the radiant intensity vary as $\cos\theta$, where this angle is measured from the surface normal (see Sec. 10.2.1). We can do this by drawing $\cos\theta$ from $\text{pr}(\cos\theta) = \cos\theta$, $(-1 < \cos\theta < 1)$.

The next step is to decide whether the photon escapes from the object without interacting, or instead undergoes an absorption or scattering process at some point. For this purpose it is necessary to specify the spatial distribution of the total attenuation coefficient $\mu_{tot}(\mathbf{r}, \mathcal{E})$. We shall use the medical terminology here and refer to this distribution as the *body*, thereby distinguishing it from the *object*, which refers to the distribution of the radiation source. The simplest assumption is that $\mu_{tot}(\mathbf{r}, \mathcal{E})$ is the constant μ_{tot} , independent of position and energy within the boundaries of a convex body. Under these assumptions, the probability of the photon escaping from the body without interacting is given by $P_{esc} = \exp[-\mu_{tot}L(\mathbf{r}, \hat{\mathbf{s}})]$, where $L(\mathbf{r}, \hat{\mathbf{s}})$ is the total length of attenuating medium between point \mathbf{r} and the detector in direction $\hat{\mathbf{s}}$. If the attenuation is not uniform, numerical integration must be used to compute P_{esc} . To decide whether the particular photon being simulated escapes, we can draw a random number t_1 uniformly from $(0, 1)$; if $t_1 < P_{esc}$, the photon escapes.

If the photon does not escape, we must decide where it interacts, whether the interaction is absorption or scattering, and in the latter case the direction of the scattered photon. For x rays or gamma rays, we must also decide whether the scattering is elastic or inelastic (Compton). Each of these decisions can be made by drawing suitably distributed random numbers. As an example, to decide where the interaction takes place, we must draw a random number from the density $\text{pr}(\ell)$ on interaction at distance ℓ from the source. For uniform attenuation, source location \mathbf{r} and propagation direction $\hat{\mathbf{s}}$, this density is given by

$$\text{pr}_\ell(\ell) = \frac{\mu_{tot} \exp(-\mu_{tot}\ell)}{1 - \exp[-\mu_{tot}L(\mathbf{r}, \hat{\mathbf{s}})]}, \quad 0 \leq \ell \leq L(\mathbf{r}, \hat{\mathbf{s}}). \quad (10.304)$$

The corresponding cumulative distribution function is

$$F_\ell(\ell) = \int_0^\ell d\ell' \text{pr}_\ell(\ell') = \frac{1 - \exp(-\mu_{tot}\ell)}{1 - \exp[-\mu_{tot}L(\mathbf{r}, \hat{\mathbf{s}})]}. \quad (10.305)$$

Following the procedure of Sec. C.7.2, we draw a random variable t_2 uniformly from $(0, 1)$ and solve the equation $t_2 = F_\ell(\ell)$; the result is

$$\ell = -\frac{1}{\mu_{tot}} \ln \{1 - t_2 + t_2 \exp[-\mu_{tot}L(\mathbf{r}, \hat{\mathbf{s}})]\}. \quad (10.306)$$

The variables generated this way will follow the PDF of (10.304). A similar procedure can be used for nonuniform attenuation, but the equation $t_2 = F_\ell(\ell)$ must be solved numerically in that case.

To decide whether the interaction after traversing distance ℓ is absorption or scattering, we draw another random number t_3 uniformly from $(0, 1)$ and choose the absorption interaction if $t_3 < \mu_{pe}/\mu_{tot}$. If the interaction is an absorption, the photon is terminated, but if it is scattering it is necessary to choose a direction for the scattered photon. This step is accomplished by the methods of Sec. C.7.2 along with knowledge of the differential scattering cross section (see Sec. 10.2.5). For Compton scattering, the energy of the scattered photon is then determined from the scattering angle and (10.226). The process is repeated until the photon either undergoes an absorption or escapes the body.

When the photon escapes the body, we have several options, depending on how we choose the reference plane separating the source and detector. As we saw by example in Sec. 10.4.2, we can choose this plane such that the photons do not encounter any apertures or image-forming elements before reaching the plane, or we can choose it immediately adjacent to the detector, or anywhere in between. If there are no obstacles between the source and the reference plane, a photon escaping the body can be propagated along a straight line until it strikes the reference plane. If, on the other hand, we choose the reference plane after some image-forming elements (lenses, pinholes, collimators, ...), then we can continue tracing the photon through these elements to the plane. In either case, if we know the response function $d_m(\mathbf{r}, \hat{\mathbf{s}}, \mathcal{E})$ analytically, we can use the photon coordinates on P to compute the contribution of that photon to \bar{g}_m . If we do not know the response analytically, we can continue the Monte Carlo simulation inside the detector. This entire process is repeated for many photons until the desired accuracy in the estimate is obtained.

Adjoint Monte Carlo and forced detection A major drawback of Monte Carlo methods as described so far is that many simulated photons—possibly a great majority—will be absorbed either in the body or in apertures outside the body and never reach the detector. Far more photons must be launched than are eventually incorporated in the simulated data set, and there will be large Poisson fluctuations in the estimated image.

One way around this problem is the *adjoint Monte Carlo* method. A Monte Carlo simulation begins with a source distribution and transports it to a detector; adjoint Monte Carlo begins with a detector response function and transports it back to all source points; thus it implements the adjoint Boltzmann equation. As a practical matter, most Monte Carlo simulation codes can be run either in the normal or adjoint mode; it does not matter to the code what one considers as source and what as detector.

Another technique for more efficiently using the simulated photons is *forced detection*. Like many other variance-reduction methods described in the literature, forced detection does not regard photons as physically indivisible but rather assigns weights to the various fates that can befall them. In straightforward Monte Carlo as described above, a scattered photon can go in an arbitrary direction, and only a small portion of these directions will lead it through the image-forming elements to the detector. In forced detection, the probability that the photon will head towards the detector and escape the body from that scattering point is computed, and then this photon is assumed to contribute to the point process on plane P weighted with this probability. Then, however, the photon is allowed to scatter in an arbitrary direction, and a similar weighted contribution is computed from the next scattering site. Thus many more terms appear in the point process, yet the weights keep the estimate of \bar{g}_m unbiased.

We must note, however, that these methods are intended for accurate and efficient estimation of mean images, not for generating sample images with realistic statistical properties. Thus variance-reduction techniques are profitable in estimating the mean image $\bar{\mathbf{g}}$, but they should be avoided if the objective is to simulate \mathbf{g} itself.

11

Poisson Statistics and Photon Counting

This chapter deals with *photon-counting detectors*, though this term is somewhat of a misnomer since what such detectors count is actually photoelectrons or photoelectric interactions, not photons. As we discussed in Chap. 10, it is usually not necessary to consider a quantized description of the radiation field at all. Photon-counting experiments can often be analyzed successfully with a semiclassical theory in which matter is treated quantum mechanically but electromagnetic radiation is assumed to obey Maxwell's equations.

Nevertheless, as we argued in Sec. 10.1, it can be very useful, both conceptually and computationally, to think of electromagnetic radiation as transported by localized excitations which, for want of a better term, we call photons. This viewpoint can be justified through quantum electrodynamics if we define localized (multi-mode) states of the radiation field and localized operators that correspond to classical concepts like irradiance and energy density. With the background from Chap. 10, therefore, we adopt the language of photons throughout most of this chapter, returning to quantum electrodynamics only in the last section.

In photon counting and many other problems, the most important probability law is the Poisson distribution. The eminent statistician Sir Ronald Fisher made this point forcefully, saying that, "Among discontinuous distributions, the Poisson series is of first importance" (Haight, 1967). There are two main reasons for this preeminence. First, the Poisson distribution arises as an almost inevitable consequence of statistical independence in counting problems. This statement is made more precise in Sec. 11.1.1 by stating three fundamental postulates from which the Poisson law can be derived. Somewhat colloquially, these postulates say merely that we are counting statistically independent events. It is not much of a stretch to say that if events are independent, the number of them in any fixed time interval must be a Poisson random variable. Conversely, when a counting distribution is determined not to be Poisson, we can usually discover a reason why the events are not independent. One of the authors of this book goes so far as to tell his students that Poisson is French for independent.

The second reason for the importance of the Poisson distribution is that it also occurs in spite of statistical dependence when the events in question are rare, in a sense to be discussed below. This result, sometimes called the *law of small numbers*, was derived by S. D. Poisson in 1837 in the course of research on the probability of judgments in civil and criminal trials.¹

When electromagnetic radiation falls on a photon-counting detector, the resulting pattern of photoelectric interactions is a spatio-temporal random process. That is, each sample function depends on both spatial and temporal variables. Which of these variables we are interested in depends on what the detector measures. In Sec. 11.1, we assume that the detector reports only the total number of accumulated counts, so the concern is with a single random variable, which under many circumstances will turn out to be Poisson distributed. In Sec. 11.2 we discuss discrete arrays of detectors where the outputs can be considered as random vectors, often described by the multivariate Poisson law. These two sections provide the basis for discussing digital imaging systems that are noise-free except for the inevitable limits imposed by counting statistics. We refer to such systems as *photon-limited* or *quantum-noise-limited*; they are the imaging counterparts of electronic systems that are limited by *shot noise*, which arises from the discrete nature of electrons.

Section 11.3 moves on to random point processes, which can be used to describe detector outputs more fully than by total counts. If the temporal waveform of the detector output is observed without regard to the spatial coordinates of the interactions, then the proper description is a temporal random process. On the other hand, if a detector (such as film) records spatial locations without regard to time of interaction, then the relevant random process is a spatial one. In both cases, we shall encounter Poisson random processes if the postulates are satisfied.

Section 11.4 deals with devices such as photomultipliers and image intensifiers where one input event initiates a random number of output events. Since many output events arise from each input event, the independence is lost and the output random process is usually not Poisson. Nevertheless, the principles developed earlier in the chapter for Poisson processes will be put to good use.

In Sec. 11.5 we look at photon counting from a quantum-mechanical perspective. Here, too, we shall see that the Poisson distribution plays a fundamental role, and that for certain kinds of light a Poisson distribution of photocounts will be observed. In fact, in most cases the classical results of the previous sections will turn out to be valid also in quantum-mechanical terms. We shall see, however, that there are also some purely quantum-mechanical forms of light for which the classical results do not hold.

Excellent general references on Poisson statistics include Haight (1967), Johnson and Kotz (1969), Feller (1968) and the Encyclopedia of Statistical Sciences (Kotz *et al.*, 1982). An exhaustive bibliography up to 1966 is given by Haight (1967). Discussions relevant to optics and imaging are given in Metz (1969), Barrett and Swindell (1981, 1996), Goodman (1985), Frieden (1983) and Snyder and Miller (1991). A comprehensive book that covers many of the topics in this chapter is Saleh (1978).
